Posterior and intraventricular tumors when complicated by hydrocephalus
Pseudotumor cerebri
Neurodegenerative Diseases
Cerebral storage disease
Gangliosidoses, particularly Tay-Sachs disease (infantile amaurotic familial idiocy), Sandhoff variant, generalized gangliosidosis
Other lipidoses and ceroid lipofuscinoses, particularly the late-onset amaurotic Familial idiocies such as those of Jansky-Bielschowsky and of Batten-Mayou-Spielmeyer-Vogt
Mucopolysaccharidoses, particularly Hurler syndrome and Hunter syndrome
Leukodystrophies (dysmyelination disorders), particularly metachromatic leukodystrophy and Canavan disease
Demyelinating sclerosis (myelinoclastic diseases), especially Schilder disease and Devic neuromyelitis optica
Special types: Dawson disease, Leigh disease, the Bassen-Kornzweig syndrome, Refsum disease
Retinal degenerations: retinitis pigmentosa and its variants, and Leber congenital type
Optic atrophies: congenital autosomal recessive type, infantile and congenital autosomal dominant types, Leber disease, and atrophies associated with hereditary ataxias—the types of Behr, of Marie, and of Sanger-Brown
Infectious Processes
Encephalitis, especially in the prenatal infection syndromes due to *Toxoplasma gondii*, cytomegalovirus, rubella virus, *Treponema pallidum*, herpes simplex
Meningitis; arachnoiditis
Chorioretinitis
Endophthalmitis
Keratitis
Hematologic Disorders
Leukemia with central nervous system involvement
Vascular and Circulatory Disorders
Collagen vascular diseases
Arteriovenous malformations—intracerebral hemorrhage, subarachnoid hemorrhage
Central retinal occlusion
Trauma
Contusion or avulsion of optic nerves, chiasm, globe, cornea
Cerebral contusion or laceration
Intracerebral, subarachnoid, or subdural hemorrhage
Drugs and Toxins
Quinine
Ethambutol
Methanol
Many others
Other
Retinopathy of prematurity
Sclerocornea
Conversion reaction
Optic neuritis
Osteopetrosis
Modified from Kliegman R: Practical Strategies in Pediatric Diagnosis and Therapy.Philadelphia, WB Saunders, 1996.

optic nerves, chiasm, or cerebrum. In some cases, precipitous loss of vision is a result of increased intracranial pressure, rapidly progressive hydrocephalus, or dysfunction of a shunt. More slowly progressive visual loss suggests tumor or neurodegenerative disease. Gliomas of the optic nerve and chiasm and craniopharyngiomas are primary diagnostic considerations in children who show progressive loss of vision.

Clinical manifestations of impairment of vision vary with the age and abilities of a child, the mode of onset, and the laterality and severity of the deficit. The first clue to amaurosis in an infant may be nystagmus or strabismus, the vision defect itself passing undetected for some time. Timidity, clumsiness, or behavioral change may be the initial clues in the very young. Deterioration in school progress and indifference to school activities are common signs in an older child. School-aged children often try to hide their disability and, in the case of very slowly progressive disorders, may not themselves realize the severity of the problem; some detect and promptly report small changes in their vision.

Any evidence of loss of vision requires prompt and thorough ophthalmic evaluation. Complete delineation of childhood amaurosis and its cause usually requires extensive investigation involving neurologic evaluation, electrophysiologic tests, neuroradiologic procedures, and sometimes metabolic and genetic studies. Furthermore, attendant special educational, social, and emotional needs must be met.

Nyctalopia.

Nyctalopia, or night blindness, is vision that is defective in reduced illumination. It generally implies impairment in function of the rods, particularly in dark adaptation time and perceptual threshold. *Stationary congenital night blindness* may occur as an autosomal dominant, autosomal recessive, or X-linked recessive condition. It may be associated with myopia, nystagmus, and disc anomaly. *Progressive night blindness* usually indicates primary or secondary retinal, choroidal, or vitreoretinal degeneration (see Chapter 621); it occurs also in vitamin A deficiency or as a result of retinotoxic drugs such as quinine.

Psychogenic Disturbances.

Vision problems of psychogenic origin are common in school-aged children. Both conversion reactions and willful feigning are encountered. The usual manifestation is a report of reduced visual acuity in one or both eyes. Another common manifestation is constriction of the visual field. In some cases, the symptom is diplopia or polyopia. See Chapters 19 and 22 .

Important clues to the diagnosis are inappropriate affect, excessive grimacing, inconsistency in performance, and suggestibility. Thorough ophthalmologic examination is essential to differentiate organic from functional visual disorders.

Affected children usually fare well with reassurance and positive suggestion. In some cases, psychiatric care is indicated. In all cases, the approach must be supportive and nonpunitive.

Dyslexia.

Dyslexia is the inability to develop the capability to read at an expected level despite an otherwise normal intellect. The terms *reading disability* and *dyslexia* are often used interchangeably. Most dyslexic individuals also display poor writing ability. Dyslexia is a primary reading disorder and should be differentiated from secondary reading difficulties due to mental retardation, environmental or educational deprivation, and physical or organic diseases. Because there is no one standard test for dyslexia, the diagnosis is usually made by comparing reading ability with intelligence and standard reading expectations. Dyslexia is a language-based disorder and is not caused by any defect in the eye or visual acuity per se, nor is it attributable to a defect in ocular motility or binocular alignment. Although ophthalmologic evaluation of children with a reading problem is recommended to diagnose and correct any concurrent ocular problems such as a refractive error, amblyopia, or strabismus, treatment directed to the eyes themselves cannot be expected to correct developmental dyslexia (Chapter 29.3).

Chapter 613 - Abnormalities of Pupil and Iris

Aniridia.

The term aniridia is a misnomer because iris tissue is usually present, although it is hypoplastic (Fig. 613–1). Two thirds of the cases are dominantly transmitted with a high degree of penetrance. The other one third of cases are sporadic and are considered to be new mutations. The condition is bilateral in 98% of all patients regardless of the means of transmission and is found in approximately 1/50,000 persons.

Aniridia is a panocular disorder and should not be thought of as an isolated iris defect. Macular and optic nerve hypoplasia are commonly present and lead to decreased vision and sensory nystagmus. The visual acuity is measured as 20/200 in most patients, although the vision may occasionally be better. Other ocular deformities are common and may involve the lens and cornea. The cornea may be small, and a cellular infiltrate (pannus) occasionally develops in the superficial layers of the peripheral cornea. Clinically this appears as a gray opacification. Lens abnormalities include cataract formation and partial or total lens dislocation. Glaucoma develops in as many as 75% of individuals with aniridia.

One fifth of sporadic aniridic patients may develop **Wilms tumor** (Chapter 491.1). Of particular interest is the association of aniridia, genitourinary anomalies, mental retardation, and a partial deletion of the short arm of chromosome 11. Among individuals thus affected, the appearance of Wilms tumor is more common. It is thought that only patients with sporadic aniridia are at risk for developing Wilms tumor, although Wilms tumor has occurred in a patient with familial aniridia. Wilms tumor usually presents before the 3rd yr. Therefore, these children should be screened using renal ultrasonography every 3–6 mo, until approximately age 5 yr of age.

Figure 613-1 Aniridia. Minimal iris tissue. (From Nelson LB, Spaeth GL, Nowinski TS, et al: Aniridia: A review. *Surv Ophthalmol* 1984;28:621.)

The gene for aniridia had been localized to the 11p13 region. This gene may be involved in properly directing the interactions between the optic cup, surface ectoderm, and neural crest cells during early formation of the iris and other ocular structures.

Coloboma of the Iris.

This developmental defect may present as a defect in a sector of the iris, a hole in the substance of the iris, or a notch in the pupillary margin. Simple colobomas are frequently transmitted as an autosomal dominant trait and may occur alone or in association with other anomalies. A coloboma is formed when the embryonic fissure fails to close completely. Because of the anatomic location of the embryonic fissure, an iris coloboma is always located inferiorly, giving the iris a keyhole appearance. An iris coloboma may be the only externally visible part of an extensive malclosure of the embryonic fissure that also involves the fundus and optic nerve. When this occurs, vision is likely to be severely affected. Therefore, all children with an iris coloboma should undergo a full ophthalmologic examination.

Microcoria.

Microcoria (congenital miosis) appears as a small pupil that does not react to light or accommodation and that dilates poorly, if at all, with medication. The condition may be unilateral or bilateral. In bilateral cases, the degree of miosis may be different in each eye. The eye may be otherwise normal or may demonstrate other abnormalities of the anterior segment. Congenital microcoria is usually transmitted as an autosomal dominant trait, although it may occur sporadically.

Congenital Mydriasis.

In this disorder, the pupils appear dilated, do not constrict significantly to light or near gaze, and respond minimally to miotic agents. The iris is otherwise normal, and affected children are usually healthy. Trauma, pharmacologic mydriasis, and neurologic disorders should be considered. Many apparent cases of congenital mydriasis show abnormalities of the central iris structures and may be considered a form of aniridia.

Dyscoria and Corectopia.

Dyscoria is abnormal shape of the pupil, and corectopia is abnormal pupillary position. They may occur together or independently as congenital or acquired anomalies.

Congenital corectopia is usually bilateral and symmetric and rarely occurs as an isolated anomaly; it is usually accompanied by dislocation of the lens (ectopia lentis et pupillae), and the lens and pupil are commonly dislocated in opposite directions. Ectopia lentis et pupillae is transmitted as an autosomal recessive disorder; consanguinity is common.

When acquired, distortion and displacement of the pupil are frequently a result of trauma or intraocular inflammation. Prolapse of the iris after perforating injuries of the eye leads to peaking of the pupil in the direction of the perforation. Posterior synechiae (adhesions of the iris to the lens) are commonly seen when inflammation

due to any cause occurs in the anterior segment.

Anisocoria.

This is inequality of the pupils. The difference in size may be due to local or neurologic disorders. As a rule, if the inequality is more pronounced in the presence of bright focal illumination or on near gaze, there is a defect in pupillary constriction and the larger pupil is abnormal. If the anisocoria is worse in reduced illumination, a defect in dilation exists and the smaller pupil is abnormal. Neurologic causes of anisocoria (parasympathetic or sympathetic lesions) must be differentiated from local causes such as synechiae (adhesions), congenital iris defects (colobomas, aniridia), and pharmacologic effects. Simple central anisocoria may occur in otherwise healthy individuals.

Dilated Fixed Pupil.

Differential diagnosis of a dilated unreactive pupil includes internal ophthalmoplegia caused by a central or peripheral lesion, Hutchinson pupil of transtentorial herniation, tonic pupil, pharmacologic blockade, and iridoplegia secondary to ocular trauma.

The most common cause of a dilated unreactive pupil is purposeful or accidental instillation of a cycloplegic agent, particularly atropine and related substances. Central lesions, such as a pinealoma, may cause internal ophthalmoplegia in children. Because the external surface of the oculomotor nerve carries the fibers responsible for pupillary constriction, compression of the nerve along its intracranial course may be associated with internal ophthalmoplegia, even before the development of ptosis or an ocular motility deficit. Although ophthalmoplegic migraine is a common cause of a 3rd nerve palsy with pupillary involvement in children, an intracranial aneurysm must also be considered in the differential diagnosis. The “blown pupil” of transtentorial herniation, occurring with increasing intracranial pressure, is generally unilateral, and patients usually are obviously ill. The pilocarpine test can help differentiate neurologic iridoplegia from pharmacologic blockade. In the case of neurologic iridoplegia, the dilated pupil constricts within minutes after instillation of 1 or 2 drops of 0.5–1% pilocarpine; if the pupil has been dilated with atropine, pilocarpine has no effect. Because pilocarpine is a long-acting drug, this test is not to be used in acute situations in which pupillary signs must be carefully monitored. Because of the consensual pupil response to light, even complete uniocular blindness does not cause a unilaterally dilated pupil.

Tonic Pupil.

This is typically a large pupil that reacts poorly to light (the reaction may be very slow or essentially nil), reacts poorly and slowly to accommodation, and redilates in a slow, tonic manner. The features of tonic pupil are explained by cholinergic supersensitivity of the sphincter after peripheral (postganglionic) denervation and imperfect reinnervation. A distinctive feature of a tonic pupil is its sensitivity to dilute cholinergic agents. Instillation of 0.125% pilocarpine causes significant constriction of the involved pupil and has little or no effect on the unaffected side. The condition is usually unilateral.

Tonic pupil may develop after the acute stage of a partial or complete iridoplegia. It can be seen after trauma to the eye or orbit and may occur in association with toxic or infectious conditions. In those in the pediatric age group, tonic pupil is uncommon. Infectious processes (primarily viral syndromes) and trauma are the primary causes. Features of tonic pupil may also be seen in infants and children with familial dysautonomia (Riley-Day syndrome), although the significance of these findings has been questioned. Tonic pupil has also been reported in young children with Charcot-Marie-Tooth disease. The occurrence of tonic pupil in association with decreased deep tendon reflexes in young women is referred to as **Adie syndrome**.

Marcus Gunn Pupil.

This relative afferent pupillary defect indicates an asymmetric, prechiasmatic, afferent conduction defect. It is best demonstrated by the swinging flashlight test; this allows comparison of the direct and consensual pupillary responses in both eyes. With patients fixing on a distant target (to control accommodation), a bright focal light is directed alternately into each eye in turn. In the presence of an afferent lesion, both the direct response to light in the affected eye and the consensual response in the fellow eye are subnormal. Swinging the light to the better or normal eye causes both pupils to react (constrict) normally. Swinging the light back to the affected eye causes both pupils to redilate to some degree, reflecting the defective conduction. This is a very sensitive and useful test for detecting and confirming optic nerve and retinal disease. This test is only abnormal if there is a “relative” difference in the conduction properties of the optic nerves. Therefore, patients with bilateral and symmetrical optic nerve disease will not demonstrate an afferent pupillary defect. A subtle relative afferent defect may be found in some children with amblyopia.

Horner Syndrome.

The principal signs of oculosympathetic paresis (Horner syndrome) are homolateral miosis, mild ptosis, and apparent enophthalmos with slight elevation of the lower lid. Patients may also have decreased facial sweating, increased amplitude of accommodation, and transient decrease in intraocular pressure. If paralysis of the ocular sympathetic fibers occurs before the age of 2 yr, heterochromia iridis with hypopigmentation of the iris may occur on the affected side.

Oculosympathetic paralysis may be caused by a lesion in the midbrain, brainstem, upper spinal cord, neck, middle fossa, or orbit. Congenital oculosympathetic paresis, often as part of Klumpke brachial palsy, is common, although the ocular signs, particularly the anisocoria, may pass undetected for years. Horner syndrome is also seen in some children after thoracic surgery, such as for congenital heart disease. Congenital Horner syndrome may occur in association with vertebral anomalies and with enterogenous cysts. In some infants and children, Horner syndrome is the presenting sign of tumor in the mediastinal or cervical region, particularly neuroblastoma. Rare causes of Horner syndrome, such as vascular lesions, also occur in the pediatric age group. In some cases, no cause of Horner syndrome can be identified. Occasionally, the condition is familial.

When the cause of Horner syndrome is in question, investigative procedures should

be implemented, including chest radiography, CT, MRI of the head and neck, and 24-hr urinary catecholamine assay. Examining old photographs and old records can sometimes be helpful in establishing the age of onset of Horner syndrome.

The *cocaine test* is useful in diagnosing oculosympathetic paralysis; a normal pupil dilates within 20–45?min after instillation of 1 or 2 drops of 4% cocaine, whereas the miotic pupil of an oculosympathetic paresis dilates poorly, if at all, with cocaine. In some cases there is denervation supersensitivity to dilute phenylephrine; 1 or 2 drops of a 1% solution dilates the affected but not the normal pupil. Furthermore, instillation of 1% hydroxyamphetamine hydrobromide dilates the pupil only if the postganglionic sympathetic neuron is intact.

Paradoxical Pupil Reaction.

Some children exhibit paradoxical constriction of the pupils to darkness. An initial brisk constriction of the pupils occurs when the light is turned off, followed by slow redilation of the pupils. The response to direct light stimulation and the near response are normal. The mechanism is not clear, but paradoxical constriction of the pupils in reduced light can be a sign of retinal or optic nerve abnormalities. The phenomenon has been observed in children with congenital stationary night blindness, albinism, retinitis pigmentosa, Leber congenital retinal amaurosis, and Best disease. It has also been observed in those with optic nerve anomalies, optic neuritis, optic atrophy, and possibly amblyopia.

Persistent Pupillary Membrane.

Involution of the pupillary membrane and anterior vascular capsule of the lens is usually completed during the 5th–6th mo of fetal development. It is common to see some remnants of the pupillary membrane in newborns, particularly in premature infants. These membranes are nonpigmented strands of obliterated vessels that cross the pupil and may secondarily attach to the lens or cornea. The remnants tend to atrophy in time and usually present no problem. In some cases, however, significant remnants that remain obscure the pupil and interfere with vision. Rarely, there is patency of the vascular elements; hyphema may result from rupture of persistent vessels.

Intervention must be considered to minimize amblyopia in infants with extensive persistent pupillary membrane of sufficient degree to interfere with vision in the early months of life. In some cases, mydriatics and occlusion therapy may be effective, but in others surgery may be needed to provide an adequate pupillary aperture.

Heterochromia.

In heterochromia, the two irides are of different color (heterochromia iridium), or a portion of an iris differs in color from the remainder (heterochromia iridis). Simple heterochromia may occur as an autosomal dominant characteristic. Congenital heterochromia is also a feature of **Waardenburg syndrome,** an autosomal dominant condition characterized principally by lateral displacement of the inner canthi and puncta, pigmentary disturbances (usually a median white forelock and patches of hypopigmentation of the skin), and defective hearing. Change in the color of the iris may occur as a result of trauma, hemorrhage, intraocular inflammation (iridocyclitis, uveitis), intraocular tumor (especially retinoblastoma), intraocular foreign body, glaucoma, iris atrophy, oculosympathetic palsy (Horner syndrome), melanosis oculi, previous intraocular surgery, and some glaucoma medications.

Other Iris Lesions.

Discrete nodules of the iris, referred to as **Lisch nodules**, are commonly seen in patients with neurofibromatosis. Lisch nodules represent melanocytic hamartomas of the iris and vary from slightly elevated pigmented areas to distinct ball-like excrescences. Lisch nodules are found in 92–100% of individuals older than 5 yr of age and having neurofibromatosis. Slit-lamp identification of these nodules may help to fulfill the criteria required to confirm the diagnosis of neurofibromatosis.

In leukemia there may be infiltration of the iris, sometimes with hypopyon, an accumulation of white blood cells in the anterior chamber, which may herald relapse or involvement of the central nervous system.

The lesion of juvenile xanthogranuloma (nevoxanthoendothelioma) may occur in the eye as a yellowish fleshy mass or plaque of the iris. Spontaneous hyphema (blood in the anterior chamber), glaucoma, or a red eye with signs of uveitis may be associated. A search for the skin lesions of xanthogranuloma (see also Chapter 75.3) should be made in any infant or young child with spontaneous hyphema. In many cases, the ocular lesion responds to topical corticosteroid therapy.

Leukokoria.

This includes any white pupillary reflex, or so-called *cat's-eye reflex*. Primary diagnostic considerations in any child with leukokoria are cataract, persistent hyperplastic primary vitreous, cicatricial retinopathy of prematurity, retinal detachment and retinoschisis, larval granulomatosis, and retinoblastoma (Fig. 613–2). Also to be considered are endophthalmitis, organized vitreous hemorrhage, leukemic ophthalmopathy, exudative retinopathy (as in *Coats disease*), and less common conditions such as medulloepithelioma, massive retinal gliosis, the retinal pseudotumor of Norrie disease, the so-called pseudoglioma of the *Bloch-Sulzberger syndrome*, retinal dysplasia, and the retinal lesions of the phakomatoses. A white reflex may also be seen with fundus coloboma, large atrophic chorioretinal scars, and ectopic medullation of retinal nerve fibers. Leukokoria is an indication for prompt and thorough evaluation.

The diagnosis can often be made by direct examination of the eye by ophthalmoscopy and biomicroscopy. Ultrasonographic and radiologic examinations are often helpful. In some cases, the final diagnosis rests with a pathologist.

Figure 613-2 Leukocoria. White pupillary reflex in a child with retinoblastoma.

Chapter 614 - Disorders of Eye Movement and Alignment

STRABISMUS

Strabismus, or misalignment of the eyes, is one of the most common eye problems encountered in children, affecting approximately 4% of children younger than 6 yr of age. This important ocular disorder can result in vision loss (amblyopia) in one eye and can have significant psychologic effects. Early detection and treatment of strabismus is essential to prevent permanent visual impairment. Of children with strabismus, 30–50% develop secondary visual loss (amblyopia). Restoration of proper alignment of the visual axis must occur at an early stage of visual development to allow these children a chance to develop normal binocular vision.

Definitions.

The word *strabismus* means “to squint or to look obliquely.” Many terms are used in discussing strabismus.

Orthophoria is the ideal condition of exact ocular balance. It implies that the oculomotor apparatus is in perfect equilibrium so that the eyes remain coordinated and aligned in all positions of gaze and at all distances. Even when fusion is interrupted, as by occlusion of one eye, truly orthophoric individuals maintain perfect alignment. Orthophoria is seldom encountered, because the majority of individuals have a small latent deviation (heterophoria).

Heterophoria is a latent tendency for the eyes to deviate. This latent deviation is normally controlled by fusional mechanisms that provide binocular vision or avoid diplopia (double vision). The eye deviates only under certain conditions, such as fatigue, illness, or stress, or during tests that interfere with maintenance of these normal fusional abilities (such as covering one eye). If the amount of heterophoria is large, it may give rise to bothersome symptoms, such as transient diplopia (double vision), headaches, or asthenopia (eyestrain). Some degree of heterophoria is found in normal individuals; it is usually asymptomatic.

Heterotropia is a misalignment of the eyes that is constant. It occurs because of an inability of the fusional mechanism to control the deviation. Tropias can be alternating, involving both eyes, or unilateral. In an alternating tropia, there is no preference for fixation of either eye, and both eyes drift at an equal rate. Vision usually develops normally in both eyes because each eye is used in turn. A unilateral tropia is a more serious situation because only one eye is constantly malaligned. The undeviated eye becomes the preferred eye, resulting in loss of vision or amblyopia of the deviated eye.

It is common in ocular misalignments to describe the type of deviation present because this indicates different causes and treatments of the strabismus. The prefixes *eso-, exo-, hyper-*, and *hypo-* are added to the terms *phoria* and *tropia* to delineate further the type of deviation. *Esophorias* and *esotropias* are inward or convergent deviations of the eyes, commonly known as *crossed eyes. Exophorias* and *exotropias* are divergent or outward-facing eye deviations, *walleyed* being the lay term. Hyperdeviations and hypodeviations designate upward or downward deviations of an eye. In cases of unilateral strabismus, the deviating eye is often part of the description of the misalignment (left esotropia).

Diagnosis.

Many techniques are used to assess ocular alignment and movement of the eyes to aid in diagnosing strabismic disorders. In a child with strabismus or any other ocular disorder, assessment of visual acuity is mandatory. Decreased vision in one eye requires evaluation for ocular deviation or other ocular abnormalities, which may be difficult to discern on a brief screening evaluation. Even strabismic deviations of only a few degrees in magnitude, too small to be evident by gross inspection, may lead to amblyopia and devastating vision loss.

Corneal light reflex tests are perhaps the most rapid and easily performed diagnostic tests for strabismus. They are particularly useful in children who are uncooperative and in those who have poor ocular fixation. To perform the Hirschberg corneal reflex test, the examiner projects a light source onto the cornea of both eyes simultaneously as a child looks directly at the light. Comparison should then be made of the placement of the corneal light reflex in each eye. In straight eyes, the light reflection appears symmetric and, because of the relationship between the cornea and the macula, slightly nasal to the center of each pupil. If strabismus is present, the reflected light is asymmetric and appears off center in one eye. Krimsky's method of the corneal reflex test uses prisms placed over one or both eyes to align the light reflections. The amount of prism needed to align the reflections is used to measure the degree of deviation of the eye. Although it is a useful screening test, corneal light reflex testing may not detect a small angle or an intermittent strabismus.

Cover tests for strabismus require a child's attention and cooperation, good eye movement capability, and reasonably good vision in each eye. If any of these are lacking, the results of these tests may not be valid. These tests consist of the cover-uncover test and the alternate cover test. In the cover-uncover test, a child looks at an object in the distance, preferably 6?m away. An eye chart is commonly used for fixation in children older than 3 yr of age. For younger children, a brightly colored or noise-making toy helps hold their attention for the test. As the child looks at the distant object, the examiner covers one eye and watches for movement of the uncovered eye. If no movement occurs, there is no apparent misalignment of that eye. After one eye is tested, the same procedure is repeated on the other eye. When performing the alternate cover test, the examiner rapidly covers and uncovers each eye, shifting back and forth from one eye to another like a windshield wiper. If the child has any ocular deviation, the eye rapidly moves as the cover is shifted to the

other eye. Both the cover-uncover test and the alternate cover test should be performed at both distance and near fixation, with and without glasses. The cover-uncover test differentiates tropias, or manifest deviations, from latent deviations, called *phorias*.

Clinical Manifestations and Treatment.

The etiologic classification of strabismus is complex, and the causative types must be distinguished; these are nonparalytic and paralytic types.

NONPARALYTIC STRABISMUS.

Nonparalytic strabismus is the most common type. The individual extraocular muscles usually have no defect. The amount of deviation is constant, or relatively constant, in the various directions of gaze.

Esodeviations. Esodeviations are the most common type of ocular misalignment in children and represent well over 50% of all ocular deviations.

Pseudostrabismus (pseudoesotropia) is one of the most common reasons a pediatric ophthalmologist is asked to evaluate an infant. This condition is characterized by the false appearance of strabismus when the visual axes are aligned accurately. This appearance may be caused by a flat, broad nasal bridge, prominent epicanthal folds, or a narrow interpupillary distance. The observer may see less white sclera nasally than would be expected, and the impression is that the eye is turned in toward the nose, especially when the child gazes to either side. Parents frequently comment that when their child looks to the side, the eye almost disappears from view. Pseudoesotropia can be differentiated from a true misalignment of the eyes when the corneal light reflex is centered in both eyes and when the cover-uncover test shows no refixation movement. Once pseudoesotropia has been confirmed, parents can be reassured that the child will outgrow the appearance of esotropia. As the child grows, the bridge of the nose becomes more prominent and displaces the epicanthal folds, and the medial sclera becomes proportional to the amount visible on the lateral aspect. It is the appearance of crossing that the child will outgrow. Many parents of children with pseudoesotropia erroneously believe that their child has an actual esotropia that will resolve on its own. Because true esotropia can develop later in children with pseudoesotropia, parents and pediatricians should be cautioned that reassessment is required if the apparent deviation does not improve.

Congenital esotropia is a confusing term. Few children who are diagnosed with this disorder are actually born with an esotropia. Most reports in the literature have therefore considered infants with confirmed onset earlier than 6 mo as having the same condition, which some observers have redesignated infantile esotropia.

The characteristic angle of congenital esodeviations is large and constant. Because of the large deviation, cross-fixation is frequently encountered. This is a condition in which the child looks to the right with the left eye and to the left with the right eye. With cross-fixation, each eye is reluctant to turn away from the nose (abduction); this condition simulates a 6th nerve palsy. Abduction can be demonstrated by the doll's head maneuver or by patching one eye for a short time. Children with congenital esotropia tend to have refractive errors similar to those of normal children of the same age. This contrasts with the characteristic high level of farsightedness associated with accommodative esotropia (see later text). Amblyopia is common in children with congenital esotropia.

The primary goal of treatment in congenital esotropia is to eliminate or reduce the deviation as much as possible. Ideally, this results in normal sight in each eye, in straight-looking eyes, and in the development of binocular vision. Early treatment is more likely to lead to the development of binocular vision, which helps to maintain long-term ocular alignment. Once any associated amblyopia is treated, surgery is performed to align the eyes. Even with successful surgical alignment, it is common for vertical deviations to develop in children with a history of congenital esotropia. One form of vertical deviation results from overaction of the inferior oblique muscles. When this occurs, side gaze produces an upshoot of the eye closest to the nose. Dissociated vertical deviation also develops in children with infantile esotropia. In this type of deviation, one eye drifts up slowly with no movement of the other eye. Surgery may be necessary to treat either or both of these conditions.

It is important that parents realize that early successful surgical alignment is only the beginning of the treatment processes. Because many children may redevelop strabismus or amblyopia, they need to be monitored closely during the visually immature period of life.

Accommodative esotropia is defined as a “convergent deviation of the eyes associated with activation of the accommodative (focusing) reflex.” It usually occurs in a child who is between 2 and 3 yr of age and who has a history of acquired intermittent or constant crossing. Amblyopia occurs in the majority of cases.

The mechanism of accommodative esotropia involves uncorrected hyperopia, accommodation, and accommodative convergence. The image entering a hyperopic (farsighted) eye is blurred. If the amount of hyperopia is not significant, the blurred image can be sharpened by accommodating (focusing of the lens of the eye). Accommodation is closely linked with convergence (eyes turning inward). If a child's hyperopic refractive error is large or if the amount of convergence that occurs in response to each unit of accommodative effort is great, esotropia may develop.

To treat accommodative esotropia, the full hyperopic (farsighted) correction is initially prescribed. These glasses eliminate a child's need to accommodate and therefore eliminate the esotropia (Fig. 614–1). Although many parents are initially concerned that their child will not want to wear glasses, the benefits of binocular vision and decreasing the focusing effort required to see clearly provide a strong stimulus to wear glasses, and they are generally accepted well. The full hyperopic correction sometimes straightens the eye position at distance fixation but leaves a residual deviation at near fixation; this may be observed or treated with bifocal lenses, antiaccommodative drops, or surgery.

It is important to warn parents of children with accommodative esotropia that the esodeviation may appear to increase without glasses after the initial correction is worn. Parents frequently state that before wearing glasses, their child had a small

esodeviation, whereas after removal of the glasses the esodeviation becomes quite large. Parents often blame the increased esodeviation on the glasses. This apparent increase is due to a child's using the appropriate amount of accommodative effort after the glasses have been worn. When these children remove their glasses, they continue to use an accommodative effort to bring objects into proper focus and increase the esodeviation.

Most children maintain straight eyes once initially treated. Because hyperopia generally decreases with age, many patients outgrow the need to wear glasses to maintain alignment. In some patients, a residual esodeviation persists even when wearing their glasses. This condition commonly occurs when there is a delay between the onset of accommodative esotropia and treatment. In others, the esotropia may initially be eliminated with glasses but crossing redevelops and is not correctable with glasses. The crossing that is no longer correctable with glasses is the deteriorated or nonaccommodative portion. Surgery for this portion of the crossing is indicated to regain binocular vision.

Exodeviations. Exodeviations are the second most common type of misalignment. The divergent deviation may be intermittent or constant. ***Intermittent exotropia*** is the most common exodeviation in childhood. It is characterized by outward drifting of one eye, which usually occurs when a child is fixating at distance. The deviation is generally more frequent with fatigue or illness. Exposure to bright light may cause reflex closure of the exotropic eye. Because the eyes initially can be kept straight

Figure 614-1 Accommodative esotropia; control of deviation with corrective lenses.

most of the time, visual acuity tends to be good in both eyes and binocular vision is initially normal.

The age of onset of intermittent exotropia varies but is often between age 6 mo and 4 yr. The decision to perform eye muscle surgery is based on the amount and frequency of the deviation. If the deviation is small and infrequent, it is reasonable just to observe the child. If the exotropia is large or increasing in frequency, surgery is indicated to maintain normal binocular vision.

Constant exotropia may rarely be congenital. Exotropia also may be associated with neurologic disease or abnormalities of the bony orbit, as in Crouzon syndrome. Exotropia that occurs later in life may represent a deterioration of an intermittent exotropia that was present in childhood. Surgery can restore binocular vision even in long-standing cases.

PARALYTIC STRABISMUS.

When an eye muscle is paretic or palsied, a characteristic muscle imbalance occurs in which the deviation of the eye varies according to the direction of gaze. Recent onset of a paretic muscle can be suggested by the symptom of double vision that increases in one direction, the findings of an ocular deviation that increases in the field of action of the paretic muscle, and an increase in the deviation when the child fixates with the paretic eye. It is important to differentiate an extraocular muscle paresis or palsy from a comitant deviation because noncomitant forms of strabismus are often associated with trauma, systemic disorders, or neurologic abnormalities.

3rd Nerve Palsy. In the pediatric population, 3rd nerve palsies are usually congenital. The congenital form is often associated with a developmental anomaly or birth trauma. Acquired 3rd nerve palsies in children can be an ominous sign and may indicate a neurologic abnormality such as an intracranial neoplasm or an aneurysm. Other less serious causes include an inflammatory or infectious lesion, head trauma, postviral syndromes, and migraines.

A 3rd nerve palsy, whether congenital or acquired, usually results in an exotropia. In this situation, the exotropia is associated with a hypotropia, or downward deviation of the affected eye, as well as complete or partial ptosis of the upper lid. This characteristic deviation results from the action of the remaining unopposed muscles, the lateral rectus muscle and the superior oblique muscle. If the internal branch of the 3rd nerve is involved, pupillary dilation may be noted as well. Eye movements are usually limited nasally, in elevation and in depression. In addition, clinical findings and treatment may be complicated in congenital and traumatic cases of 3rd nerve palsy owing to misdirection of regenerating nerve fibers, referred to as **aberrant regeneration**. This results in anomalous and paradoxical eyelid, eye, and pupil movement such as elevation of the eyelid, constriction of the pupil, or depression of the globe on attempted medial gaze.

4th Nerve Palsy. These palsies can be congenital or acquired. Because the 4th nerve has a long intracranial course, it is susceptible to damage resulting from head trauma. In children, however, 4th nerve palsies are more frequently congenital than traumatic. A palsied 4th nerve results in weakness in the superior oblique muscle, which causes an upward deviation of the eye, a hypertropia. Because the antagonist muscle, the inferior oblique, is relatively unopposed, the affected eye demonstrates an upshoot when looking toward the nose. Children typically present with a head tilt to the shoulder opposite the affected eye, their chin down and their face turned away from the affected side. This position is assumed to minimize the deviation and the associated double vision. Because the abnormal head posture maintains the child's ocular alignment, amblyopia is uncommon. Because no abnormality exists in the neck muscles, attempts to correct the head tilt by exercises and neck muscle surgery are ineffective. Recognition of a superior oblique paresis can be difficult because deviation of the head and the eye may be minimal. Eye muscle surgery can be performed to improve the ocular alignment and eliminate the abnormal head posture.

6th Nerve Palsy. These palsies produce markedly crossed eyes with limited ability to move the afflicted eye laterally. Children frequently present with their head turned toward the palsied muscle, a position that helps preserve binocular vision. The esotropia is largest when the eye is moved toward the affected muscle.

Congenital 6th nerve palsies are rare. Decreased lateral gaze in infants is often associated with other disorders, such as congenital esotropia or Duane retraction syndrome. In neonates, a transient 6th nerve paresis can occur; it usually clears spontaneously by 6 wk. It is believed that increased intracranial pressure associated

with labor and delivery is the contributing factor.

Acquired 6th nerve palsies in childhood are often an ominous sign because the 6th nerve is susceptible to increased intracranial pressure associated with hydrocephalous and intracranial tumors. Other causes of 6th nerve defects in children include trauma, vascular malformations, meningitis, and **Gradenigo syndrome.** In this latter syndrome, otitis media precipitates a mastoiditis with associated petrositis and edema of the dura. These events result in pinching the 6th nerve against the petrosphenoidal ligament as the nerve passes between the ligament and the dura on its intracranial course. The 6th nerve palsy resolves with antibiotic treatment. A benign 6th nerve palsy, which is painless and acquired, can be noted in infants and older children. This is frequently preceded by a febrile illness or upper respiratory tract infection and may be recurrent. Complete resolution of the palsy is usual. Although not uncommon, other causes of an acute 6th nerve palsy should be eliminated before this diagnosis is made.

STRABISMUS SYNDROMES.

Special types of strabismus have unusual clinical features. Most of these disorders are caused by structural anomalies of the extraocular muscles or adjacent tissues.

Double Elevator Palsy. A monocular elevation deficit in both abduction and adduction is referred to as double elevator palsy. It may represent a paresis of both elevators, the superior rectus and inferior oblique muscles, or a possible restriction to elevation from a fibrotic inferior rectus muscle. When an affected

child fixates with the nonparetic eye, the paretic eye is hypotropic and the ipsilateral upper eyelid may appear ptotic. Fixation with the paretic eye causes a hypertropia of the nonparetic eye and a disappearance of the ptosis.

Duane Syndrome. This congenital disorder of ocular motility is characterized by retraction of the globe on adduction. This is attributed to anomalous innervation, which results in cocontraction of the medial and lateral rectus muscles on attempted adduction of the affected eye. Within the spectrum of Duane syndrome, patients may exhibit impairment of abduction, impairment of adduction, or upshoot or downshoot of the involved eye on adduction. They may have esotropia, exotropia, or relatively straight eyes. Many exhibit compensatory posturing for the defect in horizontal eye movement. Some develop amblyopia. Surgery to improve ocular motility and alignment or to reduce a noticeable face turn can be helpful in selected cases.

Duane syndrome usually occurs sporadically. It is sometimes inherited as an autosomal dominant trait. It usually occurs as an isolated condition but may occur in association with various other ocular and systemic anomalies.

Möbius Syndrome. The distinctive features of Möbius syndrome are congenital facial paresis and abduction weakness. The facial palsy is commonly bilateral, frequently asymmetric, and often incomplete, tending to spare the lower face and platysma. Ectropion, epiphora, and exposure keratopathy may develop. The abduction defect may be unilateral or bilateral. Esotropia is common. The cause is unknown. Whether the primary defect is maldevelopment of cranial nerve nuclei, hypoplasia of the muscles, or a combination of central and peripheral factors is unclear. Gestational factors such as trauma, illness, and intake of various drugs, particularly thalidomide, have been implicated. Some familial cases have been reported. Associated developmental defects may include ptosis, palatal and lingual palsy, hearing loss, pectoral and lingual muscle defects, micrognathia, syndactyly, supernumerary digits, or the absence of hands, feet, fingers, or toes. Surgical correction of the esotropia is indicated in selected cases, and any attendant amblyopia should be treated.

Brown Syndrome. In this syndrome, elevation of the eye in the adducted position is restricted or absent. An associated downward deviation of the affected eye in adduction is common. A compensatory tilt of the head may occur. Various causes have been described. Some cases have been attributed to structural abnormalities such as a tight superior oblique tendon, congenital shortening or thickening of the superior oblique tendon sheath, or connective tissue trabeculae between the superior oblique tendon and the trochlea. Sometimes, no anatomic abnormality is found.

Acquired Brown syndrome may follow trauma to the orbit involving the region of the trochlea or sinus surgery. It may also occur with inflammatory processes, particularly sinusitis and juvenile rheumatoid arthritis.

Acquired inflammatory Brown syndrome may respond to treatment with steroids. Surgery may be helpful for children with true congenital Brown syndrome.

Parinaud Syndrome. This eponym designates a palsy of vertical gaze, isolated or associated with pupillary or nuclear oculomotor (cranial nerve III) paresis. It indicates a lesion affecting the mesencephalic tegmentum. The ophthalmic signs of midbrain disease include vertical gaze palsy, dissociation of the pupillary responses to light and to near focus, general pupillomotor paralysis, corectopia, dyscoria, accommodative disturbances, pathologic lid retraction, ptosis, extraocular muscle paresis, and convergence paralysis. Some cases have associated spasms of convergence, convergent retraction nystagmus, and vertical nystagmus, particularly on attempted vertical gaze. Combinations of these signs are referred to as the Koerber-Salus-Elschnig or sylvian aqueduct syndrome.

A principal cause of vertical gaze palsy and associated mesencephalic signs in children is tumor of the pineal gland or 3rd ventricle. Differential diagnosis includes trauma and demyelinating disease. In children with hydrocephalus, impairment of vertical gaze and pathologic lid retraction are referred to as the *setting-sun sign*. A transient supranuclear disorder of gaze is sometimes seen in healthy neonates.

CONGENITAL OCULAR MOTOR APRAXIA

This congenital disorder of conjugate gaze is characterized by a defect in voluntary horizontal gaze, compensatory jerking movement of the head, and retention of slow pursuit and reflexive eye movements. Additional features are absence of the fast (refixation) phase of optokinetic nystagmus and obligate contraversive deviation of

the eyes on rotation of the body. Affected children typically are unable to look quickly to either side voluntarily in response to a command or in response to an eccentrically presented object but may be able to follow a slowly moving target to either side. To compensate for the defect in purposive lateral eye movements, children jerk their head to bring the eyes into the desired position and may also blink repetitively in an attempt to change fixation. The signs tend to become less conspicuous with age.

The pathogenesis of congenital ocular motor apraxia is unknown. It may be a result of delayed myelination of the ocular motor pathways. Structural abnormalities of the central nervous system have been found in a few patients, including agenesis of the corpus callosum and cerebellar vermis, porencephaly, hamartoma of the foramen of Monro, and macrocephaly. Many children with congenital ocular motor apraxia show delayed motor and cognitive development.

A disorder of eye movement resembling congenital ocular motor apraxia may occur in patients with certain metabolic neurodegenerative diseases (particularly Gaucher disease) or with ataxia-telangiectasia, or as a sign of brain tumor.

NYSTAGMUS

Nystagmus (rhythmic oscillations of one or both eyes) may be caused by an abnormality in any one of the three basic mechanisms that regulate position and movement of the eyes: the fixation, conjugate gaze, or vestibular mechanisms. In addition, physiologic nystagmus may be elicited by appropriate stimuli (Table 614–1).

Congenital pendular nystagmus is generally associated with ocular abnormalities that lead to decreased visual acuity; common disorders that lead to early onset nystagmus include albinism, aniridia, achromatopsia, congenital cataracts, congenital macular lesions, congenital optic atrophy, and high refractive errors. In some instances, pendular nystagmus occurs as a dominant or X-linked characteristic without obvious ocular abnormalities. Rhythmic movements of the head may be associated.

Congenital idiopathic motor nystagmus is characterized by horizontal jerky oscillations with gaze preponderance; the nystagmus is coarser in one direction of gaze than in the other, with the jerk toward the direction of gaze. There are no ocular anatomic defects that cause the nystagmus and the visual acuity is generally near normal. There may be a point of reversal or a null point in which the nystagmus lessens and the vision improves; compensatory posturing, turning the head to bring the eyes into the position of least nystagmus, is characteristic. The cause of congenital jerky nystagmus is unknown; in some instances it is familial. Eye muscle surgery may be performed to eliminate abnormal head postures by bringing the point of best vision into straight-ahead gaze.

Acquired nystagmus requires prompt and thorough evaluation. Worrisome pathologic types are the gaze-paretic or gaze-evoked oscillations of cerebellar, brainstem, or cerebral disease.

TABLE 614-1 -- **Specific Patterns of Nystagmus**

Pattern	Description	Associated Conditions
Latent nystagmus	Conjugate jerk nystagmus toward viewing eye	Congenital vision defects, occurs with occlusion of eye
Manifest latent nystagmus	Fast jerk to viewing eye	Strabismus, congenital idiopathic nystagmus
Periodic alternating	Cycles of horizontal or horizontal-rotary that change direction	Caused by both visual and neurologic conditions
Seesaw nystagmus	One eye rises and intorts as other eye falls and extorts	Usually associated with optic chiasm defects
Nystagmus retractorius	Eyes jerk back into orbit or toward each other	Caused by pressure on mesencephalic tegmentum (Parinaud syndrome)
Gaze-evoked nystagmus	Jerk nystagmus in direction of gaze	Caused by medications, brainstem lesion, or labyrinthine dysfunction
Gaze-paretic nystagmus	Eyes jerk back to maintain eccentric gaze	Cerebellar disease
Downbeat nystagmus	Fast phase beating downward	Posterior fossa disease, drugs
Upbeat nystagmus	Fast phase beating upward	Brainstem and cerebellar disease; some visual conditions
Vestibular nystagmus	Horizontal-torsional or horizontal jerks	Vestibular system dysfunction
Asymmetric or onocular nystagmus	Pendular vertical nystagmus	Disease of retina and visual pathways
Spasmus nutans	Fine, rapid, pendular nystagmus	Torticollis, head nodding; idiopathic or gliomas of visual pathways

From Kliegman R: Practical Strategies in Pediatric Diagnosis and Therapy. Philadelphia, WB Saunders, 1996.

TABLE 614-2 -- **Specific Patterns of Non-Nystagmus Eye Movements**

Pattern	Description	Associated Conditions

Opsoclonus	Multidirectional conjugate movements of varying rate and amplitude	Hydrocephalus, diseases of brainstem and cerebellum, neuroblastoma
Ocular dysmetria	Overshoot of eyes on rapid fixation	Cerebellar dysfunction
Ocular flutter	Horizontal oscillations with forward gaze and sometimes with blinking	Cerebellar disease, hydrocephalus, or central nervous system neoplasm
Ocular bobbing	Downward jerk from primary gaze, remain for a few seconds, then drift back	Pontine disease
Ocular myoclonus	Rhythmic to-and-fro pendular oscillations of the eyes, with synchronous nonocular muscle movement	Damage to red nucleus, inferior olivary nucleus, and ipsilateral dentate nucleus

From Kliegman R: Practical Strategies in Pediatric Diagnosis and Therapy. Philadelphia, WB Saunders, 1996.

Nystagmus retractorius or *convergent nystagmus* is repetitive jerking of the eyes into the orbit or toward each other. It is usually seen with vertical gaze palsy as a feature of **Parinaud** or **Koerber-Salus-Elschnig** (sylvian aqueduct) **syndrome**. The causal condition may be neoplastic, vascular, or inflammatory. In children, nystagmus retractorius suggests particularly the presence of pinealoma or hydrocephalus.

Spasmus nutans is a special type of acquired nystagmus in childhood (see also Chapter 590). In its complete form, it is characterized by the triad of pendular nystagmus, head nodding, and torticollis. The nystagmus is characteristically very fine, very rapid, horizontal, and pendular; it is often asymmetric, sometimes unilateral. Signs usually develop within the 1st year or 2 of life. Components of the triad may develop at various times. In many cases, the condition is benign and self-limited, usually lasting a few months, sometimes years. The cause of this classic type of spasmus nutans, which usually resolves spontaneously, is unknown. Many children exhibiting signs resembling those of spasmus nutans have underlying brain tumors, particularly hypothalamic and chiasmal optic gliomas. Appropriate neurologic and neuroradiologic evaluation and careful monitoring of infants and children with nystagmus are therefore recommended.

OTHER ABNORMAL EYE MOVEMENTS

To be differentiated from true nystagmus are certain special types of abnormal eye movements, particularly opsoclonus, ocular dysmetria, and flutter (Table 614–2).

Opsoclonus.

Opsoclonus and ataxic conjugate movements are spontaneous, nonrhythmic, multidirectional, chaotic movements of the eyes. The eyes appear to be in agitation, with bursts of conjugate movement of varying amplitude in varying directions.

Opsoclonus is most often associated with encephalitis. It may be the first sign of neuroblastoma.

Ocular Motor Dysmetria.

This is analogous to dysmetria of the limbs. Affected individuals show a lack of precision in performing movements of refixation, characterized by an overshoot (or undershoot) of the eyes with several corrective to-and-fro oscillations on looking from one point to another. Ocular motor dysmetria is a sign of cerebellar or cerebellar pathway disease.

Flutter-Like Oscillations.

These intermittent to-and-fro horizontal oscillations of the eyes may occur spontaneously or on change of fixation. They are characteristic of cerebellar disease.

Chapter 615 - Abnormalities of the Lids

Ptosis.

In *blepharoptosis,* the upper eyelid droops below its normal level. Congenital ptosis is usually a result of a localized dystrophy of the levator muscle in which the striated muscle fibers are replaced with fibrous tissue. The condition may be unilateral or bilateral and can be familial, transmitted as a dominant trait.

Parents often comment that the eye looks smaller because of the drooping eyelid. The lid crease is decreased or absent where the levator muscle would normally insert below the skin surface. Because the levator is replaced by fibrous tissue, the lid does not move downward fully in downgaze (lid lag). If the ptosis is severe, affected children often attempt to raise the lid by lifting their brow or adapting a chin-up head posture to maintain binocular vision. **Marcus Gunn jaw-winking ptosis** accounts for 5% of ptosis in children. In this syndrome, an abnormal synkinesis exists between the 5th and 3rd cranial nerves; this causes the eyelid to elevate with movement of the jaw. The wink is produced by chewing or sucking and may be more noticeable than the ptosis itself.

Although ptosis in children is often an isolated finding, it may occur in association with other ocular or systemic disorders. Systemic disorders include myasthenia gravis, muscular dystrophy, and botulism. Ocular disorders include mechanical ptosis secondary to lid tumors, blepharophimosis syndrome, congenital fibrosis syndrome, combined levator/superior rectus maldevelopment, and congenital or acquired 3rd nerve palsy. A complete ophthalmic and systemic examination is therefore important in the evaluation of a child with ptosis.

Amblyopia may occur in children with ptosis. The amblyopia may be secondary to the lid's covering the visual axis (deprivation) or induced astigmatism due to the weight of the lid on the globe (anisometropia). When amblyopia occurs, it should generally be treated before treating the ptosis.

Treatment of ptosis in a child is indicated for elimination of an abnormal head posture, improvement in the visual field, prevention of amblyopia, and restoration of a normal eyelid appearance. The timing of surgery depends on the degree of ptosis, its cosmetic and functional severity, the presence or absence of compensatory posturing, the wishes of the parents, and the discretion of the surgeon. Surgical treatment is determined by the amount of levator function that is present. A levator resection may be used in children with moderate to good function. In patients with poor or absent function, a frontalis suspension procedure may be necessary. This technique requires that a suspension material be placed between the frontalis muscle and the tarsus of the eyelid. It allows patients to use their brow and frontalis muscle more effectively to raise their eyelid. Amblyopia remains a concern even after surgical correction and should be monitored closely.

Epicanthal Folds.

These vertical or oblique folds of skin extend on either side of the bridge of the nose from the brow or lid area, covering the inner canthal region. They are present to some degree in most young children and become less apparent with age. The folds may be sufficiently broad to cover the medial aspect of the eye, making the eyes appear crossed (pseudoesotropia). Epicanthal folds are a common feature of many syndromes, including chromosomal aberrations (trisomies) and disorders of single genes.

Lagophthalmos.

This is a condition in which complete closure of the lids over the globe is difficult or impossible. It may be paralytic, because of a facial palsy involving the orbicularis muscle, or spastic, as in thyrotoxicosis. It may be structural when retraction or shortening of the lids results from scarring or atrophy consequent to injury (burns) or disease. Infants with collodion membrane may have temporary lagophthalmos caused by the restrictive effect of the membrane on the lids. Lagophthalmos may accompany proptosis or buphthalmos when the lids, although normal, cannot effectively cover the enlarged or protuberant eye. A degree of physiologic lagophthalmos may occur normally during sleep, but functional lagophthalmos in an unconscious or debilitated patient can be a problem.

In patients with lagophthalmos, exposure of the eye may lead to drying, infection, corneal ulceration, or perforation of the cornea; the result may be loss of vision, even loss of the eye. In lagophthalmos, protection of the eye by artificial tear preparations, ophthalmic ointment, or moisture chambers is essential. Gauze pads are to be avoided, because the gauze may abrade the cornea. In some cases, surgical closure of the lids (tarsorrhaphy) may be necessary for long-term protection of the eye.

Lid Retractions.

Pathologic retraction of the lid may be myogenic or neurogenic. Myogenic retraction of the upper lid occurs in thyrotoxicosis, in which it is associated with three classic signs: a staring appearance **(Dalrymple sign),** infrequent blinking **(Stellwag sign),** and lag of the upper lid on downward gaze **(von Graefe sign).**

Neurogenic retraction of the lids may occur in conditions affecting the anterior mesencephalon. Lid retraction is a feature of the **syndrome of the sylvian aqueduct**. In children, it is commonly a sign of hydrocephalus. It may occur with meningitis. Paradoxical retraction of the lid is seen in the Marcus Gunn jaw-winking syndrome. It may also be seen with attempted eye movement after recovery from a 3rd nerve palsy, if aberrant regeneration of the oculomotor nerve fibers has occurred.

Simple staring and the physiologic or reflexive lid retraction (“eye popping”), in

contrast to pathologic lid retractions, occur in infants in response to a sudden reduction in illumination or as a startle reaction.

Ectropion, Entropion, and Epiblepharon.

Ectropion is eversion of the lid margin; it may lead to overflow of tears (epiphora) and subsequent maceration of the skin of the lid, to inflammation of exposed conjunctiva, or to superficial exposure keratopathy. Common causes are scarring consequent to inflammation, burns, or trauma, or weakness of the orbicularis muscle as a result of facial palsy; these forms may be corrected surgically. Protection of the cornea is essential. Ectropion is also seen in certain children who have faulty development of the lateral canthal ligament; this may occur in Down syndrome.

Entropion is inversion of the lid margin, which may cause discomfort and corneal damage because of the inward turning of the lashes (trichiasis). A principal cause is scarring secondary to inflammation such as occurs in trachoma or as a sequela of Stevens-Johnson syndrome. There is also a rare congenital form. Surgical correction is effective in many cases.

Epiblepharon is commonly seen in childhood and may be confused with entropion. In epiblepharon, a roll of skin beneath the lower eyelid lashes causes the lashes to be directed vertically and to touch the cornea. Unlike entropion, the eyelid margin itself is not rotated toward the cornea. Epiblepharon usually resolves spontaneously. If corneal scarring begins to occur, surgical correction may be necessary.

Blepharospasm.

This spastic or repetitive closure of the lids may be caused by irritative disease of the cornea, conjunctiva, or facial nerve; fatigue or uncorrected refractive error; or common tic. Thorough ophthalmic examination for pathologic causes, such as trichiasis, keratitis, conjunctivitis, or foreign body, is indicated. Local injection of botulinum toxin may give relief but frequently must be repeated.

Blepharitis.

This inflammation of the lid margins is characterized by erythema and crusting or scaling; the usual symptoms are irritation, burning, and itching. The condition is commonly bilateral and chronic or recurrent. The two main types are staphylococcal and seborrheic. In *staphylococcal blepharitis*, ulceration of the lid margin is common, the lashes tend to fall out, and conjunctivitis and superficial keratitis are often associated. In *seborrheic blepharitis,* the scales tend to be greasy, the lid margins are less red, and ulceration usually does not occur. The blepharitis is often of mixed type.

Thorough daily cleansing of the lid margins with a cloth or moistened cotton applicator to remove scales and crusts is important in the treatment of both forms. Staphylococcal blepharitis is treated with an antistaphylococcal antibiotic applied directly to the lid margins. When a child also has seborrhea, concurrent treatment of the scalp is important.

Pediculosis of the eyelashes may produce a clinical picture of blepharitis. The lice can be smothered with ophthalmic-grade petrolatum ointment applied to the lid margin and lashes. Nits should be mechanically removed from the lashes.

Hordeolum.

Infection of the glands of the lid may be acute or subacute; tender focal swelling and redness are noted. The usual agent is *Staphylococcus aureus.* When the meibomian glands are involved, the lesion is referred to as an *internal hordeolum;* the abscess tends to be large and may point through either the skin or the conjunctival surface. When the infection involves the glands of Zeis or Moll, the abscess tends to be smaller and more superficial and points at the lid margin; it is then referred to as an *external hordeolum* or *stye.*

Treatment is frequent warm compresses and, if necessary, surgical incision and drainage. In addition, topical antibiotic preparations are often used. Untreated, the infection may progress to cellulitis of the lid or orbit, requiring the use of systemic antibiotics.

Chalazion.

A chalazion is a granulomatous inflammation of a meibomian gland characterized by a firm, nontender nodule in the upper or lower lid. This lesion tends to be chronic and differs from internal hordeolum in the absence of acute inflammatory signs. Although many chalazia subside spontaneously, excision may be necessary if they become large enough to distort vision (by inducing astigmatism by exerting pressure on the globe) or to be a cosmetic blemish.

Coloboma of the Eyelid.

This cleftlike deformity may vary from a small indentation or notch of the free margin of the lid to a large defect involving almost the entire lid. If the gap is extensive, xerosis, ulceration, and corneal opacities may result from exposure. Early surgical correction of the lid defect is recommended. Other deformities frequently associated with lid colobomas include dermoid cysts or dermolipomas on the globe; they often occur in a position corresponding to the site of the lid defect. Lid colobomas may also be associated with extensive facial malformation, as in mandibulofacial dysostosis (Franceschetti or Treacher Collins syndrome).

Tumors of the Lid.

A number of lid tumors arise from surface structures (the epithelium and sebaceous glands). *Nevi* may appear in early childhood; most are junctional. Compound nevi tend to develop in the prepubertal years and dermal nevi at puberty. *Malignant epithelial tumors* (basal cell carcinoma, squamous cell carcinoma) are rare in children, but the basal cell nevus syndrome and the malignant lesions of xeroderma

pigmentosum and of Rothmund-Thomson syndrome may develop in childhood.

Other lid tumors arise from deeper structures (the neural, vascular, and connective tissues). *Capillary hemangiomas* are especially common in children. Many tend to regress spontaneously, although they may show alarmingly rapid growth in infancy. In many cases, the best management of such hemangiomas is patient observation, allowing spontaneous regression to occur (see Chapter 640). In the case of a rapidly expanding lesion, which may cause amblyopia by obstructing the visual axis or inducing astigmatism, corticosteroid, interferon, or surgical treatment should be considered. *Nevus flammeus* (port-wine stain), a noninvoluting hemangioma, occurs as an isolated lesion or in association with other signs of Sturge-Weber syndrome. Affected patients should be monitored for the development of glaucoma. *Lymphangiomas* of the lid appear as firm masses at or soon after birth and tend to enlarge slowly during the growing years. Associated conjunctival involvement, appearing as a clear, cystic, sinuous conjunctival mass, may provide a clue to the diagnosis. In some cases there is also orbital involvement. The treatment is surgical excision. *Plexiform neuromas* of the lids occur in children with neurofibromatosis, often with ptosis as the first sign. The lid may take on an S-shaped configuration. The lids may also be involved by other tumors, such as retinoblastoma, neuroblastoma, and rhabdomyosarcoma of the orbit; these conditions are discussed elsewhere.

Chapter 616 - Disorders of the Lacrimal System

The Tear Film.

The tear film, which bathes the eye, is actually a complex structure composed of three layers. The innermost mucin layer is secreted by the goblet and epithelial cells of the conjunctiva and the acinar cells of the lacrimal gland. It adds stability and provides an attachment for the tear film to the conjunctiva and cornea. The middle aqueous layer constitutes 98% of the tear film and is produced by the main lacrimal gland and accessory lacrimal glands. It contains various electrolytes and proteins as well as antibodies. The outermost lipid layer is produced largely from the sebaceous meibomian glands of the eyelid and retards evaporation of the tear film. Tears drain medially into the punctal openings of the lid margin and flow through the canaliculi into the lacrimal sac and then through the nasolacrimal duct into the nose.

Dacryostenosis and Dacryocystitis.

Congenital nasolacrimal duct obstruction (CNLDO), or dacryostenosis, is the most common disorder of the lacrimal system, occurring in up to 6% of newborn infants. It is usually caused by a failure of canalization of the epithelial cells that form the nasolacrimal duct as it enters the nose (valve of Hasner). Signs of CNLDO may be present at the time of birth, although the condition may not become evident until normal tear production develops. Signs of CNLDO include an excessive tear lake, overflow of tears onto the lid and cheek, and reflux of mucoid material that is produced in the lacrimal sac. Erythema or maceration of the skin may result from irritation and rubbing produced by dripping of tears and discharge. If the blockage is complete, these signs may be severe and continuous. If obstruction is only partial, the nasolacrimal duct may be capable of draining the basal tear film that is produced. However, under periods of increased tear production (exposure to cold, wind, sunlight) or increased closure of the distal end of the nasolacrimal duct (nasal mucosal edema), tear overflow may become evident or may increase.

Infants with CNLDO may develop acute infection and inflammation of the nasolacrimal sac (dacryocystitis), inflammation of the surrounding tissues (pericystitis), or rarely periorbital cellulitis. With dacryocystitis, the sac area is swollen, red, and tender, and patients may have systemic signs of infection such as fever and irritability.

The primary treatment of uncomplicated nasolacrimal obstruction is a regimen of nasolacrimal massage, usually 2–3 times a day, accompanied by cleansing of the lids with warm water. Topical antibiotics are used for significant mucopurulent drainage. Most cases of CNLDO resolve spontaneously, 96% before 1 yr of age. For cases that do not resolve by 1 yr, the nasolacrimal duct may be probed, with a cure rate of approximately 90%.

Acute dacryocystitis or *cellulitis* requires prompt treatment with antibiotics. In such cases, some form of definitive surgical intervention is usually indicated.

A *mucocele* is an unusual presentation of a nonpatent nasolacrimal sac that is obstructed both proximally and distally. Mucoceles can be seen at birth or shortly after birth as a bluish subcutaneous mass just below the medial canthal tendon. Initial treatment should include warm compresses and gentle massage of the lacrimal sac. If an infection develops, systemic administration of antibiotics is required. A probing of the nasolacrimal system may then be necessary to prevent further infection or treat abscess formation.

Not all tearing in infants and children is caused by nasolacrimal obstruction. Tearing may also be a sign of glaucoma, intraocular inflammation, or external irritation, such as that from a corneal abrasion or foreign body.

Dacryoadenitis.

Dacryoadenitis, or inflammation of the lacrimal gland, is uncommon in childhood. It may occur with mumps (in which case it is usually acute and bilateral, subsiding in a few days or weeks) or with infectious mononucleosis. *Staphylococcus aureus* may produce a suppurative dacryoadenitis. Chronic dacryoadenitis is associated with certain systemic diseases, particularly sarcoidosis, tuberculosis, and syphilis. Some systemic diseases may produce enlargement of the lacrimal and salivary glands **(Mikulicz syndrome)**.

Alacrima and “Dry Eye.”

Marked deficiency of tears may occur as an isolated unilateral or bilateral congenital defect or in association with other nervous system anomalies, such as aplasia of cranial nerve nuclei. It occurs congenitally in familial dysautonomia (Riley-Day syndrome) and in the anhidrotic type of ectodermal dysplasia; it may occur with glucocorticoid deficiency, sometimes in association with swallowing dysfunction. An acquired abnormality of any layer of the tear film may produce a dry eye. Commonly acquired disorders that may lead to a decreased or unstable tear film include Sjögren syndrome, Stevens-Johnson syndrome, vitamin A deficiency, ocular pemphigoid, trachoma, chemical burns, irradiation, and meibomian gland dysfunction. Any tear deficiency can lead to corneal ulceration, scarring, or infection. Treatment includes correction of the underlying disorder when possible and frequent instillation of an artificial tear preparation. In some cases, occlusion of the lacrimal puncta is helpful. In severe cases, tarsorrhaphy may be necessary to protect the cornea.

Chapter 617 - Disorders of the Conjunctiva

Conjunctivitis.

The conjunctiva reacts to a wide range of bacterial and viral agents, allergens, irritants, toxins, and systemic diseases. Conjunctivitis is common in childhood and may be infectious or noninfectious (Table 617–1).

Ophthalmia Neonatorum.

Ophthalmia neonatorum, a form of conjunctivitis occurring in infants younger than 4 wk of age, is the most common eye disease of newborns. Its many different etiologic agents vary greatly in their virulence and outcome. For instance, silver nitrate instillation may result in a mild self-limited conjunctivitis, whereas *Neisseria gonorrhoeae* and

TABLE 617-1 -- **The Red Eye**

Condition	Etiology	Signs and Symptoms	Treatment
Bacterial conjunctivitis	*Haemophilus influenzae, Haemophilus aegyptius, Streptococcus pneumoniae*	Mucopurulent unilateral or bilateral discharge, normal vision, photophobia	Topical antibiotics, parenteral ceftriaxone for gonococcus, *H. influenzae*
	Neisseria gonorrhoeae	Conjunctival injection and edema (chemosis); gritty sensation	
Viral conjunctivitis	Adenovirus, ECHO virus, coxsackievirus	As above; may be hemorrhagic, unilateral	Self- limited

Neonatal conjunctivitis	*Chlamydia trachomatis*, gonococcus, chemical (silver nitrate), *Staphylococcus aureus*	Palpebral conjunctival follicle or papillae; as above	Ceftriaxone for gonococcus and erythromycin for *C. trachomatis*
Allergic conjunctivitis	Seasonal pollens or allergen exposure	Itching, incidence of bilateral chemosis (edema) greater than that of erythema, tarsal papillae	Antihistamines, steroids, cromolyn
Keratitis	Herpes simplex, adenovirus, *Streptococcus pneumoniae, Staphylococcus aureus, Pseudomonas, Acanthamoeba*, chemicals	Severe pain, corneal swelling, clouding, limbus erythema, hypopyon, cataracts; contact lens history with amebic infection	Specific antibiotics for bacterial/fungal infections; keratoplasty, acyclovir for herpes
Endophthalmitis	*S. aureus, S. pneumoniae, Candida albicans*, associated surgery or trauma	Acute onset, pain, loss of vision, swelling, chemosis, redness; hypopyon and vitreous haze	Antibiotics
Anterior uveitis (iridocyclitis)	JRA, Reiter syndrome, sarcoidosis, Behçet disease, Kawasaki's disease, inflammatory bowel disease	Unilateral/bilateral; erythema, ciliary flush, irregular pupil, iris adhesions; pain, photophobia, small pupil, poor vision	Topical steroids, plus therapy for primary disease
Posterior uveitis (choroiditis)	Toxoplasmosis, histoplasmosis, *Toxocara canis*	No signs of erythema, decreased vision	Specific therapy for pathogen
Episcleritis/scleritis	Idiopathic autoimmune disease (e.g., SLE, Henoch- Schönlein purpura)	Localized pain, intense erythema, unilateral; blood vessels bigger than in conjunctivitis; scleritis may cause globe perforation	Episcleritis is self-limiting; topical steroids for fast relief
Foreign body	Occupational exposure	Unilateral, red, gritty feeling; visible or microscopic size	Irrigation, removal; check for ulceration
Blepharitis	*S. aureus, Staphylococcus epidermidis*, seborrheic, blocked lacrimal duct; rarely molluscum contagiosum, *Phthirus pubis, Pediculus capitis*	Bilateral, irritation, itching, hyperemia, crusting, affecting lid margins	Topical antibiotics, warm compresses
Dacryocystitis	Obstructed lacrimal sac: *S. aureus, H. influenzae*, pneumococcus	Pain, tenderness, erythema and exudate in area of lacrimal sac (inferomedial to inner canthus); tearing (epiphora); possible orbital cellulitis	Systemic, topical antibiotics; surgical drainage
Dacryoadenitis	*S. aureus, Streptococcus*, CMV, measles, EBV, enteroviruses; trauma, sarcoidosis, leukemia	Pain, tenderness, edema, erythema over gland area (upper temporal lid); fever, leukocytosis	Systemic antibiotics; drainage of orbital abscesses
Orbital cellulitis (postseptal cellulitis)	Paranasal sinusitis: *H. influenzae, S. aureus, S. pneumoniae*, streptococci Trauma: *S. aureus*	Rhinorrhea, chemosis, vision loss, painful extraocular motion, proptosis, ophthalmoplegia, fever, lid edema, leukocytosis	Systemic antibiotics, drainage of orbital abscesses
	Fungi: *Aspergillus, Mucor* spp. if immunodeficient		
Periorbital cellulitis (preseptal cellulitis)	Trauma: *S. aureus*, streptococci Bacteremia: pneumococcus, streptococci, *H. influenzae*	Cutaneous erythema, warmth, normal vision, minimal involvement of orbit; fever, leukocytosis, toxic appearance	Systemic antibiotics

CMV = cytomegalovirus; EBV = Epstein-Barr virus; JRA = juvenile rheumatoid arthritis; SLE = systemic lupus erythematosus.

From Behrman R, Kliegman R: Nelson's Essentials of Pediatrics, 3rd ed. Philadelphia, WB Saunders, 1998.

Pseudomonas are capable of causing corneal perforation, blindness, and death. The risk of conjunctivitis in newborns depends on frequencies of maternal infections,

prophylactic measures, circumstances during labor and delivery, and postdelivery exposures to microorganisms.

EPIDEMIOLOGY.

Conjunctivitis during the neonatal period is usually acquired during vaginal delivery and reflects the sexually transmitted diseases prevalent in the community. In 1880, 10% of European children developed gonococcal conjunctivitis at birth. Ophthalmia neonatorum was the leading cause of blindness during that period. The epidemiology of this condition changed dramatically in 1881, when Crede reported that 2% silver nitrate solution instilled in the eyes of newborns reduced the incidence of gonococcal ophthalmia from 10% to 0.3%.

During the 20th century, the incidence of gonococcal ophthalmia neonatorum decreased in industrialized countries secondary to widespread use of silver nitrate prophylaxis and prenatal screening and treatment of maternal gonorrhea. Gonococcal ophthalmia neonatorum has an incidence of 0.3/1,000 live births in the United States. In comparison, *Chlamydia trachomatis* is the most common organism causing ophthalmia neonatorum in the United States, with an incidence of 8.2/1,000 births.

CLINICAL MANIFESTATIONS.

The clinical manifestations of the various forms of ophthalmia neonatorum are not specific enough to allow an accurate diagnosis. Although the timing and character of the signs are somewhat typical for each cause of this condition, there is considerable overlap and physicians should not rely solely on clinical findings. Regardless of its cause, ophthalmia neonatorum is characterized by redness and chemosis (swelling) of the conjunctiva, edema of the eyelids, and discharge, which may be purulent.

Ophthalmia neonatorum is a potentially blinding condition. The infection may also have associated systemic manifestations that require treatment. Therefore, any newborn infant who develops signs of conjunctivitis needs a prompt and comprehensive evaluation to determine the agent causing the infection and the appropriate treatment.

The onset of inflammation caused by silver nitrate drops usually occurs within 6–12?hr after birth, with clearing by 24–48?hr. The usual incubation period for conjunctivitis due to *N. gonorrhoeae* is 2–5 days and for that due to *C. trachomatis* is 5–14 days. Gonococcal infection may be present at birth or delayed beyond 5 days of life owing to partial suppression by ocular prophylaxis. Gonococcal conjunctivitis may also begin in infancy after inoculation by the contaminated fingers of adults. The time of onset of disease with other bacteria is highly variable.

Gonococcal conjunctivitis begins with mild inflammation and a serosanguineous discharge. Within 24?hr, the discharge becomes thick and purulent, and tense edema of the eyelids with marked chemosis occurs. If proper treatment is delayed, the infection may spread to involve the deeper layers of the conjunctivae and the cornea. Complications include corneal ulceration and perforation, iridocyclitis, anterior synechiae, and rarely panophthalmitis. Conjunctivitis caused by *C. trachomatis* (inclusion blennorrhea) may vary from mild inflammation to severe swelling of the eyelids with copious purulent discharge. The process involves mainly the tarsal conjunctivae; the corneas are rarely affected. Conjunctivitis due to *Staphylococcus aureus* or other organisms is similar to that produced by *C. trachomatis.* Conjunctivitis due to *Pseudomonas aeruginosa* is uncommon, is acquired in the nursery, and is a potentially serious process. It is characterized by the appearance on day 5–18 of edema, erythema of the lids, purulent discharge, pannus formation, endophthalmitis, sepsis, shock, and death.

DIAGNOSIS.

Conjunctivitis appearing after 48?hr should be evaluated for a possibly infectious cause. Gram stain of the purulent discharge should be performed and the material cultured. If a viral etiology is suspected, a swab should be submitted in tissue culture media for virus isolation. In chlamydial conjunctivitis, the diagnosis is made by examining Giemsa-stained epithelial cells scraped from the tarsal conjunctivae for the characteristic intracytoplasmic inclusions, by isolating the organisms from a conjunctival swab using special tissue culture techniques, by immunofluorescent staining of conjunctival scrapings for chlamydial inclusions, or by tests for chlamydial antigen. The differential diagnosis includes dacryocystitis caused by congenital lacrimal duct obstruction with lacrimal sac distention (dacryocystocele).

TREATMENT.

Treatment of infants in whom gonococcal ophthalmia is suspected and the Gram stain shows the characteristic intracellular gram-negative diplococci should be initiated immediately with ceftriaxone, 50?mg/kg/24?hr for one dose not to exceed 125?mg. In addition, the eye should be irrigated initially with saline every 10–30 min, gradually increasing to 2-hr intervals until the purulent discharge has cleared. An alternative regimen includes cefotaxime (100?mg/kg/24?hr given IV or IM every 12?hr for 7 days or 100?mg/kg as a single dose). Treatment is extended if sepsis or other extraocular sites are involved (meningitis, arthritis). Inclusion blennorrhea is treated with oral erythromycin (50?mg/kg/24?hr in four divided doses) for 2 wk. This cures conjunctivitis and may prevent subsequent chlamydial pneumonia. *Pseudomonas* neonatal conjunctivitis is treated with systemic antibiotics, including an aminoglycoside, plus local saline irrigation and gentamicin ophthalmic ointment. Staphylococcal conjunctivitis is treated with parenteral methicillin and local saline irrigation.

PROGNOSIS AND PREVENTION.

Before the institution of topical ophthalmic prophylaxis at birth, gonococcal ophthalmia was a common cause of blindness or permanent eye damage. If properly applied, this form of prophylaxis is highly effective unless infection is present at birth. Drops of 0.5% erythromycin or 1% silver nitrate are instilled directly into the open eyes at birth using wax or plastic single-dose containers. Saline irrigation after silver nitrate application is unnecessary. Silver nitrate is ineffective against active infection. Povidone-iodine (2% solution) is also an effective prophylactic agent.

Identification of maternal gonococcal infection and appropriate treatment has become a standard element of routine prenatal care. An infant born to a woman who has untreated gonococcal infection should receive a single dose of ceftriaxone,

50?mg/kg (maximum 125?mg) IV or IM, in addition to topical prophylaxis. The dose should be reduced for premature infants. Penicillin (50,000 units) should be used if the mother's gonococcal isolate is known to be penicillin sensitive.

Neither topical prophylaxis nor topical treatment prevents the afebrile pneumonia that occurs in 10–20% of infants exposed to *C. trachomatis.* Although chlamydial conjunctivitis is often a self-limiting disease, chlamydial pneumonia may have serious consequences. It is important that infants with chlamydial disease receive systemic treatment. Treatment of colonized pregnant women with erythromycin may prevent neonatal disease.

Acute Purulent Conjunctivitis.

This is characterized by more or less generalized conjunctival hyperemia, edema, mucopurulent exudate, and various degrees of ocular discomfort. It is usually a result of bacterial infection. The most frequent causes are nontypable *Haemophilus influenzae* (associated with ipsilateral otitis media), pneumococci, staphylococci, and streptococci. Conjunctival smear and culture are helpful in differentiating specific types. These common forms of acute purulent conjunctivitis usually respond well to warm compresses and frequent topical instillation of antibiotic drops. **Brazilian purpuric fever** due to *Haemophilus aegyptius* manifests as conjunctivitis and sepsis. *N. gonorrhoeae* and *Chlamydia* are relatively common causes of acute purulent conjunctivitis in children beyond the newborn period, especially in adolescents. These infections require specific testing and treatment.

Viral Conjunctivitis.

This is generally characterized by a watery discharge. Follicular changes (small aggregates of lymphocytes) are often found in the palpebral conjunctiva. Conjunctivitis resulting from adenovirus infection is relatively common, sometimes with corneal involvement (see later text). Outbreaks of conjunctivitis caused by enterovirus are also encountered; this type may be hemorrhagic. Conjunctivitis is commonly associated with such systemic viral infections as the childhood exanthems, particularly measles. These types are self-limited.

Epidemic Keratoconjunctivitis.

This is caused by adenovirus type 8 and is transmitted by direct contact. It initially presents as a sensation of a foreign body beneath the lids, with itching and burning. Edema and photophobia develop rapidly, and large oval follicles appear within the conjunctiva. Preauricular adenopathy and a pseudomembrane on the conjunctival surface occur frequently. Subepithelial corneal infiltrates may develop and may cause blurring of vision; these usually disappear but may permanently reduce visual acuity. Corneal complications are less common in children than in adults. Children may have associated upper respiratory tract infection and pharyngitis. Although antibacterial drops are often prescribed, these are generally not indicated. No specific medical therapy is available to decrease the symptoms or shorten the course of the disease. Emphasis must be placed on prevention of spread of the disease. Replicating virus is present in 95% of patients 10 days after the appearance of symptoms.

Membranous and Pseudomembranous Conjunctivitis.

These types can be encountered in a number of diseases. The classic membranous conjunctivitis is that of diphtheria, accompanied by a fibrin-rich exudate that forms on the conjunctival surface and permeates the epithelium; the membrane is removed with difficulty and leaves raw bleeding areas. In pseudomembranous conjunctivitis, the layer of fibrin-rich exudate is superficial and can often be stripped easily, leaving the surface smooth. This type occurs with many bacterial and viral infections, including staphylococcal, pneumococcal, streptococcal, or chlamydial conjunctivitis, and in epidemic keratoconjunctivitis. It is also found in vernal conjunctivitis and in Stevens-Johnson disease.

Allergic Conjunctivitis.

This is usually accompanied by intense itching, tearing, and conjunctival edema. It is commonly seasonal. Cold compresses and decongestant drops give symptomatic relief. Topical mast cell stabilizers or prostaglandin inhibitors may also help. In selected cases, topical corticosteroids are used under an ophthalmologist's supervision.

Vernal Conjunctivitis.

This usually begins in the prepubertal years and may recur for many years. Atopy appears to have a role in its origin, but the pathogenesis is uncertain. Extreme itching and tearing are the usual complaints. Large, flattened, cobblestone-like papillary lesions of the palpebral conjunctivae are characteristic. A stringy exudate and a milky conjunctival pseudomembrane are frequently present. Small elevated lesions of the bulbar conjunctiva adjacent to the limbus (limbal form) may be found. Smear of the conjunctival exudate reveals many eosinophils. Topical corticosteroid therapy and cold compresses afford some relief. Topical mast cell stabilizers or prostaglandin inhibitors are useful when long-term control is needed. The long-term use of corticosteroids should be avoided.

Chemical Conjunctivitis.

This can result when an irritating substance enters the conjunctival sac (as in the acute but benign conjunctivitis caused by silver nitrate in newborns). Other common offenders are household cleaning substances, sprays, smoke, smog, and industrial pollutants. Alkalis tend to linger in the conjunctival tissues and continue to inflict damage for hours or days. Acids precipitate the proteins in tissues and so produce their effect immediately. In either case, prompt, thorough, and copious irrigation is crucial. Extensive tissue damage, even loss of the eye, can result, especially if the offending agent is an alkali.

Other Conjunctival Disorders.

Subconjunctival hemorrhage is manifested by bright or dark red patches in the bulbar conjunctiva and may result from injury or inflammation. It commonly occurs spontaneously. It may occasionally result from severe sneezing or coughing. Rarely it may be a manifestation of a blood dyscrasia.

Pinguecula is a yellowish-white, slightly elevated mass on the bulbar conjunctiva, usually in the interpalpebral region. It represents elastic and hyaline degenerative changes of the conjunctiva. No treatment is required except for cosmetic reasons, in which case simple excision suffices.

Pterygium is a fleshy triangular conjunctival lesion that may encroach on the cornea. It typically occurs in the nasal interpalpebral region. The pathologic findings are similar to those of a pinguecula. The development of pterygia is related to exposure to ultraviolet light, and it therefore is more commonly found among people who live near the equator. Removal is suggested when the lesion encroaches far onto the cornea. Recurrence after removal is common.

Dermoid cyst and *dermolipoma* are benign lesions, clinically similar in appearance. They are smooth, elevated, round to oval lesions of various sizes. The color varies from yellowish white to fleshy pink. The most frequent site is the upper outer quadrant of the globe; they also commonly occur near or straddling the limbus. Dermolipoma is composed of adipose and connective tissue. Dermoid cysts may also contain glandular tissue, hair follicles, and hair shafts. Excision for cosmetic reasons is feasible. Dermolipomas are often connected to the extraocular muscles, making their complete removal impossible without sacrificing ocular motility.

Conjunctival nevus is a small, slightly elevated lesion that may vary in pigmentation from pale salmon to dark brown. It is usually benign, but careful observation for progressive growth or changes suggestive of malignancy is advised.

Symblepharon is a cicatricial adhesion between the conjunctiva of the lid and the globe; the lower lid is usually affected. It follows operation or injuries, especially burns from lye, acids, or molten metals. It is a serious complication of Stevens-Johnson syndrome. It may interfere with motion of the eyeball and may cause diplopia. The adhesions should be separated and the raw surfaces kept from uniting during healing. Grafts of oral mucous membrane may be necessary.

Chapter 618 - Abnormalities of the Cornea

Megalocornea.

This is a nonprogressive symmetric condition characterized by an enlarged cornea (>12?mm in diameter) and an anterior segment in which there is no evidence of previous or concurrent ocular hypertension. High myopia is frequently present and may lead to reduced vision. A frequent complication is the development of lens opacities in adult life. All modes of inheritance have been described, although X-linked recessive is most common; therefore, this disorder most commonly afflicts males. Systemic abnormalities that may be associated with megalocornea include Marfan syndrome, craniosynostosis, and Alport syndrome. The cause of the enlargement of the cornea and the anterior segment is unknown, but possible explanations include a defect in the growth of the optic cup and an arrest of congenital glaucoma. The region on the X chromosome responsible for this disorder has been identified.

Pathologic corneal enlargement caused by glaucoma is to be differentiated from this anomaly. Any progressive increase in the size of the cornea, especially when accompanied by photophobia, lacrimation, or haziness of the cornea, requires prompt ophthalmologic evaluation.

Microcornea.

Microcornea, or *anterior microphthalmia,* is an abnormally small cornea in an otherwise relatively normal eye. It may be familial, with transmission being dominant more often than recessive. More commonly, a small cornea is just one feature of an otherwise developmentally abnormal or microphthalmic eye; associated defects include colobomas, microphakia, congenital cataract, glaucoma, and aniridia.

Keratoconus.

This is a disease of unclear pathogenesis characterized by progressive thinning and bulging of the central cornea, which becomes cone shaped. Although familial cases are known, most cases are sporadic. Eye rubbing and contact lens wear have been implicated as pathogenic, but the evidence to support this is equivocal. The incidence is increased in individuals with atopy, Down syndrome, Marfan syndrome, and retinitis pigmentosa.

Most cases are bilateral, but involvement may be asymmetric. The disorder usually presents and progresses rapidly during adolescence; progression slows and stabilizes when patients reach full growth. Descemet membrane may occasionally be stretched beyond its elastic breaking point, causing an acute rupture in the membrane with resultant sudden and marked corneal edema (acute hydrops) and decrease in vision. The corneal edema resolves as endothelial cells cover the defective area. Some degree of corneal scarring occurs, but the visual acuity is often better than before the initial incident. Signs of keratoconus include Munson sign (bulging of the lower eyelid on looking downward) and the presence of a Fleischer ring (a deposit of iron in the epithelium at the base of the cone). Corneal transplantation is indicated if satisfactory visual acuity cannot be attained with the use of contact lenses.

Neonatal Corneal Opacities.

Loss of the normal transparency of the cornea in neonates may occur secondary to either intrinsic hereditary or extrinsic environmental causes (Table 618–1).

Sclerocornea.

In sclerocornea, the normal translucent cornea is replaced by sclera-like tissue. Instead of a clearly demarcated cornea, white, feathery, often ill-defined and vascularized tissue develops in the peripheral cornea, appearing to blend with and extend from the sclera. The central cornea is usually clearer, but total replacement of the cornea with sclera may occur. The curvature of the cornea is often flatter, similar to the sclera. Potentially coexisting abnormalities include a shallow anterior chamber, iris abnormalities, and microphthalmos. This condition is usually bilateral. In approximately 50% of cases, a dominant or recessive inheritance has been described. Sclerocornea has been reported in association with numerous systemic abnormalities including limb deformities, craniofacial defects, and genitourinary disorders. In generalized sclerocornea, early keratoplasty should be considered in an effort to provide vision.

Peters Anomaly.

Peters anomaly is a central corneal opacity (leukoma) that is present at birth. It is often associated with iridocorneal adhesions that extend from the iris collarette to the border of the corneal opacity. Approximately one half of patients have other ocular abnormalities, which may include cataracts, glaucoma, and microcornea. As many as 80% of cases may be bilateral, and 60% are associated with systemic malformations that may affect any major organ system. Some investigators have divided Peter anomaly into two types: a mesodermal or neuroectodermal form (type I), which shows no associated lens changes, and a surface ectodermal form (type II), which does. Histologic findings include a focal absence of Descemet membrane and corneal endothelium in the region of the opacity. Peters anomaly may be caused by incomplete migration and differentiation of the precursor cells of the central corneal endothelium and Descemet membrane or a defective separation between the primitive lens and cornea during embryogenesis.

Dermoids.

Epibulbar dermoids are choristomas. They are often present at birth and may increase in size with age. They occur most frequently in the lower temporal quadrant. They most commonly straddle the limbus and extend into the peripheral cornea. Rarely, they may be confined entirely to the cornea or conjunctiva. Epibulbar dermoids may cause visual disturbance by encroaching on the visual axis or by contributing to the development of astigmatism.

A dermoid usually appears as a well-circumscribed rounded or oval, gray or pinkish-yellow mass with a dry surface from which short hairs may protrude. It may affect only the superficial layers of the cornea, although full-thickness involvement is common. Associated ocular anomalies include eyelid and iris colobomas, microphthalmos, and retinal and choroidal defects. A total of 30% of dermoids are associated with systemic abnormalities. Many of the associated anomalies involve developmental defects of the first branchial arch (vertebral anomalies, dystosis of the facial bones and dental anomalies, and Goldenhar syndrome). Epibulbar dermoids are found in 75% of cases of Goldenhar syndrome.

Dendritic Keratitis.

Infection of the cornea with the virus of herpes simplex produces a characteristic lesion of the corneal epithelium, referred to as a *dendrite*; it has a branching treelike pattern that can be demonstrated by fluorescein staining. The acute episode is accompanied by pain, photophobia, tearing, blepharospasm, and conjunctival infection. Specific treatment may include mechanical debridement of the involved corneal epithelium to remove the source of infection and eliminate an antigenic stimulus to inflammation in the adjacent stroma. Medical treatment involves the use of 5-iodo-2'-deoxyuridine (IDU), topical vidarabine, or, most commonly, trifluridine. In addition, a cycloplegic agent is useful to relieve pain from spasm of the ciliary muscle. Overly aggressive topical antiviral treatment itself can be toxic to the cornea and should be avoided. Recurrent infection and deep stromal involvement can lead to corneal scarring and loss of vision.

Topical use of corticosteroids causes exacerbation of superficial herpetic disease of the eye and may lead to corneal perforation; eye drops combining steroids and antibiotics are therefore to be avoided in treatment of red eye unless there are clear-cut indications for their use and close supervision during therapy.

Infants born to mothers infected with herpes simplex virus should be examined carefully for signs of ocular involvement.

TABLE 618-1 -- STUMPED: Differential Diagnosis of Neonatal Corneal Opacities

Diagnosis	Laterality	Opacity	Ocular Pressure	Other Ocular Abnormalities	Natural History
S–Sclerocornea	Unilateral or bilateral	Vascularized, blends with sclera, clearer centrally	Normal (or elevated)	Cornea plana	Nonprogressive
T–Tears in endothelium and Descemet's membrane					
Birth trauma	Unilateral	Diffuse edema	Normal	Possible hyphema, periorbital ecchymoses	Spontaneous improvement in 1 mo
Infantile glaucoma	Bilateral	Diffuse edema	Elevated	Megalocornea, photophobia and tearing, abnormal angle	Progressive unless treated
U–Ulcers					
Herpes simplex keratitis	Unilateral	Diffuse with geographic epithelial defect	Normal	None	Progressive
Congenital rubella	Bilateral	Disciform or diffuse edema, no frank ulceration	Normal or elevated	Microphthalmos, cataract, pigment epithelial mottling	Stable, may clear
Neurotrophic—exposure	Unilateral or bilateral	Central ulcer	Normal	Lid anomalies, congenital sensory neuropathy	Progressive
M–Metabolic (rarely present at birth) (mucopolysaccharidoses IH, IS; mucolipidoses type IV)*	Bilateral	Diffuse haze, denser peripherally	Normal	Few	Progressive
P–Posterior corneal defect	Unilateral or bilateral	Central, diffuse haze or vascularized leukoma	Normal or elevated	Anterior chamber cleavage syndrome	Stable, sometimes early clearing or vascularization
E–Endothelial dystrophy					

Congenital hereditary endothelial dystrophy	Bilateral	Diffuse corneal edema, marked corneal thickening	Normal	None	Stable
Posterior polymorphous dystrophy	Bilateral	Diffuse haze, normal corneal thickness	Normal	Occasional peripheral anterior synechiae	Slowly progressive
Congenital hereditary stromal dystrophy	Bilateral	Flaky, feathery stromal opacities; normal corneal thickness	Normal	None	Stable
D–Dermoid	Unilateral or bilateral	White vascularized mass, hair, lipid arc	Normal	None	Stable

From Nelson LB, Calhoun JH, Harley RD: Pediatric Ophthalmology, 3rd ed. Philadelphia, WB Sau p 210.

* *Mucopolysaccharidosis IH (Hurler's syndrome); mucopolysaccharidosis IS (Scheie's syndrome).*

Intravenous acyclovir is required for treatment of ocular herpes in newborns.

Corneal Ulcers.

The usual signs and symptoms are focal or diffuse corneal haze, hyperemia, lid edema, pain, photophobia, tearing, and blepharospasm. *Hypopyon* (pus in the anterior chamber) is common. Corneal ulcers require prompt treatment. They result most frequently from traumatic lesions that become secondarily infected. Many organisms are capable of infecting the cornea. One of the most troublesome is *Pseudomonas aeruginosa*; it can rapidly destroy stromal tissue and lead to corneal perforation. *Neisseria gonorrhoeae* also is particularly damaging to the cornea. Indolent ulcers may be caused by fungi, often in association with the use of contact lenses. In each case, scrapings of the cornea must be studied in an effort to identify the infectious agent and to determine the best therapy. Although aggressive local treatment is generally needed to save the eye, systemic treatment may be necessary in some cases as well. Perforation or scarring resulting from corneal ulceration is an important cause of blindness throughout the world and is estimated to be responsible for 10% of blindness in the United States.

Unexplained corneal ulcers in infants and young children should raise the question of a sensory defect, as in Riley-Day or Goldenhar-Gorlin syndrome, or of a metabolic disorder such as tyrosinemia.

Phlyctenules.

These are small, yellowish, slightly elevated lesions usually located at the corneal limbus; they may encroach on the cornea and extend centrally. A small corneal ulcer is often found at the head of the advancing lesion, with a fascicle of blood vessels behind the head of the lesion. Although once thought to represent a sign of systemic tuberculin infection, phlyctenular keratoconjunctivitis is now accepted as a morphologic expression of delayed hypersensitivity to diverse antigens. In children, it commonly occurs as a result of a hypersensitivity reaction of the conjunctiva or cornea to bacterial products. Treatment usually consists of eliminating the underlying disorder, usually staphylococcal blepharitis or meibomianitis, and suppressing the immune response with the use of topical corticosteroid therapy. A superficial stromal pannus and scarring sometimes remain after treatment.

Interstitial Keratitis.

This denotes inflammation of the corneal stroma. The most common cause is syphilis, interstitial keratitis being one of the characteristic late manifestations of congenital syphilis. The corneal changes in congenital syphilis occur in two phases. The acute phase presents between the ages of 5 and 10 yr, with an intense keratitis that may last for several months and causes a severe reduction in vision. The acute effects of syphilis are due in most part to the host immune response, such as mononuclear cell infiltrates, proliferative vascular changes, and occasionally granuloma formation. The deep inflammation produces pain, photophobia, tearing, circumcorneal injection, and corneal haze. The acute episode is followed by a chronic stage with significant regression in the corneal findings along with a parallel improvement in visual acuity. Although the corneal findings may regress with time, “ghost vessels,” which

represent the previous vascular changes, and patchy corneal scarring remain and serve as permanent stigmata of the disease.

Cogan syndrome is a nonluetic interstitial keratitis associated with hearing loss and vestibular symptoms. Although its cause is unknown, a systemic vasculitis is suspected. Prompt treatment is required to avoid permanent hearing loss. Both the corneal changes and the auditory involvement may respond to the use of immunosuppressive agents.

Less frequently, interstitial keratitis is caused by other infectious diseases, such as tuberculosis or leprosy.

Corneal Manifestations of Systemic Disease.

Several metabolic diseases produce distinctive corneal changes in childhood. Refractile polychromatic crystals are deposited throughout the cornea in cystinosis.

Corneal deposits producing various degrees of corneal haze also occur in certain of the mucopolysaccharidoses, particularly MPS IH (Hurler), MPS IS (Scheie), MPS I H/S (Hurler-Scheie compound), MPS IV (Morquio), MPS VI (Maroteaux-Lamy), and sometimes MPS VII (Sly). Corneal deposits may develop in patients with GM_1 (generalized) gangliosidosis. In Fabry disease, fine opacities radiating in a whorl or fanlike pattern occur, and corneal changes can be important in identifying the carrier state. A spraylike pattern of corneal opacities may also be seen in the Bloch-Sulzberger syndrome. In Wilson disease, the distinctive corneal sign is the Kayser-Fleischer ring, a golden brown ring in the peripheral cornea resulting from changes in Descemet membrane. Pigmented corneal rings may develop in neonates with cholestatic liver disease. Corneal changes may occur in autoimmune hypoparathyroidism and band keratopathy in patients with hypercalcemia. Transient keratitis may occur with rubeola and sometimes with rubella.

Chapter 619 - Abnormalities of the Lens

Cataracts.

A cataract is any opacity of the lens. Some are clinically unimportant, others significantly affect visual function, and many are associated with ocular or systemic disease.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of cataracts in infants and children includes a wide range of developmental disorders, infectious and inflammatory processes, metabolic diseases, and toxic and traumatic insults (Table 619–1). Cataracts may also develop secondary to intraocular processes, such as retinopathy of prematurity, persistent hyperplastic primary vitreous, retinal detachment, retinitis pigmentosa, and uveitis.

Developmental Variants. Early developmental processes may lead to various congenital lens opacities. Discrete dots or white plaquelike opacities of the lens capsule are common and sometimes involve the contiguous subcapsular region. Small opacities of the posterior capsule may be associated with persistent remnants of the primitive hyaloid vascular system (the common Mittendorf dot), whereas those of the anterior capsule may be associated with persistent strands of the pupillary membrane or vascular sheath of the lens. Congenital cataracts of this type are usually stationary and rarely interfere with vision; in some, progression occurs.

Prematurity. A special type of lens change seen in some preterm newborns is the so-called cataract of prematurity. The appearance is of a cluster of tiny vacuoles in the distribution of the Y sutures of the lens. They can be visualized with an ophthalmoscope and are best seen with the pupil well dilated. The pathogenesis is unclear. In most cases, the opacities disappear spontaneously, often within a few weeks.

Mendelian Inheritance. Many cataracts unassociated with other diseases are hereditary. The most common mode of inheritance is autosomal dominant. Penetrance and expressivity vary. Autosomal recessive inheritance occurs less frequently; it is sometimes found in populations with high rates of consanguinity. X-linked inheritance of cataracts unassociated with disease is relatively rare, whereas cataracts occurring in association with X-linked disease are seen in Lowe syndrome, Alport syndrome, and Fabry disease.

Congenital Infection Syndrome. Cataracts in infants and children frequently are a result of prenatal infection. Lens opacity may occur in any of the major congenital infection syndromes (e.g., toxoplasmosis, cytomegalovirus, syphilis, rubella, herpes simplex virus). Cataracts may also occur secondary to other perinatal infections, including measles, poliomyelitis, influenza, varicella-zoster, and vaccinia.

Metabolic Disorders. Cataracts are a prominent manifestation of many metabolic diseases, particularly certain disorders of carbohydrate, amino acid, calcium, and copper metabolism. A primary consideration in any infant with cataracts is the possibility of galactosemia (see Chapter 76.2). In classic infantile galactosemia, galactose-1-phosphate uridyl transferase deficiency, the cataract is typically of the zonular type, with haziness or opacification of one or more of the perinuclear layers of the lens; haziness or clouding of the nucleus also often occurs. In its early stages, the cataract generally has a distinctive oil droplet appearance and is best detected with the pupil fully dilated. Progression to complete opacification of the lens may occur within weeks. With early treatment (galactose-free diet), the lens changes may be reversible.

In galactokinase deficiency, cataracts are the sole clinical manifestation. The cataracts are usually zonular and may appear in the first months or years of life or later in childhood.

In children with juvenile-onset diabetes mellitus, lens changes are uncommon. Some develop snowflake-like white opacities and vacuoles of the lens. Others develop cataracts that may progress and mature rapidly, sometimes in a matter of days, especially during adolescence. An antecedent event may be the sudden development of myopia caused by changes in the optical density of the lens.

Congenital lens opacities may be seen in children of diabetic and prediabetic mothers. Hypoglycemia in neonates can also be associated with early development of cataracts. Ketotic hypoglycemia is also associated with cataracts.

2106

TABLE 619-1 -- Differential Diagnosis of Cataracts

Developmental Variants
Prematurity (Y suture vacuoles) with or without retinopathy of prematurity
Genetic Disorders
Simple Mendelian Inheritance
Autosomal dominant (most common)
Autosomal recessive
X-linked
Major Chromosomal Defects

Trisomy disorders (13, 18, 21)

Turner syndrome (45 X)

Deletion syndromes (11p13, 18p, 18q)

Duplication syndromes (3q, 20p, 10q)

Multisystem Genetic Disorders

Alport syndrome (hearing loss, renal disease)

Alström syndrome (nerve deafness, diabetes mellitus) Apert disease (craniosynostosis, syndactyly)

Cockayne syndrome (premature senility, skin photosensitivity)

Conradi disease (chondrodysplasia punctata)

Crouzon disease (dysostosis craniofacialis)

Hallermann-Streiff syndrome (microphthalmia, small pinched nose, skin atrophy, and hypotrichosis)

Hypohidrotic ectodermal dysplasia (anomalous dentition, hypohidrosis, hypotrichosis)

Ichthyosis (keratinizing disorder with thick, scaly skin)

Incontinentia pigmenti (dental anomalies, mental retardation, cutaneous lesions)

Lowe syndrome (oculocerebrorenal syndrome: hypotonia, renal disease) Marfan syndrome

Meckel-Gruber syndrome (renal dysplasia, encephalocele)

Myotonic dystrophy

Nail-patella syndrome (renal dysfunction, dysplastic nails, hypoplastic patella)

Marinesco-Sjögren syndrome (cerebellar ataxia, hypotonia)

Nevoid basal cell carcinoma syndrome (autosomal dominant, basal cell carcinoma erupts in childhood)

Peters anomaly (corneal opacifications with iris-corneal dysgenesis)

Reiger syndrome (iris dysplasia, myotonic dystrophy)

Rothmund-Thomson syndrome (poikiloderma: skin atrophy) Rubinstein-Taybi syndrome (broad great toe, mental retardation)

Smith-Lemli-Opitz syndrome (toe syndactyly, hypospadias, mental retardation)

Sotos syndrome (cerebral gigantism)

Spondyloepiphyseal dysplasia (dwarfism, short trunk)

Werner syndrome (premature aging in 2nd decade of life)

Inborn Errors of Metabolism

Abetalipoproteinemia (absent chylomicrons, retinal degeneration)

Fabry disease (a-galactosidase A deficiency)

Galactokinase deficiency

Galactosemia (galactose-1-phosphate uridyltransferase deficiency)

Homocystinemia (subluxation of lens, mental retardation)

Mannosidosis (acid a-mannosidase deficiency)

Niemann-Pick disease (sphingomyelinase deficiency)

Refsum disease (phytanic acid a-hydrolase deficiency)

Wilson disease (accumulation of copper leads to cirrhosis and neurologic symptoms)

Endocrinopathies

Hypocalcemia (hypoparathyroidism)

Hypoglycemia

Diabetes mellitus

Congenital Infections

Toxoplasmosis

Cytomegalovirus infection

Syphilis

Rubella

Perinatal herpes simplex infection

Measles (rubeola)

Poliomyelitis

Influenza

Varicella-zoster

Ocular Anomalies

Microphthalmia

Coloboma

Aniridia

Mesodermal dysgenesis

Persistent pupillary membrane

Posterior lenticonus

Persistent hyperplastic primary vitreous

Primitive hyaloid vascular system

Miscellaneous Disorders

Atopic dermatitis

Drugs (corticosteroids)

Radiation

Trauma
Idiopathic

An association between cataracts and hypocalcemia is well established. Various lens opacities may be seen in patients with hypoparathyroidism.

The oculocerebral renal syndrome of Lowe is associated with cataracts in infants. Affected male children frequently have dense bilateral cataracts at birth, often in association with glaucoma and miotic pupils. Punctate lens opacities are frequently present in heterozygous females.

The distinctive sunflower cataract of Wilson disease is not commonly seen in children. Various lens opacities may be seen in children with certain of the sphingolipidoses, mucopolysaccharidoses, and mucolipidoses, particularly Niemann-Pick disease, mucosulfatidosis, Fabry disease, and aspartylglycosaminuria.

Chromosomal Defects. Lens opacities of various types may occur in association with chromosomal defects, including 13-, 18-, and 21-trisomy; Turner syndrome; and a number of deletion (11p13, 18p, 18q) and duplication syndromes (3q, 20p, 10q).

Drugs, Toxic Agents, and Trauma. Of the various drugs and toxic agents that may produce cataracts, corticosteroids are of major importance in the pediatric age group. Steroid-related cataracts characteristically are posterior subcapsular lens opacities. The incidence and severity vary. The relative significance of dose, mode of administration, duration of treatment, and individual susceptibility is controversial, and the pathogenesis of steroid-induced cataracts is unclear. The effect on vision depends on the extent and density of the opacity. In many cases, the acuity is only minimally or moderately impaired. Reversibility of steroid-induced cataracts may occur in some cases. All children being treated with long-term steroids should have periodic eye examinations.

Trauma to the eye is a major cause of cataracts in children. Opacification of the lens may result from contusion or penetrating injury. Cataracts are an important manifestation of child abuse. Other physical agents, such as radiation, can also damage the lens and produce cataracts.

Miscellaneous Disorders. The list of multisystem syndromes and diseases associated with lens opacities and other eye anomalies is extensive. The clinical features of some of the major disorders are presented in Table 619–2 .

TREATMENT.

The treatment of cataracts that significantly interfere with vision includes the following: (1) surgical removal of lens material to provide an optically clear visual axis; (2) correction of the resultant aphakic refractive error with spectacles, contact lenses, or, in appropriate cases, intraocular lens implantation; and (3) correction of any associated sensory deprivation amblyopia. Because the use of spectacles may not be possible or may be contraindicated in children after cataract removal, the use of contact lenses for visual rehabilitation is a medical necessity. They should not be thought of as a cosmetic alternative to glasses. Treatment of the amblyopia may be the most demanding and difficult step in the visual rehabilitation of infants or children with cataracts.

PROGNOSIS.

Prognosis depends on many factors, including the nature of the cataract, the underlying disease, age of onset,

TABLE 619-2 -- Clinical Features and Ocular Changes in Developmental Pediatric Syndromes

CNS Anomalies
Anencephaly (see Chapter 585.6)
Optic nerve aplasia or hypoplasia
Holoprosencephaly (see Chapter 585.7)
Hypotelorism; in extreme form, cyclopia; in some cases, iris coloboma
Cyclopia
A single eye of variable complexity, usually accompanied by a proboscis-like structure on the forehead; often associated with holoprosencephaly; sometimes fusion of both eyes with duplication of lenses, corneas, and other structures; rosette formation in the retina; optic nerve rudimentary or absent; orbit diamond shaped
Arnold-Chiari malformation (see Chapter 585.11)
Nystagmus, usually vertical, often downbeat; ocular motor palsies with diplopia; sometimes skew deviation
Dandy-Walker syndrome (see Chapter 585.11)
Ophthalmic manifestations of increased intracranial pressure
Septo-optic dysplasia (deMorsier syndrome)
Malformation of anterior midline structures (agenesis of septum pellucidum, primitive optic ventricle, with hypoplasia of optic nerves, chiasm, and infundibulum); sometimes associated endocrine abnormalities; vision defects, strabismus, nystagmus; in some cases, other anomalies of eyes
Craniostenosis Syndromes (see Chapter 585.12)
Apert syndrome (acrocephalosyndactyly)
Orbits shallow, eyes protuberant (proptosis) and widely spaced; antimongoloid slant of palpebral fissures; ocular motor abnormalities (strabismus, partial ophthalmoplegia, nystagmus); papilledema; optic atrophy; cataracts; sometimes dislocated lenses; occasionally iris and fundus colobomas

Carpenter syndrome (acrocephalopolysyndactyly)
Orbits shallow; lateral displacement of medial canthi; epicanthus; antimongoloid slant of palpebral fissures; optic atrophy; microcornea and corneal opacities in some cases
Crouzon disease (dysostosis craniofacialis)
Eyes protuberant (proptosis) and widely spaced; luxation of globe may occur; antimongoloid slant of palpebral fissures; strabismus; papilledema; optic atrophy; vision loss; cataracts in some patients
Kleeblattschädel syndrome (cloverleaf skull)
Shallow orbits with proptosis; high risk of corneal ulceration
Miscellaneous Craniofacial Defects and Syndromes
Frontonasal dysplasia (median cleft-face syndrome)
Hypertelorism (radiographic interorbital distance 2 SD above normal for age); in some cases, anophthalmia, microphthalmia, epibulbar dermoids, lid colobomas, congenital cataracts
Opitz syndrome
Hypertelorism, particularly associated with hypospadias; antimongoloid slant of palpebral fissures; epicanthus; strabismus
Waardenburg syndrome
Lateral displacement of medial canthi and inferior puncta; heterochromia iridis, total or partial; in some cases both irides completely blue (isochromia); fundus pigmentary changes in some cases
Oculodentodigital dysplasia (Meyer-Schwickerath syndrome)
Hypotelorism, microphthalmos, microcornea, dental anomalies and enamel hypoplasia, camptodactyly, syndactyly, and other skeletal defects; persistent pupillary membrane; glaucoma
Hallermann-Streiff syndrome (dyscephalia oculomandibulofacialis)
Microphthalmos, cataract, sparse eyebrows and lashes, blue sclerae, nystagmus
Pierre Robin syndrome
Congenital glaucoma; retinal detachment; strabismus
Treacher Collins syndrome (mandibulofacial dysostosis; Franceschetti-Klein syndrome)
Antimongoloid slant of palpebral fissures; underdevelopment of supraorbital ridges, colobomas of lower eyelids and in some cases of iris or choroid
Goldenhar syndrome (oculoauriculovertebral dysplasia)
Antimongoloid slant of palpebral fissures; colobomata of eyelid, upper lid more commonly involved than lower; hypoplasia or coloboma of iris; hypertelorism; sometimes microphthalmos
Chromosomal Abnormalities
21-Trisomy (Down syndrome; see Chapter 70)
Mongoloid slant of palpebral fissures; epicanthus; dacryostenosis; blepharitis; Brushfield spots of iris; peripheral thinning of iris stroma; keratoconus and corneal hydrops; cataracts; high refractive errors; strabismus; nystagmus; increased vessels at disc
18-Trisomy (Edwards syndrome; see Chapter 70)
Ptosis; short palpebral fissures; epicanthus; hypoplastic supraorbital ridges; microphthalmia; corneal opacities; anisocoria; cataracts; fundus and disc colobomas; retinal hypopigmentation
13-Trisomy (Patau syndrome; see Chapter 70)
Microphthalmos; anophthalmos; cyclopia in some cases; dysgenesis of anterior segment (iris hypoplasia, iris adhesions, chamber angle abnormalities); corneal opacities; congenital glaucoma; cataracts; persistent hyperplastic primary Vitreous; retinal dysplasia; colobomas of iris, ciliary body, fundus; intraocular cartilage, optic nerve hypoplasia
9-Trisomy
Antimongoloid slant of palpebral fissures; deeply set eyes; corectopia; strabismus
8-Trisomy
Dysmorphic skull; strabismus
Syndrome 45X (Turner and mosaic variants; see Chapter 70)
Ptosis; epicanthus; blue sclerae; defective color vision; cataracts; strabismus; nystagmus
47, XXY; 48,XXXY; 49,XXXXY (Klinefelter) syndromes (see Chapter 577)
Hypertelorism; epicanthus; Brushfield spots of iris; myopia; strabismus
Partial deletion short arm chromosome 4 (4p –) (see Chapter 70)
Ptosis; hypertelorism; epicanthus; colobomata
Partial deletion short arm chromosome 5 (5p –) (cri-du-chat syndrome; see Chapter 70)
Antimongoloid slant of palpebral fissures; hypertelorism; epicanthus; strabismus
Partial deletion short arm chromosome 9 (9p –) (see Chapter 70)
Mongoloid slant of palpebral fissures; epicanthus; arched brows
Partial deletion long arm chromosome 13 (13q –)
Ptosis; epicanthus; hypertelorism; microphthalmos; colobomas; retinoblastoma
Partial deletion long arm chromosome 18 (18q –) (see Chapter 70)
Horizontal palpebral fissures; epicanthus; deeply set eyes; optic disc pallor; tapetoretinal degeneration; nystagmus
Partial deletion long arm chromosome 21 (21q –)
Downward slanting palpebral fissures
Partial deletion long arm chromosome 22 (22q –)
Ptosis; epicanthus

Extrachromosomal material (cat-eye syndrome)

Antimongoloid slant of palpebral fissures; epicanthus; hypertelorism; microphthalmos; colobomas of iris, fundus, optic nerve; macular defects; pale discs; cataracts; strabismus; nystagmus

Disorders of Amino Acid Metabolism

Albinism[*]

Defect in the formation of melanin; several forms:

1. *Oculocutaneous albinism, tyrosinase negative;* generalized hypopigmentation; iris blue or gray; generalized hypopigmentation of eye; typical pink or orange reflex; fundus bright, with increased choroidal vascular pattern; macula/fovea poorly defined (hypoplastic); photophobia; nystagmus; subnormal vision; often high refractive error
2. *Oculocutaneous albinism, tyrosinase positive;* pigmentation may increase with age; iris blue, yellow, or brownish; color increases with age; photophobia; nystagmus; subnormal vision, which may improve with age
3. *Amish* or *yellow mutant*; generalized albinism in which a yellowish pigment is produced instead of melanin, providing some skin and hair color
4. *Hermansky-Pudlak syndrome;* tyrosine-negative albinism associated with a hemorrhagic diathesis; iris blue-gray to brown; photophobia; nystagmus; slight to moderate vision defect
5. *Cross syndrome;* tyrosine positive; a syndrome of hypopigmentation, gingival fibromatosis, spasticity, athetoid movements, and microphthalmos; iris blue-gray, microphthalmos; cataracts; severe vision defect; nystagmus
6. *Ocular albinism;* pigment deficiency limited to the eye; generalized ocular hypopigmentation; macular hypoplasia; nystagmus (in blacks, fundus tessellated)

Alkaptonuria (see Chapter 74.2)

Black discoloration of sclera, most noticeable at insertion of extraocular muscles

Tyrosinemia (Richner-Hanhart syndrome; see Chapter 74.2)

Corneal ulceration, “herpetiform”

Cystinosis (see Chapter 521.3)

Accumulation of refractile crystals in cornea (best seen with slit lamp, but corneal haze may be detected grossly); photophobia; pigmentary retinopathy; fundi generally hypopigmented, with fine to coarse spotty pigmentation, most marked peripherally; vision usually normal to nearly normal

Homocystinemia, type I (see Chapter 74.3)

Ectopia lentis; cataract; secondary glaucoma; peripheral cystic degeneration of retina

Sulfite oxidase deficiency (see Chapter 74.4)

Subluxation of lens; spherophakia; strabismus

Hartnup disease (see Chapter 74.5)

Photophobia; nystagmus; strabismus

Maple syrup urine disease (see Chapter 74.6)

Strabismus, varying with condition of child

The Mucopolysaccharidoses (MPS)

Hurler syndrome (MPS IH; a-L-iduronidase deficiency; see Chapter 77)

Hypertelorism, prominent eyes; puffy lids; heavy brows; deposition of MPS and attendant cellular changes throughout most regions of eye, particularly the conjunctiva, cornea, sclera, iris, ciliary body, retina, and optic nerve; characteristic corneal clouding, clinically evident early in life, and progressing to dense milky “ground-glass” haze, often with associated photophobia; progressive retinal degeneration with pigmentary dispersion and clumping, arteriolar attenuation and disc pallor, and reduced ERG; optic atrophy; vision loss, principally because of corneal, retinal, and optic nerve changes; hydrocephalus and cerebral changes; glaucoma in some cases

Scheie syndrome (MPS IS; a-L-iduronidase deficiency; see Chapter 77)

Progressive corneal clouding, diffuse but sometimes more dense peripherally than centrally; progressive retinal degeneration; visual symptoms, field loss, and night blindness often commencing in 2nd or 3rd decade; glaucoma in some cases

Hurler-Scheie Compound (MPS IH/S; a-L-iduronidase deficiency; see Chapter 77)

Corneal clouding, diffuse and progressive; glaucoma in some cases; vision loss because of corneal clouding or optic nerve effects of arachnoid cysts

Hunter syndrome (MPS II; iduronosulfate sulfatase deficiency)

Phenotypically similar to MPS IH; both mild and severe forms occur; progressive retinal degeneration with pigmentary changes, arteriolar attenuation, optic atrophy, vision, loss, reduced ERG; corneas macroscopically (clinically) clear, but microscopic corneal changes documented; papilledema secondary to hydrocephalus in some cases

Sanfilippo syndrome (MPS III; type A [heparin sulfate sulfatase deficiency,

B [*N*-acetyl-a-D-glucosaminidase deficiency], and C [acetyl-Co A:a-glucosaminide *N*-acetyl transferase deficiency])

Retinal changes in some patients—arteriolar narrowing; reduced ERG; corneas clinically clear but some microscopic changes reported

Morquio syndrome (MPS IV; galactosamine-6-sulfate sulfatase deficiency in classic form, ß-galactosidase deficiency reported in variants; see Chapter 77)

Fine corneal clouding in many patients; slowly progressive; often not clinically apparent for several years

Maroteaux-Lamy syndrome (MPS VI; arylsulfatase-B deficiency; see Chapter 77)

Diffuse corneal clouding, usually evident within 1st few yr of life; tortuosity of retinal vessels in some patients; papilledema and 6th nerve paresis in some patients with hydrocephalus

Sly syndrome (MPS VII; ß-D-glucuronidase deficiency)

Some diversity of phenotype; corneas clear or cloudy; corneal haze of either fine or coarse type

Di Ferrenti syndrome (MPS VIII; *N*-acetylglucosamine-6-sulfate sulfatase deficiency)

Short stature; mild dysostosis multiplex; odontoid hypoplasia; hepatosplenomegaly; mental retardation; ophthalmologic abnormalities not yet described

The Sphingolipidoses

Generalized gangliosidosis (GM_1 gangliosidosis type 1; ß-galactosidase deficiency; see Chapter 592.1)

Diffuse corneal clouding (MPS accumulation); macular cherry red spot of retinal ganglioside accumulation; retinal vascular tortuosity and retinal hemorrhages; optic atrophy; vision loss, nystagmus, strabismus

Juvenile GM_1 gangliosidosis (GM_1 gangliosidosis type 2; ß-galactosidase deficiency; see Chapter 592.1)

Corneas clinically clear; histologic changes of retinal ganglioside storage without clinically obvious signs; optic atrophy and vision loss; nystagmus and strabismus

Tay-Sachs disease (GM_2 gangliosidosis type 1; hexosaminidase A deficiency; see Chapter 592.1)

Macular cherry red spot; optic atrophy (demyelination and degeneration of optic nerves, chiasm, and tracts); progressive loss of vision, caused by ocular and cerebral abnormalities; sequential deterioration of eye movements

Sandhoff variant (GM_2 gangliosidosis type 2; hexosaminidase A and B deficiency; see Chapter 592.1)

Macular cherry red spot; optic atrophy and progressive loss of vision; corneas clinically clear or slightly opalescent; histologic evidence of storage cytosomes in cornea

Juvenile GM_2 gangliosidosis (GM_2 gangliosidosis type 3; partial deficiency of hexosaminidase; see Chapter 592.1)

Retinal pigmentary degeneration; macular changes (cherry red spot type) in some cases; optic atrophy; blindness later in course of disease

Krabbe globoid cell leukodystrophy (galactosyl ceramide lipidosis; galactosylceramide ß-galactosidase deficiency)

Cortical blindness and optic atrophy caused by degenerative changes in brain and visual pathways; nystagmus; strabismus

Gaucher's disease (glycosyl ceramide lipidosis; glucosyl ceramide ß-glucosidase deficiency; see Chapter 75.4)

Paralytic strabismus caused by brainstem and cranial nerve involvement in neuronopathic forms; nystagmus; macular changes (grayness) in some cases; retinal hemorrhages secondary to anemia, thrombocytopenia; discrete white spots in or on retina reported in juvenile form; pingueculae (wedge-shaped conjunctival lesions) in chronic non-neuronopathic form; possibly corneal clouding

Niemann-Pick disease (sphingomyelin lipidoses; sphingomyelinase deficiency; see Chapter 75.4)

Grayish macular haze in classic infantile neuronopathic form (type A), and in subacute neurovisceral or juvenile form (type C); corneal clouding, lens opacities in some cases (type A); vertical gaze palsy in some patients

Fabry disease (glycosphingolipid lipidosis; a-galactosidase A deficiency; see Chapter 75.4)

Corneal dystrophy related to epithelial lipid deposits (radiating lines/whorls in affected males and in carrier females); aneurysmal dilatation and tortuosity of conjunctival and retinal vessels; renovascular signs of renal hypertension; papilledema; orbital and lid edema; cataracts (spokelike posterior cortical lens opacities—anterior lens opacities in some cases)

Farber disease (ceramide lipidosis; ceramidase deficiency; see Chapter 75.4)

Cherry red–like spot; grayish posterior pole; retinal pigmentary mottling; granulomas in and around eye

Ceroid Lipofuscinoses (see also Chapters 75.4 and 592.2)

Infantile (Finnish variant; unsaturated fatty acid lipidosis)

Microcephaly; marked atrophy of brain; loss of vision; granular inclusions; ataxia; myoclonus; profound dementia, decorticate state; onset 1–2 yr; death by 10 yr

Late infantile (Jansky-Bielschowsky)

Intellectual deterioration, seizures, ataxia; pigmentary retinal degeneration, in some cases, predominantly macular; ERG abnormal; optic atrophy; inclusions of curvilinear type; onset 2–4 yr; death by 10 yr

Juvenile (Batten-Mayou-Spielmeyer-Vogt)

Intellectual deterioration, seizures, ataxia, progressive loss of motor function; pigmentary retinal degeneration, resembling retinitis pigmentosa, with progressive loss of vision; in some cases predominantly macular degeneration; ERG abnormal; optic atrophy as a late manifestation; mixed inclusion bodies including curvilinear and fingerprint types, and lipofuscin in brain; onset 5–8 yr, sometimes later; death in teens or 20s

Late juvenile or adult (Kuf)

Behavior disturbances and intellectual impairment; ataxia, spasticity, myoclonic seizures; vision and fundi usually normal; macular degeneration in some cases; mostly lipofuscin in brain; onset in childhood, adolescence, or early adult life

Cherry red spot myoclonus syndrome

Macular cherry red spot; vision loss; intention myoclonus; variable inclusions in brain; light inclusions in hepatocytes and Kupffer cells; onset in childhood; survival to adulthood

Leukodystrophies (see also Chapter 592.1)

Metachromatic leukodystrophy (arylsulfatase A deficiency)

Retinal degeneration resembling retinitis pigmentosa; in some cases, early macular involvement (macular grayness with accentuation of central red spot); optic atrophy; vision loss; strabismus and nystagmus

Pelizaeus-Merzbacher disease

"Eye rolling" (rhythmic eye movements) noted soon after birth, sometimes with rotary movements of the head; optic atrophy as a late manifestation

Canavan disease

Vacuolation of ganglion cell layer of retina reportedly detectable with slit lamp; retinal pigmentary changes; optic atrophy; blindness early in course; ERG normal; VER reduced; strabismus, roving eye movements, and nystagmus

Demyelinating Scleroses (see Chapter 592.5)

Schilder disease (encephalitis periaxialis diffusa)

Involvement of visual pathways, producing retrobulbar neuritis, optic atrophy, central scotomas, chiasmal syndromes, homonymous field defects; disorders of cortical gaze functions; nystagmus

Multiple sclerosis

Optic neuritis (episodic loss of vision, typically a central scotoma, unilateral more often than bilateral, often with retrobulbar pain); other visual pathway lesions (various field defects); internuclear ophthalmoplegia; supranuclear gaze palsies; nystagmus; sheathing of peripheral retinal vessels in some cases

Neuromyelitis optica (Devick disease)

Optic neuritis (usually papillitis with visible disc edema), with resultant optic atrophy; other visual pathway lesions (various visual field defects); in some cases extraocular muscle palsies, conjugate gaze palsies, nystagmus, pupil abnormalities

Hamartomatoses and Phakomatoses

Tuberous sclerosis (Bourneville disease; see Chapter 589.2)

Retinal phakomas (glial hamartomas, ranging from small flat or slightly elevated white or yellowish lesions to large elevated refractile yellowish multinodular or cystic masses often likened to an unripe mulberry); fibroangioma of the lids; in some, papilledema or optic atrophy, vision defects, pupil or ocular motor signs related to CNS changes (tumors, hydrocephalus); occasionally iris or pigmentary changes

Neurofibromatosis (von Recklinghausen syndrome; see Chapter 589.1)

Plexiform neuromas of eyelids, often producing ptosis; episcleral and conjunctival neurofibromas; prominent corneal nerves; Lisch iris nodules; uveal hypercellularity; glaucoma (related to angle anomalies, uveal hypercellularity, neovascularization, or synechiae); hamartomas (phakomas) of disc and retina; fundus pigmentary changes likened to café-au-lait spots; optic gliomas and vision loss (presenting with proptosis, strabismus, nystagmus if intraorbital—with signs of increased intracranial pressure, hydrocephalus, or diencephalic syndrome when intracranial); orbital asymmetry; orbital wall defects; pulsatile exophthalmos, intraorbital neurofibromas, with proptosis

Angiomatosis of the retina and cerebellum (von Hippel–Lindau disease; see Chapter 589.4)

Retinal hemangioblastoma (reddish or yellowish globular mass with paired vessels coursing to and from the lesion, sometimes likened to a toy balloon in the fundus); may lead to hemorrhage, exudates, retinal detachment

Encephalofacial angiomatosis (Sturge-Weber syndrome; see Chapter 589.3)

Lid and conjunctival involvement of facial nevus flammeus; choroidal hemangioma; Dilated and tortuous retinal vessels; glaucoma, congenital or later in infancy or childhood (related to possible angle anomalies, vascular lesion, or hypersecretion); visual field defects associated with CNS lesions; hemianopia in some cases)

Angiomatosis of mid-brain and retina (Wyburn-Mason syndrome)

Extensive vascular malformations involving principally the midbrain and eye; angiomatosis of the retina; vessels dilated and tortuous; angiomatosis affecting optic nerve and orbit

Neurocutaneous Syndromes

Ataxia-telangiectasia (Louis-Barr syndrome; see Chapter 590.1)

Telangiectasias of bulbar conjunctivae, usually by the age of 4–6 yr; apraxic disorder of conjugate eye movements; horizontal and vertical gaze performed in halting dyssynergic fashion; difficulty in maintaining eccentric gaze; sometimes convergence defect; nystagmus

Sjögren-Larsson syndrome

Chorioretinal lesions; discrete defects in retinal pigment epithelium of unknown cause; circumscribed symmetric lesions of varying size in and about the macula in approximately 25% of cases

Incontinentia pigmenti (Bloch-Sulzberger syndrome; see Chapter 642)

Intraocular retrolental masses ("pseudogliomas") and membranes, apparently secondary to an underlying retinal vascular disorder characterized by aneurysmal dilatation, abnormal arteriovenous connections, and vasoproliferative changes; sometimes intraocular hemorrhage and inflammation; microphthalmos; corneal opacities; cataracts; optic atrophy

Linear nevus sebaceus of Jadassohn (see Chapter 642)

Coloboma of the eyelids, iris, and fundus; corectopia; epibulbar lipodermoids; orbital teratomas; proptosis; aberrant lacrimal gland; corneal vascularization; ocular motor palsies; nystagmus; defective vision

Xerodermic idiocy of de Sanctis and Cacchione (see Chapter 642)

Atrophy of eyelids; loss of cilia, ectropion, entropion, symblepharon, ankyloblepharon; drying and infection of conjunctiva; ulceration of cornea; iritis; photophobia

Klippel-Trénaunay-Weber syndrome (see Chapter 640)

Conjunctival telangiectasia; choroidal hemangioma; iris coloboma; heterochromia; glaucoma; strabismus

Special Neurobiothrophies

Subacute sclerosing panencephalitis (Dawson excephalitis; Van Bogaert encephalitis; see Chapter 225)

Focal retinitis (edema, hemorrhage, pigmentary changes), with chorioretinal scarring (usually macular or paramacular, usually bilateral)—may precede other neurologic manifestations; papilledema; optic atrophy; visual symptoms of retinal and optic nerve involvement; field defects of cerebral involvement; nystagmus; extraocular muscle palsies; ptosis

Subacute necrotizing encephalomyopathy (Leigh disease; see Chapter 591)

Abnormal eye movements (bizarre rolling eye movements, disconjugate eye movements, horizontal and vertical nystagmus, saccadic ocular movements); extraocular muscle palsies (sometimes complete external ophthalmoplegia); blepharoptosis; progressive optic atrophy and vision loss; sometimes retinal changes (diminished macular reflex); afferent and efferent pupil defects

Hepatolenticular degeneration (Wilson disease; see Chapter 338.2)

Kayser-Fleischer ring of cornea (copper deposition in periphery of Descemet's membrane, particularly in deepest zone adjacent to endothelium, seen as granules of golden, greenish, grayish, or brown hue); Sonnenblumenkatarakt ("sunflower" cataract); occasionally ocular motor abnormalities (jerky oscillations of eyes, involuntary upward deviation of eyes, or paresis of upward gaze); accommodation sometimes affected; in some cases, optic neuritis secondary to penicillamine therapy

Trichopoliodystrophy (Menkes syndrome; kinky hair disease)

Decrease in retinal ganglion cells, thinning of retinal nerve fiber layer, and partial atrophy of optic nerve; progressive vision loss; abnormal ERG; microcysts of pigment epithelium of iris

Abetalipoproteinemia (acanthocytosis; Bassen-Kornzweig syndrome; see Chapter 75.3)

Pigmentary retinal degeneration with progressive impairment of visual function (pigment dispersion, arteriolar attenuation, disc pallor, impaired dark adaptation); cataracts, ptosis, and ocular motor abnormalities; in some cases, progressive exotropia, paresis of medial recti, and dissociated nystagmus on lateral gaze

Heredopathia atactica polyneuritiformis (Refsum disease; phytanic acid a-hydrolase deficiency; see Chapter 75.2)

Pigmentary retinal degeneration (pigmentary clumping, arteriolar attenuation, optic atrophy, progressive impairment of night vision and visual field); ERG abnormal; sometimes vitreous opacities, cataracts, cornea guttata, miosis; ophthalmoparesis; nystagmus

Familial dysautonomia (Riley-Day syndrome; see Chapter 606.1)

Depressed or absent corneal sensation, with corneal ulceration and scarring common; defective lacrimation; tortuosity of retinal vessels; tonic pupil in some cases; myopia and exotropia common

Congenital familial sensory neuropathy with anhidrosis (Pinsky-DiGeorge syndrome; see Chapter 606.2)

Defective corneal sensation, with defective lacrimation; corneal ulceration and scarring may result

Disorders of Connective Tissues, Bones, and Joints

Arachnodactyly (Marfan syndrome; see Chapter 690)

Ectopia lentis (lens dislocation, usually upward) and iridodonesis (tremulous iris); microphakia, spherophakia; cataract; myopia; glaucoma; retinal changes; degeneration, detachment

Cutis hyperelastica (Ehlers-Danlos syndrome; see Chapter 649)

Epicanthus; blue sclera; keratoconus; subluxation of lens; retinal detachment

Pseudoxanthoma elasticum (see Chapter 649

Angioid streaks (breaks in Bruch's membrane appearing as dark lines in the fundus radiating from the disc); tendency to retinal hemorrhage

Osteogenesis imperfecta (see Chapter 689)

Blue sclera; prominent eyes; in some cases, megalocornea, keratoconus, corneal opacities

Polyostotic fibrous dysplasia (McCune-Albright syndrome; see Chapter 556.6)

Thickening of bones of orbit

Osteopetrosis (Albers-Schönberg disease; "marble bones"; see Chapter 687)

Vision loss and extraocular muscle palsies, caused by bony overgrowth of cranial foramina; in some cases, retinal degeneration, optic atrophy

Chondrodystrophia calcificans congenita (Conradi syndrome; see Chapter 648)

Cataract, optic atropy; hypertelorism

Spondyloepiphyseal dysplasia congenita (see Chapter 683)

Myopia; retinal detachment; cataract; buphthalmos

Spondyloepiphyseal dysplasia variants (see Chapter 683)

Punctate corneal dystrophy without impairment of vision

Hereditary onycho-osteodysplasia (nail-patella syndrome)

Dark "cloverleaf" pigmentation of iris; cataract; microphakia; microcornea; keratoconus; ptosis

Progressive arthro-ophthalmopathy (Stickler's syndrome)

Pain and stiffness of joints with bony enlargement; kyphosis, cleft palate; Pierre

Robin anomaly; deafness; progressive myopia; retinal detachment; glaucoma

Dermatologic Disorders

Focal dermal hypoplasia (Goltz syndrome; see Chapter 638)

Nystagmus; strabismus; microphthalmos; coloboma

Hypohidrotic (anhidrotic) ectodermal dysplasia (see Chapter 638)

Deficiency of tears, leading to keratopathy, photophobia; stenosis of the lacrimal puncta; cataracts; lashes and brows sparse

Dyskeratosis congenita (see Chapter 638)

Bullous conjunctivitis, with minimal scarring of cornea; chronic blepharitis; loss of lashes and ectropion; keratinization of lacrimal puncta

Ichthyosis (see Chapter 648)

Conjunctivitis, ectropion, and corneal erosions in lamellar and sex-linked forms; cataracts in congenital and vulgaris forms

Basal cell nevus syndrome (see Chapter 660)

Prominent supraorbital ridges; hypertelorism or dystopia canthorum; cataracts; coloboma; vision defects; strabismus

Juvenile xanthogranuloma (nevoxanthoendothelioma; see Chapter 660)

Xanthogranuloma in ocular tissues, as infiltrates in orbit, iris, episclera, ciliary body; presenting signs may be proptosis, heterochromia, spontaneous hyphema, uveitis, glaucoma

Poikiloderma congenitale (Rothmund-Thomson syndrome; see Chapter 646)

Sparse eyebrows and eyelashes; cataracts (onset 2–7 yr); corneal dystrophy

Bloom syndrome (see Chapter 646)

Conjunctivitis; conjunctival telangiectasias; drusen at posterior pole of fundus

Syndromes of Multiple Developmental Abnormalities

Cornelia de Lange syndrome

Microbrachycephaly, short neck, low hairline, anteverted nares, micrognathism, and low-set ears; physical and mental retardation; limb defects including micromelia-phocomelia, oligodactyly, polydactyly; cardiac and urogenital anomalies; synophrys (confluent eyebrows) and long, curly eyelashes; ptosis; epicanthus; microphthalmos with eccentric pupils; corneal opacities; optic atrophy; strabismus

Fraser syndrome

Facial, genitourinary, skeletal anomalies (including lateral cleft of nostril, ear deformity, renal agenesis, hydronephrosis, hypospadias, cryptorchidism, syndactyly); cerebral defects, meningoencephalocele; cryptophthalmos (eye hidden, fused lids—absence of palpebral fissure), sometimes with symblepharon (adhesion of lid to globe); microphthalmos in some cases; flat supraorbital ridge

Rieger syndrome

Various dental and limb anomalies; occasionally intellectual retardation, muscular dystrophy, and myotonic dystrophy; dysplasia of anterior segment of the eye; posterior embryotoxon (prominence and anterior displacement of Schwalbe's line), often with bands of iris tissue attached (Axenfeld syndrome); iris hypoplasia; glaucoma; cataracts; ectopia lentis; colobomas; micro-or megalocornea; strabismus; ptosis; optic atrophy

Peters syndrome

Skeletal anomalies; developmental defects of the gastrointestinal tract and CNS; hydrocephalus and mental retardation; central defect of Descemet membrane, with central corneal leukoma, shallow anterior chamber, peripheral anterior synechia; cataracts

Lenz syndrome

Microcephaly, mental retardation; short stature, digital anomalies, and dental defects; colobomatous microphthalmos; blepharoptosis; nystagmus; strabismus

Meckel syndrome (Meckel-Gruber syndrome)

Microcephaly, occipital encephalocele, or anencephaly; polycystic kidneys; polydactyly; congenital heart disease; genital abnormalities; microphthalmos, anophthalmos, cryptophthalmos; sclerocornea; partial aniridia; cataract; retinal dysplasia; optic nerve hypoplasia

Otopalatodigital syndrome (Rubinstein-Taybi syndrome)

Intellectual and growth retardation; abnormally broad thumbs and broad great toes; characteristic facies with hypoplasia of maxilla and mandible, beaked nose, posterior rotation of ears; hypertrichosis; cryptorchidism; cardiac and renal anomalies; hypertelorism, with epicanthus, ptosis, and antimongoloid slant of palpebral fissures; cataract, colobomas, strabismus

Seckel syndrome

Growth retardation with small head circumference and characteristic face, narrow with beaklike nose (“bird head”); micrognathia and apparent prominence of maxilla; sometimes musculoskeletal and genitourinary anomalies; hypertelorism, with antimongoloid slant of palpebral fissures, prominent eyes; strabismus

Freeman-Sheldon syndrome

Syndrome characterized by masklike face with small pursed mouth, “whistling face”; ulnar deviation of the hand and fingers; talipes equinovarus; deep-set eyes; epicanthus, blepharophimosis, ptosis; strabismus

Aicardi's syndrome

Agenesis of the corpus callosum, with cortical heterotopia; seizures; mental retardation; costovertebral anomalies; multiple discrete chorioretinal defects of varying size; sometimes microphthalmos

Wildervanck syndrome

Association of the Klippel-Feil malformation with congenital deafness and Duane syndrome; unilateral or bilateral (congenital defect in abduction with retraction of the globe or attempted adduction of the affected eye); epibulbar dermoid cysts

Falls-Kertesz syndrome

Pterygium coli; later onset of lymphedema of lower extremities; distichiasis of all four lids; partial ectropion of lower lids

Kartagener syndrome (see Chapter 403)

Pigmentary retinal disorder; cataracts

Miscellaneous Multisystem Disorders

Oculocerebrorenal syndrome (Lowe syndrome; see Chapter 521.4)

Congenital cataracts in affected males; fine lens opacities in carrier females; glaucoma; rarely, microphthalmos

Cerebrohepatorenal syndrome (Zellweger syndrome) (congenital adrenoleukodystrophy)

Profound hypotonia, growth retardation, and failure to thrive; hepatomegaly, jaundice, hypoprothrombinemia; renal cortical cysts; characteristic facies, flat profile; accumulation of iron in various organs; mild hypertelorism, flat supraorbital ridges, and epicanthal folds, cataracts; glaucoma (also, nonglaucomatous corneal haze); vitreous opacities; optic nerve hypoplasia; retinal pigmentary disorder (fundi generally hypopigmented with fine to coarse spotty pigmentation, most marked peripherally)

Laurence-Moon-Biedl syndrome (see Chapter 43)

Pleomorphic pigmentary retinal degeneration (retinitis pigmentosa type, with prominent macular involvement in some cases), with progressive vision impairment

Prader-Willi syndrome

Hypotonia, hypomentia, hypogonadism, and obesity, with tendency to diabetes mellitus; strabismus

Cockayne syndrome (see Chapter 646)

Pigmentary retinal degeneration; optic atrophy, cataracts; photophobia

Werner syndrome

Syndrome of premature aging, in the 2nd decade, with cessation of growth, graying of the hair, alopecia, scleroderma-like changes of the skin, atherosclerosis, and diabetes mellitus; hypogonadism, increased risk of neoplasia; cataracts, juvenile onset; pigmentary retinal degeneration (“retinitis pigmentosa”); macular degeneration; glaucoma

Asphyxiating thoracic dysplasia (Jeune syndrome; see Chapter 409)

Pigmentary retinal degeneration, with progressive vision impairment in some cases

Alström syndrome

Nerve deafness, diabetes mellitus, and obesity in childhood; pigmentary retinal degeneration; cataracts

Renal-retinal dystrophy

Interstitial nephritis; progressive pigmentary retinal degeneration, with attenuation of arterioles, reduced ERG, optic atrophy, and loss of vision

Usher syndrome

Nerve deafness; pigmentary retinal degeneration (“retinitis pigmentosa”); cataracts

Norrie disease

A syndrome of retinal malformation, mental retardation, and deafness; congenital retinal pseudoglioma; persistent hyperplastic primary vitreous, with vision loss; degenerative changes with phthisis bulbi; corneal opacities; cataracts

Congenital Infection Syndromes

Congenital rubella (see Chapter 226)

Ophthalmic sequelae, both teratogenic and inflammatory; bilateral or unilateral effects; persistence of virus in the eye for months or years; microphthalmia; cataract (usually a dense, pearly, nuclear opacity with relatively clearer cortical rim); iris hypoplasia, atrophy synechiae (pupils often difficult to dilate); congenital glaucoma; transient nonglaucomatous corneal clouding in a newborn; retinopathy (pigmentary “salt and pepper” mottling, focal or generalized, without loss of function); acute maculopathy (submacular neovascularization) as a delayed complication later in childhood in some cases, with attendant vision impairment; optic atrophy; vision defects and ocular motor abnormalities (nystagmus, strabismus) related not only to ocular involvement but also to effects of encephalomyelitis

Congenital cytomegalovirus infection (see Chapter 234)

Chorioretinitis (single or multifocal atrophic and pigmented fundus lesions, more often peripheral than macular—sometimes perivascular retinal exudates and hemorrhages); anterior uveitis, conjunctivitis, and corneal clouding; optic atrophy; optic nerve hypoplasia; coloboma; microphthalmos; vision defects with strabismus, nystagmus

Congenital toxoplasmosis (see Chapter 266)

Retinochoroditis (retinitis, with secondary choroiditis; often with exudate into vitreous in early stages, resulting in single or multifocal atrophic and pigmented scars); often large macular lesions; satellite lesions and recurrent inflammation common in later years caused by persistence of organism in eye; vision loss, optic atrophy, retinal detachment, cataract, and glaucoma common; attendant oculomotor abnormalities (strabismus, nystagmus) attributed to ocular and/or CNS involvement; congenital anomalies of eye (e.g., microphthalmos)

Congenital syphilis (see Chapter 200)

Perivascular infiltration by *T. pallidum*, with inflammation in the cornea, uvea, retina, and optic nerve; persistence of the organism in the eye for years; interstitial keratitis, usually appearing after age 5 or 6 yr (iridocyclitis and intense photophobia in acute phase, vascularization and corneal opacification later, with decreased vision); retinopathy (“salt and pepper” pigmentary changes, frequently with arteriolar attenuation and disc pallor); retinal periphlebitis, sometimes with vascular occlusion; exudative uveitis in some cases; phthisis may result; disc edema; optic atrophy

ERG = electroretinogram; VER = visual evoked response; CNS = central nervous system.

* *To be differentiated from these forms of albinism is the Chédiak-Higashi syndrome in which the defect is in the morphology of the melanosomes, not in the formation of melanin. Ocular signs include hypopigmentation of iris and fundus, photophobia, nystagmus, and papilledema with lymphocytic infiltration of the optic nerve.*

age of intervention, duration and severity of any attendant amblyopia, and presence of any associated ocular abnormalities (e.g., microphthalmia, retinal lesions, optic atrophy, glaucoma, nystagmus, strabismus). Persistent amblyopia is the most common cause of poor visual recovery after cataract surgery in children. Secondary conditions and complications may develop in children who have had cataract surgery, including inflammatory sequelae, secondary membranes, glaucoma, retinal detachment, and changes in the axial length of the eye. All these should be considered in planning treatment.

Ectopia Lentis.

Normally, the lens is suspended in place behind the iris diaphragm by the zonular fibers of the ciliary body. Abnormalities of the suspensory system resulting from a developmental defect, disease, or trauma may result in instability or displacement of the lens. Displacement of the lens is classified as luxation (dislocation—complete displacement of the lens) or as subluxation (partial displacement—shifting or tilting of the lens). Symptoms include blurring of vision, which is often the result of refractive changes such as myopia, astigmatism, or aphakic hyperopia. Some patients experience diplopia. An important sign of displacement is iridodonesis, a tremulousness of the iris caused by the loss of its usual support. Also, the anterior chamber may appear deeper than normal. Sometimes the equatorial region (“edge”) of the displaced lens may be visible in the pupillary aperture. On ophthalmoscopy, this may appear as a black crescent. Also, the difference between the phakic and aphakic portions can be appreciated when focusing on the fundus.

DIFFERENTIAL DIAGNOSIS.

A major cause of lens displacement is trauma. Displacement may occur as a result of ocular disease, such as uveitis, intraocular tumor, congenital glaucoma, high myopia, megalocornea, or aniridia, or in association with cataract. There are also heritable forms of ectopia lentis and those associated with systemic disease.

Displacement of the lens occurring as a heritable ocular condition unassociated with systemic abnormalities is referred to as *simple ectopia lentis*. Simple ectopia lentis is usually transmitted as an autosomal dominant condition. The lens is generally displaced upward and temporally. The ectopia may be present at birth or may appear later in life. Another form of heritable dislocation is *ectopia lentis et pupillae.* In this condition, both the lens and pupil are displaced, usually in opposite directions. This condition is generally bilateral, with one eye being almost a mirror image of the other. Ectopia lentis et pupillae is a recessive condition, although variable expression with some intermingling with simple ectopia lentis has been reported.

Systemic disorders associated with displacement of the lens include Marfan syndrome, homocystinuria, Weill-Marchesani syndrome, and sulfite oxidase deficiency. Ectopia lentis occurs in approximately 80% of patients with Marfan syndrome, and in about 50% of patients, the ectopia is evident by the age of 5 yr. In most cases, the lens is displaced superiorly and temporally; it is almost always bilateral and relatively symmetric. In homocystinuria, the lens is usually displaced inferiorly and somewhat nasally. It occurs early in life and is often evident by 5 yr of age. In Weill-Marchesani syndrome, the displacement of the lens is often downward and forward, and the lens tends to be small and round.

Ectopia lentis is also associated occasionally with other conditions, including Ehlers-Danlos, Sturge-Weber, Crouzon, and Klippel-Feil syndrome; oxycephaly; and mandibulofacial dysostosis. A syndrome of dominantly inherited blepharoptosis, high myopia, and ectopia lentis has also been described.

TREATMENT AND PROGNOSIS.

Displacement of the lens often results only in optical problems; in other cases, however, more serious complications may develop, such as glaucoma, uveitis, retinal detachment, or cataract. Management must be individualized according to the type of displacement, its etiology, and the presence of any complicating ocular or systemic conditions. For many patients, optical correction by spectacles or contact lenses can be provided. Manipulation of the iris diaphragm with mydriatic or miotic drops may sometimes help improve vision. In selected cases, the best treatment is surgical removal of the lens. In many children, treatment of any associated amblyopia must be instituted early. In addition, for children with ectopia lentis, safety precautions should be taken to prevent injury to the eye.

Microspherophakia.

The term *microspherophakia* refers to a small, round lens that may occur as an isolated anomaly (probably autosomal recessive) or in association with other ocular abnormalities, such as ectopia lentis, myopia, or retinal detachment (possibly autosomal dominant). Microspherophakia may also occur in association with various systemic disorders, including Marfan syndrome, Marchesani syndrome, Alport syndrome, mandibulofacial dysostosis, and Klinefelter syndrome.

Anterior Lenticonus.

Anterior lenticonus is a rare bilateral condition in which the anterior surface of the lens bulges centrally. It may be accompanied by lens opacities or other eye anomalies and is a prominent feature of Alport syndrome. The increased curvature of the central area may cause high myopia.

Posterior Lenticonus.

Posterior lenticonus, which occurs more commonly than anterior lenticonus, is characterized by a circumscribed round or oval bulge of the posterior lens capsule and cortex, restricted to the 2–7?mm central (axial) region. In the early stages, by the red reflex test, this may look like an oil droplet. It occurs in infants and young children, and it tends to increase with age. Usually the lens material within and surrounding the capsular bulge eventually becomes opacified. Posterior lenticonus usually occurs as an isolated ocular anomaly. It is generally unilateral but may be bilateral. It is believed to be sporadic, although autosomal dominant heredity has been suggested in some cases. Infants or children with posterior lenticonus may require lens surgery for progressive cataract, optical correction, amblyopia treatment, and care of secondary conditions, such as strabismus.

Chapter 620 - Disorders of the Uveal Tract

Uveitis (Iritis, Cyclitis, Chorioretinitis).

The uveal tract (the inner vascular coat of the eye, consisting of the iris, ciliary body, and choroid) is subject to inflammatory involvement in a number of systemic diseases, both infectious and noninfectious, and in response to exogenous factors, including trauma and toxic agents (Box 620–1). Inflammation may affect any one portion of the uveal tract preferentially or all parts together.

Iritis may occur alone or in conjunction with inflammation of the ciliary body as iridocyclitis or in association with pars planitis. Pain, photophobia, and lacrimation are the characteristic symptoms of acute anterior uveitis, but the inflammation may develop insidiously without disturbing symptoms. Signs of anterior uveitis include conjunctival hyperemia, particularly in the perilimbal region (ciliary flush), and cells and protein (“flare”) in the aqueous humor (Fig. 620–1). Inflammatory deposits on

the posterior surface of the cornea (keratic precipitates [KPs]) and congestion of the iris may also be seen. More chronic cases may show degenerative changes of the cornea (band keratopathy), lenticular opacities (cataract), development of glaucoma, and impairment of vision. The cause of anterior uveitis is often obscure; primary considerations in children are rheumatoid disease, particularly pauciarticular rheumatoid arthritis, Kawasaki disease, Reiter syndrome, and sarcoidosis. Iritis may be secondary to corneal disease, such as herpetic keratitis or a bacterial or fungal corneal ulcer, or to a corneal abrasion or foreign body. Traumatic iritis and iridocyclitis are especially common in children.

Iridocyclitis that occurs in children with arthritis deserves special mention. Unlike most forms of anterior uveitis, it rarely creates pain, photophobia, or conjunctival hyperemia. Loss of vision may not be noticed until severe and irreversible damage

Figure 620-1 Cell and flare in the anterior chamber. The flare represents protein leakage. (Courtesy of Peter Buch, C.R.A.)

has occurred. Because of the lack of symptoms and the high incidence of uveitis in these children, routine periodic screening is necessary.

Choroiditis, inflammation of the posterior portion of the uveal tract, invariably also involves the retina; when both are obviously affected, the condition is termed *chorioretinitis*. The causes of posterior uveitis are numerous; the more common are toxoplasmosis, histoplasmosis, cytomegalic inclusion disease, sarcoidosis, syphilis, tuberculosis, and toxocariasis (Fig. 620–2). Depending on the etiology, the inflammatory signs may be diffuse or focal. Vitreous reaction often occurs as well. With many types, the result is atrophic chorioretinal scarring demarcated by pigmentation, often with visual impairment. Secondary complications include retinal detachment, glaucoma, and phthisis.

Panophthalmitis is inflammation involving all parts of the eye. It is frequently suppurative, most often as a result of a perforating injury or of septicemia. It produces severe pain, marked congestion of the eye, inflammation of the adjacent orbital tissues and eyelids, and loss of vision. In many cases, the eye is lost despite intensive treatment of the infection and inflammation. Enucleation of the eye or evisceration of the orbit may be necessary.

Sympathetic ophthalmia is a rare type of inflammatory response that affects the uninjured eye after a perforating injury. It may occur weeks, months, or even years after the injury. A hypersensitivity phenomenon is the most probable cause. Loss of vision in the uninjured (sympathizing) eye may result. Removal of the injured eye prevents the development of sympathetic ophthalmia but does not stop the progression of the disease once it has occurred. Therefore, early enucleation should be considered if there is no hope of visual recovery after a severe injury.

TREATMENT.

The various forms of intraocular inflammation are treated according to their etiologic factors. When infection is proved or suspected, appropriate systemic antimicrobial therapy is used. In some cases, subconjunctival or intravitreal injection of antibiotics is indicated. Prevention or reduction of inflammatory sequelae is also important; in selected cases, topical or systemic corticosteroids are used. Systemic immunosuppressive agents may also be required. Cycloplegic agents, particularly atropine, are also used to reduce inflammation and to prevent adhesion of the iris to the lens, especially in anterior uveitis.

Chapter 621 - Disorders of the Retina and Vitreous

Retinopathy of Prematurity (ROP).

This retinal vasculopathy occurs almost exclusively in preterm infants (see Chapter 86.2). It may be acute (early stages) or chronic (late stages). Clinical manifestations range from mild, usually transient changes of the peripheral retina to severe progressive vasoproliferation, scarring, and potentially blinding retinal detachment. ROP includes all stages of the disease and its sequelae. Retrolental fibroplasia (RLF), the previous name for this disease, described only the cicatricial stages.

PATHOGENESIS.

Beginning at 16 wk of gestation, retinal angiogenesis normally proceeds from the optic disc to the periphery, reaching the outer rim of the retina (ora serrata) nasally at about 36 wk and extending temporally by approximately 40 wk. Injury to the process results in various pathologic and clinical changes. The first observation in the acute phase is cessation of vasculogenesis. Rather than a gradual transition from vascularized to avascular retina, there is an abrupt termination of the vessels, marked by a line in the retina. The line may then grow into a ridge composed of mesenchymal and endothelial cells. Cell division and differentiation may later resume, and vascularization of the retina may proceed. Alternatively, there may be progression to an abnormal proliferation of vessels out of the plane of the retina, into the vitreous, and over the surface of the retina. Cicatrization and traction on the retina may follow, leading to detachment.

The risk factors associated with ROP are not fully known, but prematurity and the associated retinal immaturity at birth represent the major factors. Hyperoxia is also a major factor, but other problems, such as respiratory distress, apnea, bradycardia, heart disease, infection, hypoxia, hypercarbia, acidosis, anemia, and the need for transfusion are thought by some to be contributory factors. Generally, the lower the birthweight and the sicker the infant, the greater the risk for ROP.

The basic pathogenesis of ROP is still unknown. Exposure to the extrauterine environment including the necessarily high inspired oxygen concentrations produces cellular damage, perhaps mediated by free radicals. Later in the course of the disease, peripheral hypoxia develops and vascular endothelial growth factors are produced in the nonvascularized retina. These growth factors stimulate abnormal vasculogenesis, and neovascularization may occur. This may then lead to scarring and vision loss.

CLASSIFICATION.

The currently used international classification of ROP describes the location, extent, and severity of the disease. To delineate location, the retina is divided into three concentric zones, centered on the optic disc. Zone I, the posterior or inner zone, extends twice the disc-macular distance, or 30 degrees in all directions from the optic disc. Zone II, the middle zone, extends from the outer edge of zone I to the ora serrata nasally and to the anatomic equator temporally. Zone III, the outer zone, is the residual crescent that extends from the outer border of zone II to the ora serrata temporally, this area of the retina being vascularized. The extent of involvement is described by the number of circumferential clock hours involved.

The phases and severity of the disease process are classified into five stages. Stage 1 is characterized by a demarcation line that separates vascularized from avascular retina. This line lies within the plane of the retina and appears relatively flat and white. Often noted is abnormal branching or arcading of the retinal vessels that lead into the line. Stage 2 is characterized by a ridge; the demarcation line has grown, acquiring height, width, and volume and extending up and out of the plane of the retina. It may change from white to pink. Vessels may leave the plane of the retina to enter the ridge. Stage 3 is characterized by the presence of a ridge and by the development of extraretinal fibrovascular tissue (Fig. 621–1 *A*). Stage 4 is characterized by subtotal retinal detachment caused by traction from the proliferating tissue in the vitreous or on the retina. Stage 4 is subdivided into two phases: (1) subtotal retinal detachment not involving the macula and (2) subtotal retinal detachment involving the macula. Stage 5 is total retinal detachment.

When signs of posterior retinal vascular changes accompany the active stages of ROP, the term *plus disease* is used (see Fig. 621–1*B*). Patients reaching the point of dilatation and tortuosity of the retinal vessels also frequently demonstrate the associated findings of engorgement of the iris, pupillary rigidity, and vitreous haze.

CLINICAL MANIFESTATIONS AND PROGNOSIS.

In more than 90% of at-risk infants, the course is one of spontaneous arrest and regression of the usually asymmetric disease process, with little or no residual effects or visual disability. Fewer than 10% of infants have progression toward severe disease, with significant extraretinal vasoproliferation, cicatrization, detachment of the retina, and impairment of vision.

Some children with arrested or regressed ROP are left with demarcation lines, undervascularization of the peripheral retina, or abnormal branching, tortuosity, or straightening of the retinal vessels. Some are left with retinal pigmentary changes, dragging of the retina (so-called dragged disc), ectopia of the macula, retinal folds, or retinal breaks. Others proceed to total retinal detachment, which commonly assumes a funnel-like configuration. The clinical picture is often that of a retrolental membrane, producing leukokoria (a white reflex in the pupil). Some patients develop cataract, glaucoma, and signs of inflammation. The end stage is often a painful blind eye or a degenerated phthisical eye. The spectrum of ROP also includes myopia, which is often progressive and of significant degree in infancy. The incidence of anisometropia, strabismus, amblyopia, and nystagmus may also be increased.

DIAGNOSIS.

Systematic ophthalmologic examination of infants at risk is recommended. Guidelines vary but generally include infants weighing less than 1,500?g at birth and those born before 28 wk of gestational age. Infants born weighing

Figure 621-1 Retinopathy of prematurity (ROP). *A*, In stage 3, there is a ridge and extraretinal vascular tissue. *B*, Retinal vessels are dilated and tortuous in active ROP plus disease.

more than 1,500?g, who have an unstable clinical course and who are thought to be at high risk, should also be examined for ROP. The initial examination should be performed at 4–6 wk of chronological age or at 31–33 wk postconceptional age. ROP is diagnosed most often at 32–44 wk after conception. The examination can be stressful to fragile preterm infants, and the dilating drops can have untoward side effects; thus, discretion must be used in timing the eye examination, and infants must be carefully monitored during and after the examination. Follow-up is based on the initial findings and risk factors but is usually 2 wk or less.

TREATMENT.

In selected cases, cryotherapy or laser photocoagulation of the avascular retina reduces the more severe complications of progressive ROP. Advances in vitreoretinal surgical techniques have led to limited success in reattaching the retina in infants with total retinal detachment (stage 5 ROP), but the visual results are often disappointing. The efficacy of laser photocoagulation in infants with earlier stages of ROP is being evaluated.

PREVENTION.

Prevention of ROP ultimately depends on prevention of premature birth and its attendant problems. Despite advances in technology and the meticulous care given to high-risk infants in modern nurseries, ROP continues to occur. Oxygen alone is neither sufficient nor necessary to produce ROP, and no safe level of oxygen has yet been determined. Each infant must be treated with whatever is necessary to sustain life and neurologic function. Some investigators have suggested the use of supplemental vitamin E for its antioxidant properties in infants at risk for ROP. Its efficacy has not been proven; at certain dosage levels, it may produce untoward side effects (see Chapter 86.2).

Persistent Hyperplastic Primary Vitreous (PHPV).

PHPV includes a spectrum of manifestations caused by the persistence of various portions of the fetal hyaloid vascular system and associated fibrovascular tissue.

During development of the eye, the hyaloid artery extends from the optic disc to the posterior aspect of the lens; it sends branches into the vitreous and ramifies to form the posterior portion of the vascular capsule of the lens. The posterior portion of the hyaloid system normally regresses by the 7th fetal mo and the anterior portion by the 8th fetal mo. Small remnants of the system, such as a tuft of tissue at the disc (Bergmeister papilla) or a tag of tissue on the posterior capsule of the lens (Mittendorf dot), are common findings in healthy persons. More extensive remnants and associated complications constitute PHPV. Two major forms are described, anterior PHPV and posterior PHPV. Variability is great, and mixed or intermediate forms occur.

The usual *clinical manifestation* of anterior PHPV is the presence of a vascularized plaque of tissue on the back surface of the lens in an eye that is microphthalmic or slightly smaller than normal. The condition is usually unilateral and may occur in infants with no other abnormalities and no history of prematurity. The fibrovascular tissue tends to undergo gradual contracture. The ciliary processes become elongated, and the anterior chamber may become shallow. The lens usually is smaller than normal and may be clear but often becomes cataractous and may swell or absorb fluid. Large or anomalous vessels of the iris may be present. The anterior chamber angle may have abnormalities. In time, the cornea may become cloudy.

Anterior PHPV is usually noted in the 1st wk or mo of life. The most frequent presenting signs are leukokoria (white pupillary reflex), strabismus, and nystagmus. The course is usually progressive and the outcome poor. Major complications are spontaneous intraocular hemorrhage, swelling of the lens caused by rupture of the posterior capsule, and glaucoma. The eye may eventually deteriorate.

Surgery is performed in an effort to prevent complications, to preserve the eye and a reasonably good cosmetic appearance, and, in some cases, to salvage vision. Surgical *treatment* usually involves aspirating the lens and excising the abnormal tissue. If useful vision is to be attained, refractive correction and aggressive amblyopia therapy are required. In some cases, the affected eye is enucleated, because distinguishing between this white mass and retinoblastoma can be difficult. Ultrasonography and CT are valuable diagnostic aids.

The spectrum of posterior PHPV includes fibroglial veils around the disc and macula, vitreous membranes and stalks

---

containing hyaloid artery remnants projecting from the disc, and meridional retinal folds. Traction detachment of the retina may occur. Vision may be impaired, but the eye is usually retained.

Retinoblastoma (also see Chapter 494).

Retinoblastoma (Fig. 621–2) is the most common primary malignant intraocular tumor of childhood. It occurs in approximately 1/18,000 infants; 250–300 new cases are diagnosed in the United States annually. Hereditary and nonhereditary patterns of transmission occur; there is no sex or race predilection. The hereditary form is usually bilateral and multifocal, whereas the nonhereditary form is generally unilateral and unifocal. Fifteen percent of unilateral cases are hereditary. Bilateral cases often present earlier than unilateral cases. Unilateral tumors are often large by the time they are discovered. The average age at diagnosis is 15 mo for bilateral cases, compared with 25 mo for unilateral cases. It is unusual for a child to present with a retinoblastoma after 2 yr of age. Rarely, the tumor is discovered at birth, during adolescence, or even in adulthood.

The *clinical manifestations* of retinoblastoma vary, depending on the stage at which the tumor is detected. The initial sign in the majority of patients is a white pupillary reflex (leukokoria). Leukokoria results because of the reflection of light off the white tumor. The second most frequent initial sign of retinoblastoma is strabismus. Less frequent presenting signs include pseudohypopyon (tumor cells layered inferiorly in front of the iris), caused by tumor seeding in the anterior chamber of the eye; hyphema (blood layered in front of the iris), secondary to iris neovascularization; vitreous hemorrhage; or signs of orbital cellulitis. On examination, the tumor appears as a white mass, sometimes small and relatively flat, sometimes large and protuberant. It may appear nodular. Vitreous haze or tumor seeding may be evident.

The retinoblastoma gene is a recessive suppressor gene located on chromosome 13 at the 13q14 region. Because of the hereditary nature of retinoblastoma, family members of affected children should undergo a complete ophthalmologic examination and genetic counseling. Newborn siblings and children of affected patients should be referred to an ophthalmologist shortly after birth, when the peripheral retina can be evaluated without the need for an examination under anesthesia.

The *diagnosis* of a retinoblastoma is made by direct observation by an experienced ophthalmologist. Ancillary testing such as CT scanning or ultrasonography may help to confirm the diagnosis

Figure 621-2 Retinoblastoma.

and demonstrate calcification within the mass. A definitive diagnosis occasionally cannot be made, and removal of the eye must be considered to avoid the possibility of lethal metastasis of the tumor. Because a biopsy can lead to spread of the tumor, histologic confirmation before enucleation is not possible in most cases. Therefore, removal of a blind eye in which the diagnosis of retinoblastoma is likely may be appropriate.

Treatment varies, depending on the size and location of the tumor as well as whether it is unilateral or bilateral. Advanced tumors may be treated by enucleation. Other treatment modalities include the use of external beam irradiation, radiation plaque therapy, laser or cryotherapy, and chemotherapy.

The *prognosis* for children with retinoblastoma depends on the size and extension of the tumor. When confined to the eye, most tumors can be cured. The prognosis for long-term survival is poor when the tumor has extended into the orbit or along the

optic nerve.

Retinitis Pigmentosa.

This progressive retinal degeneration is characterized by pigmentary changes, arteriolar attenuation, usually some degree of optic atrophy, and progressive impairment of visual function. Dispersion and aggregation of the retinal pigment produce various ophthalmoscopically visible changes, ranging from granularity or mottling of the retinal pigment pattern to distinctive focal pigment aggregates with the configuration of bone spicules (Fig. 621–3). Other ocular findings include subcapsular cataract, glaucoma, and keratoconus.

Impairment of night vision or dark adaptation is often the first *clinical manifestation*. Progressive loss of peripheral vision, often in the form of an expanding ring scotoma or concentric contraction of the field, is usual. There may be loss of central vision. Retinal function, as measured by electroretinography (ERG), is characteristically reduced. Manifestations commonly begin in childhood. The disorder may be autosomal recessive, autosomal dominant, or sex linked.

A special form of retinitis pigmentosa is **Leber congenital retinal amaurosis**, in which the retinal changes tend to be pleomorphic, with various degrees of pigment disorder, arteriolar attenuation, and optic atrophy. The retina may appear normal during infancy. Vision impairment is usually evident soon after birth, and the ERG findings are abnormal early.

Clinically similar, secondary pigmentary retinal degenerations to be differentiated from retinitis pigmentosa occur in a wide variety of metabolic diseases, neurodegenerative processes, and multifaceted syndromes. Examples include the

Figure 621-3 Retinitis pigmentosa.

progressive retinal changes of the mucopolysaccharidoses (particularly Hurler, Hunter, Scheie, and Sanfilippo syndromes) and certain of the late-onset gangliosidoses (Batten-Mayou, Spielmeyer-Vogt, and Jansky-Bielschowsky diseases), the progressive retinal degeneration that is associated with progressive external ophthalmoplegia (Kearns-Sayre syndrome), and the retinitis pigmentosa-like changes in the Laurence-Moon and Bardet-Biedl syndromes. The retinal manifestations of abetalipoproteinemia (Bassen-Kornzweig syndrome) and Refsum disease are similar to those found in retinitis pigmentosa. The diagnosis of these latter two disorders in a patient with presumed retinitis pigmentosa is important because treatment is possible. There is also an association of retinitis pigmentosa and congenital hearing loss, as in Usher syndrome.

Stargardt Disease (Fundus Flavimaculatus).

This autosomal recessive retinal disorder is characterized by slowly progressive bilateral macular degeneration and vision impairment. It usually appears at 8–14 yr of age, and affected children are often initially misdiagnosed as having functional visual loss. The foveal reflex becomes obtunded or appears grayish, pigment spots develop in the macular area, and macular depigmentation and chorioretinal atrophy eventually occur. Macular hemorrhages also may develop. Some patients also have white or yellow spots beyond the macula or pigmentary changes in the periphery; the term *fundus flavimaculatus* is commonly used for this condition. It is now recognized that Stargardt disease and fundus flavimaculatus represent different parts on the spectrum of the same disease. Central visual acuity is reduced, often to 20/200, but total loss of vision does not occur. ERG findings vary. The condition is not associated with central nervous system abnormalities and is to be differentiated from the macular changes of many progressive metabolic neurodegenerative diseases. The genetic mutation responsible for Stargardt macular dystrophy has been identified.

Best Vitelliform Degeneration.

This macular dystrophy is characterized by a distinctive yellow or orange discoid subretinal lesion in the macula, resembling the intact yolk of a fried egg. Diagnosis is usually made at 3–15 yr of age, with a mean age of presentation of 6 yr. Vision is usually normal at this stage. The condition may be progressive; the yolklike lesion may eventually degenerate (“scramble”) and result in pigmentation, chorioretinal atrophy, and vision impairment. The condition is usually bilateral. There is no association with systemic abnormalities. Inheritance is usually autosomal dominant. In vitelliform macular degeneration, the ERG response is normal. The electrooculogram findings are abnormal in affected patients and carriers, and this test is useful in diagnosis and in genetic counseling.

Cherry Red Spot.

Because of the special histologic features of the macula, certain pathologic processes affecting the retina produce an ophthalmoscopically visible sign referred to as a cherry red spot, a bright to dull red spot at the center of the macula surrounded and accentuated by a grayish-white or yellowish halo. The halo is a result of a loss of transparency of the retinal ganglion cell layer secondary to edema, lipid accumulation, or both. Because ganglion cells are not present in the fovea, the retina surrounding the fovea is opacified but the fovea transmits the normal underlying choroidal color (red), accounting for the presence of the cherry red spot. A cherry red spot typically occurs in certain sphingolipidoses, principally in Tay-Sachs disease (GM_2 type 1), in the Sandhoff variant (GM_2 type 2), and in generalized gangliosidosis (GM_1 type 1). Similar but less distinctive macular changes occur in some cases of metachromatic leukodystrophy (sulfatide lipidosis), in some forms of neuronopathic Niemann-Pick disease, and in certain mucolipidoses. The cherry red spot that characteristically occurs as a result of retinal ischemia secondary to vasospasm, ocular contusion, or occlusion of the central retinal artery must be differentiated from the cherry red spot of neurodegenerative disease.

Phakomas.

These are the herald lesions of the hamartomatous disorders. In Bourneville disease (**tuberous sclerosis**), the distinctive ocular lesion is a refractile, yellowish, multinodular cystic lesion arising from the disc or retina; the appearance of this

typical lesion is often compared with that of an unripe mulberry (Fig. 621–4). Equally characteristic and more common in tuberous sclerosis are flatter, yellow to whitish retinal lesions, varying in size from minute dots to large lesions approaching the size of the disc. These lesions are benign astrocytic proliferations. Rarely, similar retinal phakomas occur in von **Recklinghausen disease (neurofibromatosis)**. In von Hippel-Lindau disease (angiomatosis of the retina and cerebellum), the distinctive fundus lesion is a hemangioblastoma; this vascular lesion usually appears as a reddish globular mass with large paired arteries and veins passing to and from the lesion. In **Sturge-Weber syndrome** (encephalofacial angiomatosis), the fundus abnormality is a choroidal hemangioma; the hemangioma may impart a dark color to the affected area of the fundus, but the lesion is best seen with fluorescein angiography.

Figure 621-4 Retinal phakoma of tuberous sclerosis.

Retinoschisis.

Congenital hereditary retinoschisis, also referred to as *juvenile X-linked retinoschisis*, is a bilateral vitreoretinal dystrophy that appears early in life, often in infancy. It is characterized by splitting of the retina into inner and outer layers. The usual ophthalmoscopic finding in affected males is an elevation of the inner layer of the retina, most commonly in the inferotemporal quadrant of the fundus, often with round or oval holes visible in the inner layer. Schisis of the fovea is virtually pathognomonic and is found in almost 100% of patients. Ophthalmoscopically, this appears in early stages as small, fine striae in the internal limiting membrane. These striae radiate outward in a petaloid or spoke wheel configuration. In some cases, frank retinal detachment or vitreous hemorrhage occurs.

Vision impairment varies from mild to severe; visual acuity may worsen with age, but good vision is often retained. Carrier females are asymptomatic, but linkage studies may be useful to help detect carriers.

Retinal Detachment.

A retinal detachment is a separation of the outer layers of the retina from the underlying retinal pigment epithelium (RPE). During embryogenesis, the retina and RPE are initially separated. During ocular development, they join together and are held in apposition to each other by various physiologic mechanisms. Pathologic events leading to a retinal detachment return the retina-RPE to its former separated state. The detachment can occur as a congenital anomaly but more commonly arises secondary to other ocular abnormalities or trauma. Three types of detachment are described; each may occur in children. *Rhegmatogenous detachments* result from a break in the retina that allows fluid to enter the subretinal space. In children, these are usually a result of trauma (such as child abuse) but may occur secondary to myopia or ROP or after congenital cataract surgery. *Tractional retinal detachments* result when vitreoretinal membranes pull on the retina. They can occur in diabetes, sickle cell disease, and ROP. *Exudative retinal detachments* result when exudation exceeds absorption. This can be seen in Coats disease, retinoblastoma, and ocular inflammation.

The presenting sign of retinal detachment in an infant or child may be loss of vision, secondary strabismus or nystagmus, or leukokoria (white pupillary reflex). In addition to direct examination of the eye, special diagnostic studies such as ultrasonography and neuroimaging (CT, MRI) may be necessary to establish the cause of the detachment and the appropriate treatment. Prompt care is essential if vision is to be salvaged.

Coats Disease.

This exudative retinopathy of unknown cause is characterized by telangiectasis of retinal vessels with leakage of plasma to form intraretinal and subretinal exudates and by retinal hemorrhages and detachment. The condition is usually unilateral. It predominantly affects boys, usually appearing in the first decade. The condition is nonfamilial and for the most part occurs in otherwise healthy children. The most frequent presenting signs are blurring of vision, leukokoria, and strabismus. Rubeosis of the iris, glaucoma, and cataract may develop. Treatment with photocoagulation or cryotherapy may be helpful.

Familial Exudative Vitreoretinopathy (FEV).

This progressive retinal vascular disorder is of unknown cause, but clinical and angiographic findings suggest an aberration of vascular development. Avascularity of the peripheral temporal retina is a significant finding in most cases, with abrupt cessation of the retinal capillary network in the region of the equator. The avascular zone often has a wedge- or V-shaped pattern in the temporal meridian. Glial proliferation or well-marked retinochoroidal atrophy may be found in the avascular zone. Excessive branching of retinal arteries and veins, dilatation of the capillaries, arteriovenous shunt formation, neovascularization, and leakage from retinal vessels of the farthest vascularized retina occur. Vitreoretinal adhesions are usually present at the peripheral margin of the vascularized retina. Traction, retinal dragging and temporal displacement of the macula, falciform retinal folds, and retinal detachment are common. Intraretinal or subretinal exudation, retinal hemorrhage, and recurrent vitreous hemorrhages may develop. Patients may also develop cataracts and glaucoma. Vision impairment of varying severity occurs. The condition is usually bilateral. FEV is usually an autosomal dominant condition with incomplete penetrance. Asymptomatic family members often display a zone of avascular peripheral retina.

The findings in FEV may resemble those of ROP in the cicatricial stages, but unlike ROP, the neovascularization of FEV seems to develop years after birth and most patients with FEV have no history of prematurity, oxygen therapy, prenatal or postnatal injury or infection, or developmental abnormalities. FEV is also to be differentiated from Coats disease, angiomatosis of the retina, peripheral uveitis, and other disorders of the posterior segment.

Hypertensive Retinopathy.

In the early stages of hypertension, no retinal changes may be observable.

Generalized constriction and irregular narrowing of the arterioles are usually the first signs in the fundus. Other alterations include retinal edema, flame-shaped hemorrhages, cotton-wool spots (retinal nerve fiber layer infarcts), and papilledema (Fig. 621–5). These changes are reversible if the disease can be controlled in the early stages, but in long-standing hypertension, irreversible changes may occur. Thickening of the vessel wall may produce a silver- or copper-wire appearance. Hypertensive retinal changes in a child should alert the physician to renal disease, pheochromocytoma, collagen disease, and cardiovascular disorders, particularly coarctation of the aorta.

Diabetic Retinopathy.

The retinal changes of diabetes mellitus are classified as nonproliferative or proliferative. *Nonproliferative diabetic retinopathy* is characterized by retinal microaneurysms, venous dilatation, retinal hemorrhages, and exudates. The microaneurysms appear as tiny red dots. The hemorrhages may be of both the dot and blot type, representing deep intraretinal bleeding, and the splinter or flame-shaped type, involving the superficial nerve fiber layer. The exudates tend to be deep and to appear waxy. There may also be superficial nerve fiber infarcts called *cytoid bodies* or cotton-wool spots, as well as retinal edema. These signs may wax and wane. They are seen primarily in the posterior pole, around the disc and macula, well within the range of direct ophthalmoscopy. Involvement of the macula may lead to decreased vision.

Figure 621-5 Hypertensive retinopathy.

Proliferative retinopathy, the more serious form, is characterized by neovascularization and proliferation of fibrovascular tissue on the retina, extending into the vitreous. Neovascularization may occur on the optic disc (NVD), elsewhere on the retina (NVE), or on the iris and in the anterior chamber angle (NVI, or rubeosis irides) (Fig. 621–6). Traction on these new vessels leads to hemorrhage and eventually scarring. The vision-threatening complications of proliferative diabetic retinopathy are retinal and vitreous hemorrhages, cicatrization, traction, and retinal detachment. Neovascularization of the iris may lead to secondary glaucoma if not treated promptly.

Diabetic retinopathy involves the alteration and nonperfusion of retinal capillaries, retinal ischemia, and neovascularization, but its pathogenesis is not yet completely understood, either in terms of location of the primary pathogenetic mechanism (retinal vessels vs surrounding neuronal or glial tissue) or the specific biochemical factors involved. The better the degree of long-term metabolic control, the lower the risk of diabetic retinopathy.

Clinically, the prevalence and course of retinopathy relate to a patient's age and to duration of disease. Detectable microvascular changes are rare in prepubertal children, with the prevalence of retinopathy increasing significantly after puberty, especially after the age of 15 yr. The incidence of retinopathy is low during the first 5 yr of disease and increases progressively thereafter, with the incidence of proliferative retinopathy becoming substantial after 10 yr and with increased risk of visual impairment after 15 yr or more. Periodic ophthalmologic evaluation is recommended for all patients with diabetes mellitus.

In addition to retinopathy, patients with juvenile-onset diabetes may develop optic neuropathy, characterized by swelling of the disc and blurring of vision. Patients with diabetes may also develop cataracts, even at an early age, sometimes with rapid progression.

Macular edema is the leading cause of visual loss in diabetic persons. Photocoagulation may be used to decrease the risk of continued vision loss in patients with macular edema. Proliferative retinopathy causes the most severe vision loss and can lead to total loss of vision and even loss of the eye.

Patients who have proliferative disease and who display certain high-risk characteristics should undergo panretinal photocoagulation (PRP) to preserve their central vision. Neovascularization of the iris is also treated with PRP to stop the development of neovascular glaucoma. Vitrectomy and other intraocular surgery may be necessary in patients with nonresolving vitreous hemorrhage or traction retinal detachment.

Figure 621-6 Proliferative diabetic retinopathy with neovascularization of the disc (NVD).

The value of technologic advances, such as insulin infusion pumps and pancreatic transplants, in preventing ocular complications is under investigation (see Chapter 583).

Subacute Bacterial Endocarditis.

At some time during the course of the disease, retinopathy is present in approximately 40% of cases of subacute bacterial endocarditis. The lesions include hemorrhages, hemorrhages with white centers *(Roth spots)*, papilledema, and, rarely, embolic occlusion of the central retinal artery.

Blood Disorders.

In primary and secondary anemias, retinopathy in the form of hemorrhages and cotton-wool patches may occur. Vision can be affected if hemorrhage occurs in the macular area. The hemorrhages may be light and feathery or dense and preretinal. In polycythemia vera, the retinal veins are dark, dilated, and tortuous. Retinal hemorrhages, retinal edema, and papilledema may be observed. In leukemia, the veins are characteristically dilated, with sausage-shaped constrictions; hemorrhages, particularly white-centered hemorrhages and exudates, are common during the acute stage. In the sickling disorders, fundus changes include vascular tortuosity, arterial and venous occlusions, “salmon patches,” refractile deposits, pigmented lesions, arteriolar-venous anastomoses, and neovascularization (with “sea-fan” formations), sometimes leading to vitreous hemorrhage and retinal detachment. Individuals with Hb SC and Hb S-ß-thalassemia hemoglobinopathies are at a higher risk for the development of retinopathy than are those with HbSS disease. It is

thought that the more anemic state of those patients with SS disease offers protection from vascular occlusions in the retina.

Trauma-Related Retinopathy.

Retinal changes may occur in patients who suffer trauma to other parts of the body. The occurrence of retinal hemorrhages in infants who have been physically abused is well documented (see Chapter 35). Retinal, subretinal, subhyaloid, and vitreous hemorrhages have been described. Often there are no signs of direct trauma to the eye, periocular region, or head. Such cases may result from violent shaking of an infant, and permanent retinal damage may result. Retinal, subhyaloid, and vitreous hemorrhages are common in patients with traumatic and nontraumatic subarachnoid hemorrhage, an association referred to as **Terson syndrome**.

In patients with head or chest trauma, a traumatic retinal angiopathy known as **Purtscher retinopathy** may occur. This is characterized by retinal hemorrhage, cotton-wool spots, possible disc swelling, and decreased vision. The pathogenesis is unclear, but there is evidence for arteriolar obstruction in this condition. A Purtscher-like fundus picture may also occur in several nontraumatic settings, such as acute pancreatitis, lupus erythematosus, and childbirth.

Medullated Nerve Fibers.

Myelination of the optic nerve fibers normally terminates at the level of the disc, but in some individuals, ectopic medullation extends to nerve fibers of the retina. The condition is most commonly seen adjacent to the disc, although more peripheral areas of the retina may be involved. The characteristic ophthalmoscopic picture is a focal white patch with a feathered edge or brush-stroke appearance. Because the macula is generally unaffected, the visual prognosis is good. A relative or absolute visual field defect corresponding to areas of ectopic medullation is usually the only associated ocular abnormality. Extensive unilateral involvement, however, has been associated with ipsilateral myopia, amblyopia, and strabismus. If unilateral high myopia and amblyopia are present, appropriate optical correction and occlusion therapy should be instituted. For unknown reasons, the disorder is more commonly encountered in patients with craniofacial dysostosis, oxycephaly, neurofibromatosis, and Down syndrome.

Coloboma of The Fundus.

The term *coloboma* describes a defect such as a gap, notch, fissure, or hole. The typical fundus coloboma is a result of malclosure of the embryonic fissure, which leaves a gap in the retina, RPE, and choroid, thus baring the underlying sclera. The defect may be extensive, involving the ciliary body, iris, and even lens, or it may be localized to one or more portions of the fissure. The usual appearance is of a well-circumscribed, wedge-shaped white area extending inferonasally below the disc, sometimes involving or engulfing the disc. In some cases there is ectasia or cyst formation in the area of the defect. Less extensive colobomatous defects may appear as only single or multiple focal punched-out chorioretinal defects or anomalous pigmentation of the fundus in the line of the embryonic fissure. Colobomas may occur in one or both eyes. A visual field defect usually corresponds to the chorioretinal defect. Visual acuity may be impaired, particularly if the defect involves the disc or macula.

Fundus colobomas may occur in isolation as sporadic defects or as an inherited condition. Isolated colobomatous anomalies are commonly inherited in an autosomal dominant manner with highly variable penetrance and expressivity. Family members of affected patients should receive appropriate genetic counseling. Colobomas may also be associated with such abnormalities as microphthalmia, glioneuroma of the eye, cyclopia, or encephale. They occur in children with various chromosomal disorders, including 13-trisomy, 18-trisomy, triploidy, cat's eye syndrome, and 4p-. Ocular colobomata also occur in many multisystem disorders, including the CHARGE[*] association; Joubert, Aicardi, Meckel, Warburg, and Rubinstein-Taybi syndromes; linear sebaceous nevus; Goldenhar and Lenz microphthalmia syndromes; and Goltz focal dermal hypoplasia.

Chapter 622 - Abnormalities of the Optic Nerve

Optic Nerve Aplasia.

This rare congenital anomaly is typically unilateral. The optic nerve, retinal ganglion cells, and retinal blood vessels are absent. A vestigial dural sheath usually connects with the sclera in a normal position, but no neural tissue is present within this sheath. Optic nerve aplasia typically occurs sporadically in an otherwise healthy person. A wide variety of ocular abnormalities may occur, but colobomas are the most frequent associated finding.

Optic Nerve Hypoplasia.

Hypoplasia of the optic nerve is a nonprogressive condition characterized by a subnormal number of optic nerve axons with normal mesodermal elements and glial supporting tissue. In typical cases, the nerve head is small and pale, with a pale or pigmented peripapillary halo or double ring sign.

This anomaly is associated with defects of vision and of visual fields of varying severity, ranging from blindness to normal or near-normal vision. It may be associated with systemic anomalies that most commonly involve the central nervous system (CNS). Protean CNS defects such as hydranencephaly or anencephaly or more focal lesions compatible with continued development of a patient may accompany optic nerve hypoplasia, but unilateral or bilateral optic nerve hypoplasia may be found without any concomitant defects.

Optic nerve hypoplasia is a principal feature of **septo-optic dysplasia of de Morsier**, a developmental disorder characterized by the association of anomalies of the midline structures of the brain with hypoplasia of the optic nerves, optic chiasm, and optic tracts; typically noted are agenesis of the septum pellucidum, partial or complete agenesis of the corpus callosum, and malformation of the fornix, with a large chiasmatic cistern. Patients may have hypothalamic abnormalities and endocrine defects, ranging from panhypopituitarism to isolated deficiency of growth hormone, hypothyroidism, or diabetes insipidus. Neonatal hypoglycemia and seizures are important presenting signs in affected infants.

Bilateral subtle hypoplasia may be difficult to diagnose from the appearance of the disc alone because no comparison with a contralateral uninvolved eye is possible. However, it is important to establish the diagnosis because this eliminates confusion with optic atrophy or glaucoma and may explain the cause of decreased vision in a patient unresponsive to amblyopia therapy. Endocrine function should be watched closely in patients with optic nerve hypoplasia.

The etiology of optic nerve hypoplasia remains unclear. Early gestational injuries to midline CNS structures with secondary axonal injury or a disruption of normal neuronal guidance mechanisms that affect both optic nerve and cerebral neurons may account for these commonly associated disorders. Optic nerve hypoplasia may occur with somewhat increased frequency in infants of diabetic mothers and has been associated with maternal use of dilantin, quinine, LSD (lysergic acid diethylamide), and alcohol during pregnancy.

Morning Glory Disc Anomaly.

This term describes a congenital malformation of the optic nerve characterized by an enlarged, excavated, funnel-shaped disc with an elevated rim, resembling a morning glory flower. White glial tissue is present in the central part of the disc. The retinal vessels are abnormal and appear at the peripheral disc and course over the elevated pink rim in a radial fashion. Pigmentary mottling of the peripapillary region is usually seen. Most cases are unilateral. Females are affected twice as often as males. Visual acuity is usually severely reduced, and retinal detachment occurs in approximately one third of involved eyes. The association between basal encephaloceles and the morning glory disc anomaly has been well established.

Tilted Disc.

In this congenital anomaly, the vertical axis of the optic disc is directed obliquely, so that the upper temporal portion of the nerve head is more prominent and anterior to the lower nasal portion of the disc. The retinal vessels emerge from the upper temporal portion of the disc rather than from the nasal side. Often noted is a peripapillary crescent or conus. Associated visual field defects and myopic astigmatism may be found. Clinical recognition of the tilted disc syndrome is important to avoid confusion of its disc and visual field signs with those of papilledema and intracranial tumor.

Drusen of the Optic Nerve.

These globular, acellular bodies are thought to arise from axoplasmic derivatives of disintegrating nerve fibers. Drusen may be buried within the optic nerve, producing elevation of the optic nerve head (which can be confused with papilledema), or they may be partially or completely exposed, appearing as refractile bodies at the surface of the disc. Visual field defects and spontaneous peripapillary nerve fiber layer hemorrhages may occur in association with drusen. Drusen may occur as an autosomal dominant condition. They have also been observed in children with various neurologic disorders, including primary megalencephaly, seizures, learning disorders, mental retardation, schizophrenia, tuberous sclerosis, Down syndrome, and intracranial tumors.

Papilledema.

The term *papilledema* ("choked disc") is reserved to describe swelling of the nerve head secondary to increased intracranial pressure (ICP). *Clinical manifestations* of papilledema include edematous blurring of the disc margins, fullness or elevation of the nerve head, partial or complete obliteration of the disc cup, capillary congestion and hyperemia of the nerve head, generalized engorgement of the veins, loss of spontaneous venous pulsation, nerve fiber layer hemorrhages around the disc, and peripapillary exudates (see Fig. 584–1). In some cases, edema extending into the macula may produce a fan- or star-shaped figure. In addition, concentric peripapillary retinal wrinkling (Paton lines) may be noted. Transient obscuration of vision may occur, lasting seconds and associated with postural changes. Vision, however, is usually normal in acute papilledema. Normally, when the ICP is relieved, the papilledema resolves and the disc returns to a normal or nearly normal appearance within 6–8 wk. Sustained chronic papilledema or long-standing unrelieved increased ICP may, however, lead to permanent nerve fiber damage, atrophic changes of the disc, macular scarring, and impairment of vision. In cases of impending or progressive vision loss caused by papilledema in patients with benign intracranial hypertension, decompression of the optic nerve by slitting the sheath may preserve vision.

The *pathophysiology* of papilledema is probably as follows: elevation of intracranial subarachnoid cerebrospinal fluid (CSF) pressure, elevation of CSF pressure in the sheath of the optic nerve, elevation of tissue pressure in the optic nerve, stasis of axoplasmic flow and swelling of the nerve fibers in the optic nerve head, and secondary vascular changes and the characteristic ophthalmoscopic signs of venous stasis. Associated neuro-ophthalmic signs of increased ICP in infants and children include abducent palsy and attendant esotropia, lid retraction, paresis of upward gaze, tonic downward deviation of the eyes, and convergent nystagmus.

The common *etiologies* of papilledema in childhood are intracranial tumors and obstructive hydrocephalus, intracranial hemorrhage, the cerebral edema of trauma, meningoencephalitis and toxic encephalopathy, and certain metabolic diseases. Whatever the cause, the optic disc signs of increased ICP in early childhood may occasionally be modified by the distensibility of the young skull. In the absence of conditions associated with early closure of sutures and early obliteration of the fontanel (craniosynostosis, Crouzon disease, and Apert syndromes), infants with increased ICP may not develop papilledema.

The *differential diagnosis* of papilledema includes structural changes of the disc ("pseudopapilledema," "pseudoneuritis," drusen, and medullated fibers), with which it may be confused, and the disc swelling of hypertension and diabetes mellitus. Unless retinal hemorrhage or edema involves the macular area, the preservation of good central vision and the absence of an afferent pupillary defect (Marcus Gunn pupil) help to differentiate acute papilledema from the edema of the optic nerve head found in acute optic neuritis.

Papilledema is a neurologic emergency. It can be accompanied by other signs of increased ICP, including headaches, nausea, and vomiting. Neuroimaging should be performed; if no intracranial masses are detected, a lumbar puncture and determination of CSF pressure should follow.

Optic Neuritis.

This is any inflammation, demyelinization, or degeneration of the optic nerve with attendant impairment of function. The process is usually acute, with rapidly progressive loss of vision. It may be unilateral or bilateral. Pain on movement of the globe or pain on palpation of the globe may precede or accompany the onset of visual symptoms.

When the retrobulbar portion of the nerve is affected without ophthalmoscopically visible signs of inflammation at the disc, the term *retrobulbar neuritis* is applied. When there is ophthalmoscopically visible evidence of inflammation of the nerve head, the term *papillitis* or *intraocular optic neuritis* is used. When there is involvement of both the retina and papilla, the term *optic neuroretinitis* is used.

In childhood, optic neuritis may occur as an isolated condition or as a manifestation of a neurologic or systemic disease. It may occur with bacterial meningitis or with viral infection (often accompanying encephalomyelitis following an exanthem). It may signify one of the many demyelinating diseases of childhood. Although a significant percentage of adults who experience an episode of optic neuritis eventually develop other symptoms associated with multiple sclerosis, children with optic neuritis are seemingly at less risk. Bilateral optic neuritis in children may be associated with neuromyelitis optica (Devic disease). This syndrome is characterized by rapid and severe bilateral visual loss accompanied by transverse myelitis and paraplegia. Optic neuritis may also be secondary to an exogenous toxin or drug, such as with lead poisoning or as a complication of long-term high-dose treatment with chloramphenicol or vincristine therapy. Extensive pediatric neurologic and ophthalmic investigation, including neuroradiologic and electrophysiologic studies, is usually required.

In most cases of acute optic neuritis, some improvement in vision begins within 1–4 wk after onset, and vision may improve to normal or near normal within weeks or months. The course varies with etiology. Although central vision may fully recover, it is common to find permanent defects in other areas of visual function (contrast sensitivity, color, brightness sense, and motion perception).

A *treatment* trial demonstrated that intravenous corticosteroids may help to speed the visual recovery in young adults but do not alter the long-term visual outcome. Therefore, their use has been reserved by some physicians for cases with severe vision loss or significant discomfort. Orally administered corticosteroids should not be used because they are associated with a significant increase in the recurrence rate of optic neuritis. It is unknown to what degree the results of the aforementioned trial may be extrapolated to optic neuritis in childhood.

Leber Optic Neuropathy.

This entity is characterized by sudden loss of central vision occurring in the 2nd and 3rd decades of life, primarily affecting young males. A characteristic peripapillary telangiectatic microangiopathy occurs not only in the presymptomatic phase of involved eyes but also in a high number of asymptomatic offspring in the female line. Disc hyperemia and edema mark the acute phase of visual loss. One eye is usually affected before the other. In time, progressive optic atrophy and vision loss usually ensue. The tortuous angiopathy becomes less obvious. Although visual function after the initial loss generally remains stable, a significant and sometimes complete recovery may occur in as many as one third of affected individuals. This recovery may take place years or decades after the initial episode of acute vision loss. The peripapillary angiopathy, the lack of short-term remission, and the degree of symmetry serve to distinguish most cases of Leber disease from the optic neuritis of multiple sclerosis.

Leber optic neuropathy is maternally inherited and is caused by defective cytoplasmic mitochondrial DNA. Multiple point mutations in the mitochondrial DNA that lead to the development of the disorder have been found. Because of the mitochondrial nature of the disorder, skeletal and cardiac muscle disorders, including electrocardiographic abnormalities, may also be encountered in affected individuals.

Optic Atrophy.

This denotes degeneration of optic nerve axons, with attendant loss of function. The ophthalmoscopic signs of optic atrophy are pallor of the disc and loss of substance of the nerve head, sometimes with enlargement of the disc cup. The associated vision defect varies with the nature and site of the primary disease or lesion.

Optic atrophy is the common expression of a wide variety of congenital or acquired pathologic processes. The cause may be traumatic, inflammatory, degenerative, neoplastic, or vascular; intracranial tumors and hydrocephalus are principal causes of optic atrophy in children. In some cases, progressive optic atrophy is hereditary. Dominantly inherited infantile optic atrophy is a relatively mild heredodegenerative type that tends to progress through childhood and adolescence. Autosomal recessively inherited congenital optic atrophy is a rare condition that is evident at birth or develops at a very early age; the visual defect is usually profound. Behr optic atrophy is a hereditary type associated with hypertonia of the extremities, increased deep tendon reflexes, mild cerebellar ataxia, some degree of mental deficiency, and possibly external ophthalmoplegia. This disorder afflicts principally boys age 3–11 yr. Some forms of heredodegenerative optic atrophy are associated with sensorineural hearing loss, as may occur in some children with juvenile-onset (insulin-dependent) diabetes mellitus. In the absence of an obvious cause, optic atrophy in an infant or child warrants extensive etiologic investigation.

Optic Nerve Glioma.

Optic nerve glioma, more properly referred to as juvenile pilocytic astrocytoma, is the most frequent tumor of the optic nerve in childhood. This neuroglial tumor may develop in the intraorbital, intracanalicular, or intracranial portion of the nerve; the chiasm is often involved.

The tumor is a cytologic benign hamartoma that is generally stationary or only slowly progressive. The principal manifestations when the tumor occurs in the intraorbital portion of the nerve are unilateral loss of vision, proptosis, and deviation of the eye; optic atrophy or congestion of the optic nerve head may occur. Chiasmal involvement may be attended by defects of vision and visual fields (often bitemporal hemianopia), increased ICP, papilledema or optic atrophy, hypothalamic dysfunction, pituitary dysfunction, and sometimes nystagmus or strabismus. Juvenile pilocytic astrocytomas occur with increased frequency in patients with neurofibromatosis.

Treatment of optic pathway gliomas is controversial. The best management is usually periodic observation. Surgical removal may be appropriate when the tumor is confined to the intraorbital, intracanalicular, or prechiasmal portion of the nerve if a patient has unsightly proptosis with complete or nearly complete loss of vision of the affected eye. When the chiasm is involved, resection is not usually indicated and radiation and chemotherapy may be necessary.

Traumatic Optic Neuropathies.

Injury to the optic nerve may result from both direct and indirect trauma. Direct trauma to the optic nerve is a result of a penetrating injury to the orbit with transection or contusion of the nerve. Blunt trauma to the orbit may also lead to severe visual loss if the traumatic force is transmitted to the optic canal and causes disruption of the blood supply to the intracanalicular portion of the nerve. Treatment may include high-dose corticosteroids or optic canal decompression.

Chapter 623 - Childhood Glaucoma

Glaucoma is a general term used to indicate damage to the optic nerve with visual field loss that is caused by or related to elevated pressure within the eye. It is classified according to the age of the affected individual at presentation and the association of other ocular or systemic conditions. Glaucoma that begins within the first 3 yr of life is called *infantile* (congenital); that which begins between the ages of 3 and 30 yr is called *juvenile*.

Primary glaucoma indicates that the cause is an isolated anomaly of the drainage apparatus of the eye (trabecular meshwork). More than 50% of infantile glaucoma is primary. In secondary glaucoma, other ocular or systemic abnormalities are associated, even if a similar developmental defect of the trabecular meshwork is also present. Primary infantile glaucoma occurs with an incidence of only 0.03%.

Clinical Manifestations.

The symptoms of infantile glaucoma include the classic triad of epiphora (tearing), photophobia (sensitivity to light), and blepharospasm (eyelid squeezing). Each can be attributed to corneal irritation. Only about 30% of affected infants demonstrate the classic symptom complex. Other signs include corneal edema, corneal and ocular enlargement, conjunctival injection, and visual impairment.

The sclera and cornea are more elastic in early childhood than later in life. An increase in intraocular pressure (IOP), therefore, leads to an expansion of the globe, including the cornea, and the development of buphthalmos (“ox eye”). If the cornea continues to enlarge, breaks occur in the endothelial basement membrane (Descemet membrane) and may lead to permanent corneal scarring. These breaks in Descemet membrane (Haab striae) are visible as horizontal edematous lines that cross or curve around the central cornea. They rarely occur beyond 3 yr of age or in corneas less than 12.0?mm in diameter. The cornea also becomes edematous and cloudy, with increased IOP. The corneal edema leads to tearing and photophobia. Glaucoma should be considered in a child suspected of having a nasolacrimal duct obstruction if any of these other signs or symptoms are present.

Children with unilateral glaucoma generally present early because the difference in the corneal size between the eyes can be noticed. When the disease is bilateral, parents may not recognize the increased corneal size. Many parents view the large eyes as attractive and do not seek help until other symptoms develop.

Cupping of the optic nerve head is detected by ocular examination. The optic nerve of an infant is easily distended by excessive pressure. Deep, central cupping readily occurs and may regress with normalization of pressure.

Some infants and children with early onset glaucoma have more extensive maldevelopment of the anterior segment of the eye. The **neurocristopathies**, once known as mesodermal dysgenesis, comprise a spectrum of conditions relating to abnormal embryologic development of the anterior segment. They are usually bilateral and may include abnormalities of the iris, cornea, and lens. Other ocular anomalies that may be associated with glaucoma in infants and children are aniridia, cataract, spherophakia, and ectopia lentis. Glaucoma may also develop secondary to persistent hyperplastic primary vitreous or retinopathy of prematurity.

Trauma, intraocular hemorrhage, ocular inflammatory disease, and intraocular tumor are also important causes of glaucoma in the pediatric population. Systemic disorders associated with glaucoma in infants and children are Sturge-Weber syndrome, von Recklinghausen disease, Lowe syndrome, Marfan syndrome, congenital rubella, a number of chromosomal syndromes, and juvenile xanthogranuloma.

Diagnosis and Treatment.

The diagnosis of infantile glaucoma is made on recognition of the signs and symptoms. Although measurement of IOP may be helpful in monitoring treatment response, it is not a vital part of the diagnostic process. Once the diagnosis is established, treatment is started promptly. Unlike adult glaucoma, in which medication is often the first line of therapy, for infantile glaucoma the treatment is primarily surgical. Procedures used to treat glaucoma in children include surgery to establish a more normal anterior chamber angle (goniotomy and trabeculotomy), to create a site for aqueous fluid to exit the eye (trabeculectomy and seton surgery), or to reduce aqueous fluid production (cyclocryotherapy and photocyclocoagulation). Many children frequently require several operations to lower and maintain their IOP adequately, and long-term medical therapy may be necessary as well. Although vision may be reduced secondary to glaucomatous optic nerve damage or corneal scarring, amblyopia is the most common cause of loss of vision in these children.

Chapter 624 - Orbital Abnormalities

Hypertelorism and Hypotelorism.

Hypertelorism is wide separation of the eyes or an increased interorbital distance, which may occur as a morphogenetic variant, a primary deformity, or a secondary phenomenon in association with developmental abnormalities, such as frontal meningocele or encephalocele or the persistence of a facial cleft. Often associated are strabismus, generally exotropia, and sometimes optic atrophy.

Hypotelorism refers to narrowness of the interorbital distance, which may occur as a morphogenetic variant alone or in association with other anomalies, such as epicanthus or holoprosencephaly or secondary to a cranial dystrophy, such as scaphocephaly.

Exophthalmos and Enophthalmos.

Protrusion of the eye is referred to as *exophthalmos* or *proptosis*. It may be caused by shallowness of the orbits, as in many craniofacial malformations, or by increased tissue mass within the orbit, as with neoplastic, vascular, and inflammatory disorders. Ocular complications include exposure keratopathy, ocular motor disturbances, and optic atrophy with loss of vision.

Posterior displacement or sinking of the eye back into the orbit is referred to as *enophthalmos*. This may occur with orbital fracture or with atrophy of orbital tissue.

Orbital Cellulitis.

This is a condition involving inflammation of the tissues of the orbit, with proptosis, limitation of movement of the eye, edema of the conjunctiva (chemosis), and inflammation and swelling of the eyelids. Patients often feel some discomfort, usually with general symptoms of toxicity, fever, and leukocytosis. Also see Chapter 178 .

Orbital cellulitis may follow direct infection of the orbit from a wound, metastatic deposition of organisms during bacteremia, or more often direct extension or venous spread of infection from contiguous sites such as the lids, conjunctiva, globe, lacrimal gland, nasolacrimal sac, or commonly the paranasal sinuses. In some cases, primary or metastatic tumor in the orbit can produce the clinical picture of orbital cellulitis. The most common cause of orbital cellulitis in children is paranasal sinusitis. Frequent pathogenic organisms include nontypable *Haemophilus influenzae, Staphylococcus aureus*, group A ß-hemolytic streptococci, *Streptococcus*

pneumoniae, and anaerobic bacteria.

The orbital inflammatory *clinical manifestations* of paranasal sinusitis vary with the location and extent of involvement. Stage 1 is swelling of the lids—the edema of impaired venous drainage or the reactive inflammation of underlying periostitis; in this stage, the infection is still confined to the sinus. The 2nd stage is subperiosteal abscess, a collection of pus between the periosteum and the wall of the orbit, often with localized tenderness, displacement of the globe, and some limitation of eye movement. The 3rd stage is true orbital cellulitis, diffuse inflammation of the tissues within the orbit, with proptosis and impairment of ocular motility. The 4th stage is orbital abscess, resulting from localization of infection in the orbit or from extension of a subperiosteal abscess through the periosteum.

The potential for complications is great. Involvement of the optic nerve may result in loss of vision. Extension of infection from the orbit into the cranial cavity may lead to cavernous sinus thrombosis or meningitis or to epidural, subdural, or brain abscesses.

Orbital cellulitis must be recognized promptly and treated aggressively (see Chapter 178). Hospitalization and systemic antibiotic therapy are usually indicated. In some cases, surgical intervention is necessary to drain infected sinuses or a subperiosteal or orbital abscess.

Periorbital Cellulitis.

Inflammation of the lids and periorbital tissues without signs of true orbital involvement (such as proptosis or limitation of eye movement) is generally referred to as periorbital or preseptal cellulitis. This is common in young children and may be caused by trauma, by an infected wound, or by abscess of the lid or periorbital region (e.g., pyoderma, hordeolum, conjunctivitis, dacryocystitis, or insect bite). It may be associated with respiratory infection or more often bacteremia, often with *H. influenzae* type b, streptococci, or pneumococci. What initially appears to be periorbital or preseptal cellulitis may be the first sign of sinusitis that may occasionally progress to true orbital cellulitis. Prompt antibiotic therapy and careful monitoring for signs of sepsis and local progression are essential. See Chapter 365 .

Orbital Inflammation.

Inflammatory disease involving the orbit may be primary or secondary to systemic disease. Idiopathic orbital inflammation (orbital pseudotumor) represents a wide spectrum of clinical entities. Symptoms at the time of presentation may include pain, eyelid swelling, proptosis, and fever. The inflammation may involve a single extraocular muscle (myositis) or the entire orbit. Confusion with orbital cellulitis is common but can be differentiated by the lack of associated sinus disease, its appearance on CT scan, and lack of improvement with systemic antibiotics. Treatment includes the use of high-dose systemic corticosteroids. Immunotherapy or radiation treatment may be necessary for resistant or recurrent cases.

Thyroid-related ophthalmopathy (TRO) is believed to be secondary to an immune mechanism, leading to inflammation and deposition of mucopolysaccharides and collagen in the extraocular muscles and orbital fat. Involvement of the extraocular muscles may lead to a restrictive strabismus. Lid retraction and exophthalmos may cause corneal exposure and infection or perforation. Involvement of the posterior orbit can compress the optic nerve. Treatment of TRO may include the use of systemic corticosteroids, radiation of the orbit, eyelid surgery, strabismus surgery, or orbital decompression to eliminate symptoms and protect vision. The degree of orbital involvement is often independent of the status of the systemic disease. Also see Chapter 562 .

Other systemic disorders that may cause inflammatory disease within the orbit include lymphoma, sarcoidosis, amyloidosis, polyarteritis nodosa, systemic lupus erythematosus, dermatomyositis, Wegener granulomatosis, and juvenile xanthogranuloma.

Tumors of the Orbit.

Various tumors occur in and about the orbit in childhood. Among benign tumors, the most common are vascular lesions (principally hemangiomas) and dermoids. Among

---

malignant neoplasms, rhabdomyosarcoma, lymphosarcoma, and metastatic neuroblastoma are the most frequent. Optic gliomas and retinoblastomas that extend into the orbit also occur.

The effects of orbital tumors vary with their locations and growth patterns. The principal signs are proptosis, resistance to retroplacement of the eye, and impairment of eye movement. A palpable mass may be found. Other significant signs are ptosis, optic nerve head congestion, optic atrophy, and loss of vision. Bruit and visible pulsation of the globe are important clues to vascular lesions.

Evaluation of orbital tumors includes ultrasonography, MRI, and CT. Pseudotumor of the orbit also must be considered in children with signs of a mass lesion.

Chapter 625 - Injuries to the Eye

About one third of all blindness in children results from trauma. Children and adolescents account for a disproportionate number of episodes of ocular trauma. Boys ages 11–15 yr are the most vulnerable; their injuries outnumber those in girls by a ratio of about 4:1. The majority of injuries are related to sports, toy darts, other projectiles, sticks, stones, fireworks, and air-powered BB guns. The last causes particularly devastating ocular and orbital injuries. Much of the trauma is avoidable. See Chapter 50 .

Ecchymoses and Swelling of the Eyelids.

These are common after blunt trauma. Hemorrhage into the lids and periorbital region (“black eye” or “shiner”) is usually of no consequence and absorbs spontaneously, but it should prompt careful examination of the eye for deeper, more serious injury, such as a blowout fracture of the orbit, an intraocular hemorrhage, or rupture of the globe.

Lacerations of the Eyelids.

These require careful management. Horizontal laceration of the upper lid may involve the levator, the tarsal plate, or the orbital septum. Faulty repair can result in ptosis, distortion of the lid, or herniation of orbital fat. Lacerations involving the lid margins require meticulous surgical apposition to prevent notching, eversion, or inversion of the margin or misdirection of the lashes that might lead to epiphora (tear overflow), wetting defects of the cornea, and chronic irritation. Lacerations situated near the medial canthus may involve the punctum, canaliculi, or nasolacrimal duct and require microsurgical repair by an experienced ophthalmic surgeon. In all cases of lid laceration, examination of the globe for perforating injury is mandatory.

Superficial Abrasions of the Cornea.

When the corneal epithelium is scratched, abraded, or denuded, it exposes the underlying epithelial basement layer and superficial corneal nerves. This is accompanied by pain, tearing, photophobia, and decreased vision. Corneal abrasions are detected by instilling fluorescein dye and inspecting the cornea using a blue-filtered light. A slit lamp is ideal for this examination, but a hand-held Wood's lamp is adequate for young children.

Treatment of a corneal abrasion is directed at promoting healing and relieving pain. Abrasions are treated with frequent applications of a topical antibiotic ointment until

the epithelium is completely healed. The use of a semi-pressure patch does not improve healing time or decrease pain. Furthermore, an improperly applied patch may itself abrade the cornea. A topical cycloplegic agent (cyclopentolate hydrochloride 1%) can relieve the pain from ciliary spasm in patients with large abrasions. Topical anesthetics should not be given at home because they retard epithelial healing and inhibit the natural blinking reflex.

Foreign Body on or in the Cornea or Conjunctiva.

This usually produces acute discomfort, lacrimation, and inflammation. Most foreign bodies can be detected by examination in good light with the aid of magnification; a direct ophthalmoscope set on a high plus lens (+10 or +12) is helpful. In many cases, slit-lamp examination is necessary, especially if the particle is deep or metallic. Some conjunctival foreign bodies tend to lodge under the upper eyelid, causing the sensation of corneal foreign body as they come into contact with the globe on eyelid movement; they may also produce vertically oriented linear corneal abrasions. Finding these abrasions should lead to a suspicion of such a foreign body, and eversion of the lid may be necessary (Chapter 610). If a foreign body is suspected but not found, further examination is indicated. If the history suggests injury with a high-velocity particle, roentgenographic examination of the eye may be needed to explore the possibility of intraocular foreign body.

Removal of a foreign body can be facilitated by instillation of a drop of topical anesthetic. Many foreign bodies can be removed by irrigating or by gently wiping them away with a moistened cotton-tipped applicator. Embedded foreign bodies should be treated by an ophthalmologist. Removal of corneal foreign bodies may leave epithelial defects, which are treated as corneal abrasions. Metallic foreign bodies may cause rust to form in the corneal tissues; examination by an ophthalmologist a day or two after removal of a foreign body is recommended, because a rust ring would require further treatment (curettage).

Lacerations and Perforating Wounds of the Cornea or Sclera.

These require immediate referral to an ophthalmologist and prompt surgical repair if the eye and vision are to be saved. Important clues to perforating injury of the eye are collapse of the anterior chamber, distortion and displacement of the pupil, and protrusion of dark tissue (uvea) into the wound. Emergency treatment consists of protecting the injured eye from further damage by applying a sterile bandage and a rigid eye shield. If these medical supplies are not on hand, an adequate eye shield can be fashioned from a plastic or Styrofoam cup or from a piece of cardboard bent into a box or cone shape. Manipulation should be kept to a minimum, and no medication should be instilled except under the direction of an ophthalmologist.

Hyphema.

This is the presence of blood in the anterior chamber of the eye. It may occur with either a blunt or perforating injury. Hyphema appears as a bright or dark red fluid level between the cornea and iris or as a diffuse murkiness of the aqueous humor. Children with hyphema have pain and may be somnolent. The treatment of hyphema usually includes bed rest, with the head elevated 30–45 degrees to promote settling and resorption of the blood. Hospitalization and sedation may be necessary to ensure compliance in some children. In most cases, topical mydriatics, topical or oral corticosteroids, or oral aminocaproic acid are used

---

to prevent rebleeding. Secondary bleeding typically occurs 3–5 days after the initial hemorrhage, increasing the risk of sequelae. The blood in the anterior chamber may produce elevation of intraocular pressure and blood staining of the cornea. These complications may affect vision. In such cases, surgical evacuation of the clot and irrigation of the anterior chamber may be necessary. Patients with sickle cell disease or trait are at higher risk for acute loss of vision and rebleeding and may require more aggressive intervention. Individuals with a history of traumatic hyphema have an increased incidence of glaucoma later in life.

Chemical Injuries.

Chemical burns of the cornea and adnexal tissue are among the most urgent of ocular emergencies. Alkali burns are usually more destructive than acid burns because they react with fats to form soaps, which damage cell membranes, allowing further penetration of the alkali into the eye. Acids generally cause less severe, more localized tissue damage. The corneal epithelium offers moderate protection against weak acids, and little damage occurs unless the pH is 2.5 or less. Most stronger acids precipitate tissue proteins, creating a physical barrier against their further penetration.

Mild acid or alkali burns are characterized by conjunctival injection and swelling and mild corneal epithelial erosions. The corneal stroma may be mildly edematous, and the anterior chamber may have mild to moderate cell and flare reactions. With strong acids, the cornea and conjunctiva rapidly become white and opaque. The corneal epithelium may slough, leaving a relatively clear stroma; this appearance may initially mask the severity of the burn. Severe alkali burns are characterized by corneal opacification.

Emergency treatment of a chemical burn begins with copious immediate irrigation with water or saline. Local debridement and removal of foreign particles should be performed while still irrigating. If the nature of the chemical injury is unknown, the use of pH test paper is helpful in determining whether the agent was basic or acidic. Irrigation should continue for at least 30?min or until 2?L of irrigant has been instilled in mild cases and for 2–4?hr or until 10?L of irrigant has been instilled in severe cases. At the end of irrigation, the pH should be within a normal range (7.3–7.7). The pH should be checked again approximately 30?min after irrigation to ensure that it has not changed.

Fractures.

A *direct orbital floor fracture* is a floor fracture associated with an orbital rim fracture. An *indirect orbital floor fracture* is an isolated floor fracture and is more commonly known as a blowout fracture. Floor fractures are common when objects larger than the orbital opening, such as a ball, fist, or the dashboard of an automobile, strike the

orbit, particularly the inferior lateral orbit.

The most obvious clinical sign of an orbital floor fracture is limitation of upward gaze. Additional signs include lower eyelid ecchymosis, nosebleed, orbital emphysema, and hypesthesia of the ipsilateral cheek and upper lip. The last results from disruption of the infraorbital nerve as it traverses the orbital floor.

The best imaging techniques to visualize orbital fractures are plain-film radiography and CT. The Waters' view best demonstrates the orbital floor and maxillary sinus.

Treatment for children with acute orbital fractures includes antibiotic prophylaxis, nasal decongestants, and ice packs. If entrapment of the extraocular muscles (resulting in restriction of movement of the eye and diplopia) and herniation of orbital fat or of the eye itself (resulting in enophthalmos) occur, then surgical repair may be necessary.

Penetrating Wounds of the Orbit.

These demand careful evaluation for possible damage to the eye, the optic nerve, or the brain. Examination should include investigation for retained foreign body. Orbital hemorrhage and infection are common with penetrating wounds of the orbit; such injuries must be treated as emergencies.

Child Abuse.

This is a major cause of injuries to the eye and orbital region. The manifestations are numerous and may have a prominent role in recognition of this syndrome. The possibility of nonaccidental trauma must be considered in any child with ecchymosis or laceration of the lids, hemorrhage in or about the eye, cataract or dislocated lens, retinal detachment, or fracture of the orbit (Fig. 625–1). Also see Chapter 35 .

Fireworks-Related Injuries.

Injuries related to the use of fireworks can be the most devastating of all ocular trauma that occurs in children. At least one fifth of emergency room visits for fireworks-related injuries are for ocular trauma. In the United States, a majority of these injuries take place around Independence Day, and most occur despite adult supervision.

Sports-Related Ocular Injuries and Their Prevention.

Although sports injuries occur in all age groups, far more children and adolescents participate in high-risk sports than do adults. The greater number of participating children, their athletic immaturity, and the increased likelihood of their using inadequate or improper eye protection account for their disproportionate share of sports-related eye injuries. See Chapters 677 and 681 .

The sports with the highest risk of eye injury are those in which no eye protection can be worn, including boxing, wrestling, and martial arts. High-risk sports include those that use a rapidly moving ball or puck, bat, stick, racquet, or arrow (baseball, hockey, lacrosse, racquet sports, and archery) or involve aggressive body contact (football and basketball). Related to both risk and frequency of participation, the highest percentage of eye injuries are in basketball and baseball.

Protective eyewear, designed for a specific activity, is available for most sports. For basketball, racquet sports, and other recreational activities that do not require a helmet or face mask, molded polycarbonate sports goggles that are secured to the head by an elastic strap are suggested. For hockey, football, lacrosse, and baseball (batter), specific helmets with polycarbonate face shields and guards are available. Children should also wear sports goggles under the helmets. For baseball, goggles and helmets should be worn for batting, catching, and base running; goggles alone are usually sufficient for other positions.

Part 29 - The Ear

Chapter 626 - Clinical Manifestations

Joseph Haddad Jr.

Eight prominent signs and symptoms are associated primarily with diseases of the ear and temporal bone. They are as follows:

Otalgia.

This is usually associated with inflammation of the external or middle ear, but it may represent pain referred from involvement of the teeth, temporomandibular joint, or pharynx. In young infants, pulling or rubbing the ear with general irritability or poor sleep, especially when associated with fever, may be the only sign of ear pain. Ear pulling alone is not diagnostic of ear pathology.

Purulent Otorrhea.

This is a sign of otitis externa, otitis media with perforation of the tympanic membrane (TM), and/or drainage from the middle ear through a patent tympanostomy tube. Bloody discharge may be associated with acute or chronic inflammation (often with granulation tissue), trauma, neoplasm, foreign body, or blood dyscrasia. Clear drainage suggests a perforation of the TM with a serous middle-ear effusion or, rarely, a cerebrospinal fluid leak draining through defects (congenital or traumatic) in the external auditory canal or from the middle ear.

Hearing Loss.

This results from disease of either the external or middle ear (conductive hearing

loss) or from pathology in the inner ear, retrocochlear structures, or central auditory pathways (sensorineural hearing loss). The most common cause of hearing loss in children is otitis media (OM).

Swelling.

Swelling around the ear is most commonly a result of inflammation (external otitis, perichondritis, mastoiditis), trauma (hematoma), benign cystic masses, or neoplasm.

Vertigo.

This is an uncommon complaint in children; the child or parent may not volunteer information about balance unless asked directly. *Vertigo*, a specific type of dizziness, is defined as any hallucination, illusion, or sensation of motion; *dizziness* refers to an altered orientation in space and is less specific than vertigo. The most frequent cause of dizziness in young children is eustachian tube–middle-ear disease, but true vertigo may also be caused by labyrinthitis, perilymphatic fistula between the inner and middle ear due to trauma or a congenital inner ear defect, cholesteatoma in the mastoid or middle ear, vestibular neuronitis, benign paroxysmal vertigo, Meniere disease, or disease of the central nervous system. Older children may describe a feeling of room-spinning or turning; younger children may express the dysequilibrium only by falling, stumbling, or clumsiness.

Nystagmus.

Unidirectional, horizontal, or jerk nystagmus, usually associated with vertigo, is vestibular in origin.

Tinnitus.

Although infrequently described spontaneously by children, tinnitus is common, especially in patients with eustachian tube–middle-ear disease or with sensorineural hearing loss (SNHL). Children may describe tinnitus if asked directly about it, including laterality and the quality of the sound.

Facial Paralysis.

The facial nerve may be dehiscent in its course through the middle ear in up to 50% of patients; infection with local inflammation (most commonly in acute OM) may lead to a temporary paralysis of the facial nerve. It may also be due to cholesteatoma, Bell palsy, the Ramsay Hunt syndrome (herpes zoster oticus), Lyme disease, fracture, neoplasm, or infection of the temporal bone. Congenital facial paralysis may be due to birth trauma or congenital abnormality of the 7th nerve or may be associated with other cranial nerve abnormalities and craniofacial anomalies.

Physical Examination.

Complete examination with special attention to the head and neck may reveal a condition that may predispose to or be associated with ear disease in children. The facial appearance and the character of speech may give clues to an abnormality of the ear or hearing. Many craniofacial anomalies, such as cleft palate, mandibulofacial dysostosis (Treacher Collins syndrome), and trisomy 21 (Down syndrome), are associated with disorders of the ear and eustachian tube. Mouth breathing and hyponasality may indicate intranasal or postnasal obstruction; hypernasality is a sign of velopharyngeal insufficiency. Examining the oropharyngeal cavity may uncover an overt cleft palate or a submucous cleft (usually associated with a bifid uvula), both of which predispose to OM with effusion. A nasopharyngeal tumor with nasal and eustachian tube blockage may be associated with OM.

The *position* of the patient for examination of the ear, nose, and throat depends on the patient's age, ability to cooperate, clinical setting, and examiner preference. The child can be examined on an examination table or in the parent's lap. The presence of a parent or assistant is usually necessary to minimize movement and improve the examination (Fig. 626–1) An examining table may be desirable for uncooperative older infants or when a procedure, such as microscopic evaluation or tympanocentesis, is performed. Lap examination is adequate and preferable in most infants and young children; the parent

Figure 626-1 Methods of restraining an infant for examination and for procedures such as tympanocentesis or myringotomy. (From Bluestone CD, Klein JO: *Otitis Media in Infants and Children*, 2nd ed. Philadelphia, WB Saunders, 1995, p 91.)

---

may assist in restraining the child by folding the child's wrists and arms over the child's own abdomen with one hand and holding the child's head against the parent's chest with the other hand. If necessary, the child's legs can be held between the parent's knees. To avoid ear trauma with movement, the examiner should hold the otoscope with the hand placed firmly against the child's head or face, so that the otoscope moves with the head. Pulling up and out on the pinna straightens the ear canal and allows better exposure of the TM.

When e*xamining the ear*, inspection of the auricle and external auditory meatus for infection may aid in the evaluation of complications of OM. For instance, external otitis may result from acute OM with discharge, or inflammation of the posterior auricular area may indicate a periosteitis or subperiosteal abscess extending from the mastoid air cells. The presence of preauricular pits or skin tags should also be noted, because affected children have a slightly higher incidence of SNHL.

The presence of wax in the ear canal may interfere with examination. **Removal of cerumen** is usually done with the surgical head of the otoscope, which allows passage of a wire loop or a blunt curette under direct visualization. Other methods include gentle irrigation of the ear canal with warm water (irrigate only when the TM is intact) or instillation of a solution such as diluted hydrogen peroxide in the ear canal for a few minutes to soften the wax for suction removal or irrigation. Some commercial preparations (trolamine polypeptide oleate-condensate [Cerumenex]) may cause dermatitis of the external canal with chronic use and should be used only

under a physician's supervision.

Inflammation of the ear canal with associated pain often indicates external otitis. Abnormalities of the external auditory canal include stenosis (common in children with trisomy 21), bony exostoses, otorrhea, and the presence of foreign bodies. Cholesteatoma of the middle ear may manifest in the canal as intermittent foul-smelling drainage, sometimes associated with white debris; cholesteatoma of the external canal may appear as a white pearl-like mass in the canal skin. White or gray debris of the canal suggests fungal external otitis. Newborn ear canals are filled with vernix caseosa, which is soft and pale yellow and should disappear shortly after birth.

The TM and its mobility are best assessed with a pneumatic otoscope. The normal TM is in a neutral position; a bulging TM may be caused by increased middle-ear air pressure, with or without pus or effusion in the middle ear; visualization of the malleus and annulus may be obscured by a bulging drum. Retraction of the TM usually indicates negative middle-ear pressure, but it may also result from previous middle-ear disease with fixation of the ossicles, ossicular ligaments, or TM. When retraction is present, the bony malleus appears more prominent and the incus may be more visible posterior to the malleus.

The normal TM has a silvery-gray waxed paper appearance; a white or yellow TM may indicate a middle-ear effusion. A red TM alone may not indicate pathology, because the blood vessels of the membrane may be engorged as a result of crying, sneezing, or nose-blowing. A normal TM is translucent, allowing the observer to visualize the middle-ear landmarks—incus, promontory, round window niche, and frequently the chorda tympani nerve. If a middle-ear effusion is present, an air-fluid level or bubbles may be visible. Inability to visualize the middle-ear structures indicates opacification of the drum, usually caused by thickening of the TM, a middle-ear effusion, or both. Assessment of the light reflex is generally not helpful, as a middle ear with effusion reflects light as well as a normal ear.

TM mobility is helpful in assessing middle ear pressures and the presence or absence of fluid. To best perform pneumatic otoscopy, a speculum of adequate size is used to obtain a good seal and allow air movement in the canal. A rubber ring around the tip of the speculum may help to obtain a better canal seal. Normal middle-ear pressure is characterized by a neutral TM position and brisk TM movement to both positive and negative pressures.

Eardrum retraction is most common when negative middle-ear pressure is present; with even moderate negative middle-ear pressure there is no visible inward movement with applied positive pressure in the ear canal. However, negative canal pressure, which is produced by releasing the rubber bulb of the pneumatic otoscope, may cause the TM to bounce out toward the neutral position. A retracted TM may occur in both the presence and absence of middle-ear fluid, and if the middle-ear fluid is mixed with air, the TM may still have some mobility. Outward eardrum movement is less likely in the presence of severe negative middle-ear pressure or middle-ear effusion.

The TM that exhibits fullness (bulging) moves to applied positive pressure but not to applied negative pressure if the pressure within the middle ear is positive and some air is present. A full TM and positive middle-ear pressure without an effusion may be seen in young infants who are crying during the otoscopic examination, in older infants and children with nasal obstruction, and in the early stage of acute OM. When the middle-ear–mastoid air cell system is filled with an effusion and little or no air is present, the mobility of the TM is severely decreased or absent in response to both applied positive and negative pressures.

Aspiration of the middle ear is the definitive method of verifying the presence and type of a middle-ear effusion. Diagnostic tympanocentesis is performed by inserting, through the inferior portion of the TM, an 18-gauge spinal needle attached to a syringe or a collection trap (Fig. 626–2). Culturing of the ear canal and alcohol cleansing should precede tympanocentesis and culture of the middle-ear aspirate; a canal culture is taken to help determine whether organisms cultured from the middle ear are contaminants from the external canal or true pathogens.

Further diagnostic studies of the ear and hearing include audiometric evaluation, impedance audiometry (tympanometry), acoustic reflectometry, and specialized eustachian tube function studies. Diagnostic imaging studies, including computed tomography and magnetic resonance imaging, often provide further information about anatomic abnormalities and the extent of inflammatory processes or neoplasms. Specialized assessment of labyrinthine function should be considered in the evaluation of a child with a suspected vestibular disorder (Chapter 631).

Figure 626-2 Tympanocentesis can be performed with a needle attached to a tuberculin syringe (*left*) or by using an Alden-Senturia collection trap (Storz Instrument Co, St. Louis). (From Bluestone CD, Klein JO: *Otitis Media in Infants and Children*, 2nd ed. Philadelphia, WB Saunders, 1995, p 127.)

Chapter 627 - Hearing Loss

Joseph Haddad Jr.

Incidence and Prevalence.

Although estimates vary because of differences in criteria for defining hearing impairment, the age group surveyed, and the testing methods used, from 1–2 newborns/1,000 live births have moderate (30–50?dB), severe (50–70?dB), or profound (70?dB or greater) bilateral sensorineural hearing loss (SNHL), including 0.5–1/1,000 with bilateral SNHL exceeding 75?dB. An additional 1–2/1,000 may have milder or unilateral impairments; by age 19 yr, the prevalence doubles. Unilateral SNHL of 45?dB or greater occurs in 3/1,000 U.S. school children; hearing loss of 26?dB or greater occurs in 13/1,000. Onset of hearing loss can occur at any time in childhood. When considering less severe hearing loss, or the transient conductive hearing loss (CHL) that commonly accompanies middle-ear disease in young children, the number of affected children increases substantially.

Types of Hearing Loss.

Hearing loss can be peripheral or central in origin. Peripheral hearing loss is commonly caused by dysfunction in the transmission of sound through the external or middle ear or by abnormal transduction of sound energy into neural activity in the inner ear and the 8th nerve. Peripheral hearing loss can be conductive, sensorineural, or mixed. *CHL* is the most common type in children and occurs when sound transmission is physically impeded in the external and/or middle ear. Common causes of CHL in the ear canal include atresia or stenosis, impacted cerumen, or foreign bodies; in the middle ear, perforation of the tympanic membrane (TM), discontinuity or fixation of the ossicular chain, otitis media (OM) with effusion, otosclerosis, and cholesteatoma can cause CHL. Damage to or maldevelopment of structures in the inner ear can cause *SNHL*; these include hair cell destruction from noise, disease, or ototoxic agents; cochlear malformation; perilymphatic fistula of the round or oval window membrane; and lesions of the acoustic division of the 8th nerve. A combined CHL and SNHL is considered a *mixed hearing loss*.

Auditory deficits originating along the central auditory nervous system pathways from the proximal 8th nerve to the cerebral cortex are generally considered central (or retrocochlear) hearing losses. Tumors or demyelinating disease of the 8th nerve and cerebellopontine angle can cause hearing deficits but spare the outer, middle, and inner ear. These causes of hearing loss are rare in children. Other forms of central auditory deficits, known as *central auditory processing disorders*, include those that make it difficult even for children with normal hearing to listen selectively in the presence of noise, to combine information from the two ears properly, to process speech when it is slightly degraded, and to integrate auditory information that is delivered faster than at a slow rate. These deficits may manifest as poor attention, or academic or behavior problems in school. Strategies for coping with such disorders are available in older children, and identification and documentation of the central auditory processing disorder is often valuable because parents and teachers are made aware of a valid reason for the child's poor attention or behavior and adjustments can be made.

Etiology.

The etiology of a hearing impairment depends on whether the hearing loss is conductive or sensorineural. Most CHL is acquired, with middle ear fluid the most common cause. Congenital causes include anomalies of the pinna, external ear canal, TM, and ossicles. Rarely, congenital cholesteatoma or other masses in the middle ear may present as CHL. TM perforation (trauma, OM), ossicular discontinuity (infection, cholesteatoma, trauma), tympanosclerosis, acquired cholesteatoma, or masses in the ear canal or middle ear (Langerhans' cell histiocytosis, salivary gland tumors, glomus tumors, rhabdomyosarcoma) may also present as CHL. Uncommon diseases affecting the middle ear and temporal bone that may present with CHL include otosclerosis, osteopetrosis, fibrous dysplasia, and osteogenesis imperfecta.

SNHL may be congenital or acquired. Causes of SNHL include genetic, infectious, autoimmune, anatomic, traumatic, ototoxic, and idiopathic factors. The most common *infectious* cause of congenital SNHL is cytomegalovirus (CMV), which infects 1/100 newborns in the United States. Of these, 6,000–8,000 infants per year will have clinical manifestations, including approximately 75% with SNHL. Congenital CMV warrants special attention because it is associated with hearing loss in its symptomatic and asymptomatic forms; the hearing loss may be progressive. Some children with congenital CMV have suddenly lost residual hearing at age 4–5 yr. Other less common congenital infectious causes of SNHL include toxoplasmosis and syphilis. Congenital CMV, toxoplasmosis, and syphilis may also present with delayed onset of SNHL, months to years after birth. Rubella, once the most common viral cause of congenital SNHL, is now very uncommon because of effective vaccination programs. Prenatal infection with herpes is rare, and hearing loss as the only manifestation is very unusual.

Other postnatal infectious causes of SNHL include Group B streptococcal sepsis in newborns and bacterial meningitis. *Streptococcus pneumoniae* is the most common cause of bacterial meningitis that results in SNHL after the neonatal period; this cause may become less frequent with the routine administration of pneumococcal conjugate vaccine. *Haemophilus influenzae*, once the most common cause of meningitis resulting in SNHL, is now rare owing to the Hib vaccine. Uncommon infectious causes of SNHL include Lyme disease, parvovirus B19, and varicella. Mumps, rubella, and rubeola, all once common causes of SNHL in children, are rare

owing to vaccination programs.

Genetic causes of SNHL are probably responsible for as many as 50% of SNHL cases. These disorders may be associated with other abnormalities, may be part of a named syndrome, or may exist in isolation. SNHL often occurs with abnormalities of the ear and eye and with disorders of the metabolic, musculoskeletal, integumentary, renal, and nervous systems. Autosomal dominant hearing losses account for about 10% of all cases of childhood SNHL. Waardenburg (types I and II) and branchio-otorenal syndromes represent two of the most common autosomal dominant syndromic types of SNHL. Autosomal recessive genetic SNHL, both syndromic and nonsyndromic, accounts for about 80% of all childhood cases of SNHL. Usher syndrome (types I, II, and III), Pendred syndrome, and the Jervell and Lange-Nielsen syndromes (a form of the long Q-T syndrome) are three of the most common syndromic recessive types of SNHL. Whereas children with an easily identified syndrome or with anomalies of the outer ear may be identified as being at risk for hearing loss and monitored adequately, nonsyndromic children present greater difficulty. Mutations of the connexin-26 and -30 genes have been identified in autosomal recessive and autosomal dominant and in sporadic nonsyndromic patients with SNHL. Sex-linked disorders associated with SNHL, thought to account for 1–2% of SNHL, include Norrie disease, the otopalatal digital syndrome, and Alport syndrome. Chromosomal abnormalities such as 13–15-trisomy, 18-trisomy, and 21-trisomy can also be accompanied by hearing impairment. Patients with Turner syndrome have monosomy for all or part of one X chromosome and may have CHL, SNHL, or mixed hearing loss. The hearing loss may be progressive. Mitochondrial genetic abnormalities may also result in SNHL.

Agenesis or malformation of cochlear structures, including the Scheibe, Mondini, Alexander, and Michel anomalies, and enlarged vestibular aqueducts and semicircular canal anomalies may be genetic. These anomalies probably occur before the 8th wk of gestation and result from arrest in normal development, aberrant development, or both. Many of these anomalies have

also been described in association with other congenital conditions such as intrauterine infections (CMV, rubella). These abnormalities are quite common; in as many as 20% of children with SNHL, obvious or subtle temporal bone abnormalities are seen on high-resolution computed tomography scanning or magnetic resonance imaging.

CHL can also be genetic. Conditions, diseases, or syndromes that include craniofacial abnormalities are often associated with conductive hearing loss and possibly with SNHL. Pierre Robin, Treacher Collins, Klippel-Feil, Crouzon, and branchio-otorenal syndromes and osteogenesis imperfecta are often associated with hearing loss. Congenital anomalies causing CHL include malformations of the ossicles and middle-ear structures and atresia of the external auditory canal.

Many genetically determined causes of hearing impairment, including both syndromic and nonsyndromic, do not express themselves until some time after birth. Alport, Alström, and Down syndromes, von Recklinghausen disease, and Hunter-Hurler syndrome are genetic diseases that may have SNHL as a late manifestation.

SNHL may also occur secondary to exposure to *toxins, chemicals, and antimicrobials*. Early in pregnancy, the embryo is particularly vulnerable to the effects of toxic substances. Ototoxic drugs, including aminoglycosides, loop diuretics, and chemotherapeutic agents (cisplatin) may also cause SNHL. Congenital SNHL may occur secondary to exposure to these drugs as well as to thalidomide and retinoids. Certain chemicals, such as quinine, lead, and arsenic, may cause hearing loss both prenatally and postnatally.

Trauma, including temporal bone fractures, inner ear concussion, head trauma, iatrogenic trauma (surgery, extracorporeal membrane oxygenation [ECMO]), radiation, and noise may also cause SNHL. Other uncommon causes of SNHL in children include immune disease (systemic or limited to the inner ear), metabolic abnormalities, and neoplasms of the temporal bone.

Box 627–1 lists some factors that place a newborn at risk for hearing impairment. These factors account for about 50% of cases of moderate to profound SNHL in neonates.

Effects of Hearing Impairment.

These depend on the nature and degree of the hearing loss and on the individual characteristics of the child. Hearing loss may be unilateral or bilateral, conductive, sensorineural, or mixed; mild, moderate, severe, or profound; of sudden or gradual onset; stable, progressive, or fluctuating; and affecting a part, or all, of the audible spectrum. Other factors such as intelligence, medical or physical condition (including accompanying syndromes), family support, age at onset, age at time of identification, and promptness of intervention also affect the impact of hearing loss on a child.

Most hearing-impaired children have some usable hearing. Only 6% of those in the hearing-impaired population have bilateral profound hearing loss. Hearing loss very early in life can affect the development of speech and language, social and emotional development, behavior, attention, and academic achievement. Some cases of hearing impairment are misdiagnosed because affected children have sufficient hearing to respond to environmental sounds and can learn some speech and language but when challenged in the classroom cannot perform to full potential.

Even mild or unilateral hearing loss may have a detrimental effect on the development of a young child and on school performance. Children with such hearing impairments have greater difficulty when listening conditions are unfavorable (background noise and poor acoustics), as may occur in a classroom. The fact that schools are auditory-verbal environments is unappreciated by those who minimize the impact of hearing impairment on learning. Hearing loss should be considered in any child with speech and language difficulties or below-par performance, poor behavior, or inattention in school (Table 627–1).

Box 627-1. Indicators Associated With Sensorineural and/or Conductive Hearing Loss

For use with neonates (birth through age 28 days) when universal screening is not available

Family history of hereditary childhood sensorineural hearing loss

In utero infection, such as cytomegalovirus, rubella, syphilis, herpes simplex, or toxoplasmosis

Craniofacial anomalies, including those with morphologic abnormalities of the pinna and ear canal

Birth weight less than 1500?g (3.3?lb)

Hyperbilirubinemia at a serum level requiring exchange transfusion

Ototoxic medications, including but not limited to the aminoglycosides, used in multiple courses or in combination with loop diuretics

Bacterial meningitis

Apgar scores of 0 to 4 at 1?min or 0 to 6 at 5?min

Mechanical ventilation lasting 5 days or longer

Stigmata or other findings associated with a syndrome known to include a sensorineural and/or conductive hearing loss

For use with infants (age 29 days through 2 yr) when certain health conditions develop that require rescreening

Parent/caregiver concern regarding hearing, speech, language, and/or developmental delay

conditions develop that require rescreening

Parent/caregiver concern regarding hearing, speech, language, and/or developmental delay

Bacterial meningitis and other infections associated with sensorineural hearing loss

Head trauma associated with loss of consciousness or skull fracture

Stigmata or other findings associated with a syndrome known to include a sensorineural and/or conductive hearing loss

Ototoxic medications, including but not limited to chemotherapeutic agents or aminoglycosides used in multiple courses or in combination with loop diuretics

Recurrent or persistent otitis media with effusion for at least 3 mo

For use with infants (age 29 days through 3 yr) who require periodic monitoring of hearing

(Some newborns and infants may pass initial hearing screening but require periodic monitoring of hearing to detect delayed-onset sensorineural and/or conductive hearing loss. Infants with these indicators require hearing evaluation at least every 6 mo until age 3 yr, and at appropriate intervals thereafter.)

Indicators associated with delayed-onset sensorineural hearing loss include:

Family history of hereditary childhood hearing loss

In utero infection, such as cytomegalovirus, rubella, syphilis, herpes simplex, or toxoplasmosis

Neurofibromatosis type II and neurodegenerative disorders

herpes simplex, or toxoplasmosis

Neurofibromatosis type II and neurodegenerative disorders

Indicators associated with conductive hearing loss include:

Recurrent or persistent otitis media with effusion

Anatomic deformities and other disorders that affect eustachian tube function

Neurodegenerative disorders

A

Adapted from American Academy of Pediatrics, Joint Committee on Infant Hearing: Joint Committee on Infant Hearing 1994 Position Statement. *Pediatrics* 1995;95:152.

Children with moderate, severe, or profound hearing impairment and those with other handicapping conditions are often educated in classes or schools for children with special needs. The auditory management and choices about modes of communication and education for children with hearing handicaps must be individualized because these children are not a homogeneous group. A team approach to individual case management is essential because each child and family unit represents unique needs and abilities.

Hearing Screening.

Hearing impairment can have a major impact on the development of a child and because early identification improves prognosis, screening programs have been widely and strongly advocated. Data from the Colorado newborn screening program suggest that if hearing-impaired infants are identified and treated by age 6 mo, these children (with the exception of those with bilateral profound impairment) should develop the same level of language as their age-matched peers who are not hearing impaired. This is compelling support for the establishment of mandated newborn hearing screening programs for all children. The American Academy of Pediatrics endorses the goal of universal

TABLE 627-1 -- **Hearing Handicap as a Function of Average Hearing Threshold Level of the Better Ear**

Average Threshold Level (dB) at 500–2,000 Hz (ANSI)	Description	Common Causes	What Can Be Heard Without Amplification	Degree of Handicap (if Not Treated in 1st yr of Life)	Probable Needs
0–15	Normal range	Conductive hearing loss	All speech sounds	None	None
16–25	Slight hearing loss	Otitis media, TM perforation, tympanosclerosis; eustachian tube dysfunction; some SNHL	Vowel sounds heard clearly, may miss unvoiced consonant sounds	Mild auditory dysfunction in language learning. Difficulty in perceiving some speech sounds	Consideration of need for hearing aid; speech reading; auditory training Speech therapy Preferential seating Appropriate surgery
25–30	Mild	Otitis media, TM perforation, tympanosclerosis, severe eustachian dysfunction, SNHL	Hears only some of speech sounds, the louder voiced sounds	Auditory learning dysfunction Mild language retardation Mild speech problems Inattention	Hearing aid Lip reading Auditory training Speech therapy Appropriate surgery
30–50	Moderate hearing loss	Chronic otitis, ear canal/middle ear anomaly, SNHL	Misses most speech sounds at normal conversational level	Speech problems Language retardation Learning dysfunction Inattention	All of the above, plus consideration of special classroom situation
50–70	Severe hearing loss	SNHL or mixed loss due to a combination of middle-ear disease and sensorineural involvement	Hears no speech sound of normal conversations	Severe speech problems Language retardation Learning dysfunction Inattention	All of the above; probable assignment to special classes

70+	Profound hearing loss	SNHL or mixed	Hears no speech or other sounds	Severe speech problems Language retardation Learning dysfunction Inattention	All of the above; probable assignment to special classes or schools

ANSI = American National Standards Institute;TM = tympanic membrane; SNHL = sensorineural hearing loss.

Modified from Northern JL, Downs MP: Hearing in Children, 4th ed. Baltimore, Williams & Wilkins, 1991.

detection of hearing loss in infants before 3 mo of age, with appropriate intervention no later than 6 mo of age. At present, hearing screening has been mandated in 32 states in the United States.

Until mandated screening programs are universally established, many hospitals will continue to use other criteria to screen for hearing loss. Some use the high-risk criteria (see Box 627–1) to decide which infants to screen, some screen all infants who require intensive care, and some do both. The problem with using high-risk criteria to screen is that 50% of the cases of hearing impairment will be missed because the infants are hearing impaired but do not meet any of the high-risk criteria, or they develop hearing loss after the neonatal period.

The recommended hearing screening techniques are either otoacoustic emissions (OAE) testing or auditory brainstem evoked responses (ABR). The ABR test, an auditory evoked electrophysiologic response that correlates highly with hearing, has been used successfully and cost-effectively to screen newborns and to identify further the degree and type of hearing loss. OAE tests, used successfully in many newborn screening programs, are quick, easy to administer and inexpensive, and provide a sensitive indication of the presence of hearing loss. Results are relatively easy to interpret. OAEs are absent if hearing is worse than 30–40?dB, no matter what the cause; those children who fail OAEs undergo an ABR for a more definitive evaluation. Screening methods such as observing behavioral responses to uncalibrated noisemakers or using automated systems such as the Crib-o-gram or the auditory response cradle (in which movement of the infant in response to sound is recorded by motion sensors) are not recommended.

Many children become hearing impaired after the neonatal period and, therefore, are not identified by newborn screening programs. It is often not until children are in preschool or kindergarten that further hearing screening takes place. Consequently, primary care physicians and pediatricians should be alert to the signs and symptoms of childhood hearing impairment, so that those with hearing impairment who are not screened formally can be identified as early as possible.

IDENTIFICATION OF HEARING IMPAIRMENT.

The impact of hearing impairment is greatest on an infant who has yet to develop language; therefore, identification, diagnosis, description, and treatment should begin as soon as possible. In general, infants with a prenatal or perinatal history that puts them at risk (see Box 627–1) or those who have failed a formal hearing screening should be closely monitored by an experienced clinical audiologist until a reliable assessment of auditory function has been obtained. Pediatricians should encourage families to cooperate with the follow-up plan. Infants who are born at risk but who have not been screened as neonates (often because of transfer from one hospital to another) should have a hearing screening by age 3 mo.

Hearing-impaired infants who are born at risk or screened for hearing loss in a neonatal hearing screening program account for only a portion of those in the pediatric hearing-impaired population. Those who are congenitally deaf because of autosomal recessive inheritance or subclinical congenital infection are often not identified until the 2nd or 3rd yr of life. Usually, the more severe the hearing loss, the earlier is the age at identification, but identification often occurs later than the age necessary for an optimal outcome. Children with normal hearing have developed an extensive language by age 3 yr. Parental concern about hearing and any delayed development of speech and language should alert the pediatrician; parental concern usually precedes formal identification and diagnosis of hearing impairment by 6 mo–1 yr. Table 627–2 presents guidelines for screening language development in young children, and Table 627–3 provides guidelines for identifying children with abnormal auditory behavior. Failure to fulfill these criteria should be reason for an audiologic evaluation.

Clinical Audiologic Evaluation.

Even the youngest infants can be evaluated for auditory function. When hearing impairment is suspected in a young child, reliable and valid estimates of auditory function can be obtained. Successful treatment strategies for hearing-impaired children rely on prompt identification and

TABLE 627-2 -- **Criteria for Referral for Audiologic Assessment**

Age (mo)	Referral Guidelines for Children with “Speech” Delay
12	No differentiated babbling or vocal imitation
18	No use of single words
24	Single-word vocabulary of = 10 words
30	Fewer than 100 words; no evidence of two-word combinations; unintelligible

36	Fewer than 200 words; no use of telegraphic sentences, clarity < 50%
48	Fewer than 600 words; no use of simple sentences; clarity = 80%

ongoing assessment to define the dimensions of auditory function. Cooperation among the pediatrician and those specializing in such areas as audiology, speech and language pathology, education, and child development is necessary to optimize auditory-verbal development. Therapy for hearing-impaired children includes considering (and often fitting) an amplification device; monitoring hearing and auditory skills, counseling parents and families, advising teachers, and dealing with public agencies.

AUDIOMETRY.

The technique of the audiologic evaluation varies as a function of the age or developmental level of the child, the reason for the evaluation, and the child's otologic condition or history. An audiogram provides the fundamental description of hearing sensitivity (Fig. 627–1). Hearing thresholds are assessed as a function of frequency using pure tones (sine waves) at octave intervals from 250–8,000?Hz. Earphones are typically used, and hearing is assessed independently for each ear. *Air-conducted* signals are presented through earphones (or loudspeakers) and are used to provide information about the sensitivity of the auditory system. These same test sounds can be delivered to the ear through an oscillator that is placed on the head, usually on the mastoid. Such signals are considered *bone-conducted* because the bones of the skull transmit vibrations as sound energy directly to the inner ear, essentially bypassing the outer and middle ears. In a normal ear, the air and bone conduction thresholds are the same; they are also the same in those with SNHL. In those with CHL, the air and bone conduction thresholds differ. This is called the *air-bone gap*; it indicates the amount of hearing loss attributable to dysfunction in the outer and/or middle ear. With mixed hearing loss, both the bone and air conduction thresholds are abnormal, and there is an air-bone gap.

SPEECH RECOGNITION THRESHOLD.

Another measure useful in describing auditory function is the speech recognition threshold (SRT), which is the lowest intensity level at which a score of approximately 50% correct is obtained on a task of recognizing spondee words. Spondee words are two-syllable words

TABLE 627-3 -- Guidelines for Referral of Children Suspected of Having Hearing Loss

Age (mo)	Normal Development
0–4	Should startle to loud sounds, quiet to mother's voice, momentarily cease activity when sound is presented at a conversational level
5–6	Should correctly localize to sound presented in a horizontal plane, begin to imitate sounds in own speech repertoire or at least reciprocally vocalize with an adult
7–12	Should correctly localize to sound presented in any plane Should respond to name, even when spoken quietly
13–15	Should point toward an unexpected sound or to familiar objects or persons when asked
16–18	Should follow simple directions without gestural or other visual cues; can be trained to reach toward an interesting toy at midline when a sound is presented
19–24	Should point to body parts when asked; by 21–24 mo, can be trained to perform play audiometry

From Matkin ND: Early recognition and referral of hearing-impaired children. Pediatr Rev 1984;6:151. Reproduced by permission of Pediatrics.

Figure 627-1 Audiogram showing bilateral conductive hearing loss.

or phrases that have equal stress on each syllable (baseball, hotdog, pancake). Listeners must be familiar with all the words for a valid test result to be obtained. The SRT should correspond to the average of pure-tone thresholds at 500, 1,000, and 2,000?Hz, the pure-tone average (PTA). The SRT is relevant as an indicator of a child's potential for development and use of speech and language; it also serves as a check of the validity of a test because children with nonorganic hearing loss (malingerers) may show a discrepancy between the PTA and SRT.

The basic battery of hearing tests concludes with an assessment of a child's ability to

understand monosyllabic words when presented at a comfortable listening level. Performance on such word intelligibility tests assists in the differential diagnosis of hearing impairment and provides a measure of how well a child performs when speech is presented at loudness levels similar to those encountered in the environment.

PLAY AUDIOMETRY.

Hearing testing is age-dependent. For children at or above the developmental level of a 5 or 6 yr old, conventional test methods can be used. For children 2½–5 yr old, play audiometry can be used. Responses in play audiometry are usually conditioned motor activities associated with a game, such as dropping blocks in a bucket, placing rings on a peg, or completing a puzzle. The technique can be used to obtain a reliable audiogram for a preschool child. For those who will not or cannot repeat words clearly for the SRT and word intelligibility tasks, pictures can be used with a pointing response.

VISUAL REINFORCEMENT AUDIOMETRY.

For those between the ages of about 6 mo and 2½ yr, visual reinforcement audiometry (VRA) is commonly used. In this technique, the child is observed for a head-turning response upon activation of an

---

animated (mechanical) toy reinforcer. If infants are properly conditioned, by giving sounds associated with the visual toy cue, VRA can provide reliable estimates of hearing sensitivity for tones and speech sounds. In most applications of VRA, sounds are presented by loudspeakers in a sound field, so no ear-specific information is obtained. Assessment of an infant is often designed to rule out hearing loss that would affect the development of speech and language. Normal sound field response levels of infants indicate sufficient hearing for this purpose despite the possibility of different hearing levels in the two ears.

BEHAVIORAL OBSERVATION AUDIOMETRY.

Used as a screening device for infants younger than 5 mo, behavioral observation audiometry (BOA) is limited to unconditioned, reflexive responses to complex (not frequency-specific) test sounds, such as noise, speech, or music presented using calibrated signals from a loudspeaker or uncalibrated noisemakers. Response levels can vary widely within and among infants and usually do not represent a reliable estimate of sensitivity.

Assessment of a child with suspected hearing loss is not complete until pure-tone hearing thresholds and SRTs (a reliable audiogram) have been obtained in each ear. BOA and VRA in sound-field testing give estimates of hearing responsivity in the better hearing ear.

ACOUSTIC IMMITTANCE TESTING.

This is a standard part of the clinical audiologic test battery and includes tympanometry. Acoustic immittance testing is a useful objective assessment technique that provides information about the status of the middle ear. Tympanometry can be performed in a physician's office and is helpful in the diagnosis and management of OM with effusion, a common cause of mild to moderate hearing loss in young children.

Tympanometry. This technique provides a graph of the ability of the middle ear to transmit sound energy (admittance, or compliance) or impede sound energy (impedance) as a function of air pressure in the external ear canal. Because most immittance test instruments measure acoustic admittance, the term *admittance* is used here. The principles apply to whatever units of measurement are used.

A probe is inserted into the entrance of the external ear canal so that an airtight seal is obtained. The probe varies air pressure, presents a tone, and measures sound pressure level in the ear canal through the probe assembly. The sound pressure measured in the ear canal relative to the known intensity of the probe signal is used to estimate the acoustic admittance of the ear canal and middle-ear system. Admittance can be expressed in a unit called a millimho (mmho) or as a volume of air (mL) with equivalent acoustic admittance. The test is performed so that an estimate of the volume of air enclosed between the probe tip and TM can be made. The acoustic admittance of this volume of air is deducted from the overall admittance measure to obtain a measure of the admittance of the middle-ear system alone. Estimating ear canal volume also has a diagnostic benefit because an abnormally large value is consistent with the presence of an opening in the TM (perforation or tube).

With elimination of the admittance of the air mass in the external auditory canal, it is assumed that the remaining admittance measure accurately reflects the admittance of the entire middle-ear system. Its value is largely controlled by the dynamics of the TM. Abnormalities of the TM can dictate the shape of tympanograms and thus obscure abnormalities medial to the TM. In addition, the frequency of the probe tone, the speed and direction of the air pressure change, and the air pressure at which the tympanogram is initiated can all influence the outcome.

When air pressure in the ear canal is equal to that in the middle ear, the middle-ear system is functioning optimally. Therefore, the ear canal pressure at which there is the greatest flow of energy (admittance) should be a reasonable estimate of the air pressure in the middle-ear space. This pressure is determined by finding the admittance maximum (peak) on the tympanogram and obtaining its value on the *x*-axis. The value on the *y*-axis at the tympanogram peak is an estimate of peak admittance. This peak measure is sometimes referred to as static acoustic admittance, even though it is estimated from a dynamic measure (Fig. 630–6 *A*). Table 627–4 presents the norms for peak admittance based on admittance tympanometry for normal adults and children.

Tympanometry in Otitis Media with Effusion. Children with OME often have reduced peak admittance or high negative tympanometric peak pressures (Fig.

630–6 *C*); however, in the diagnosis of effusion, the tympanometric measure with the greatest sensitivity and specificity is the tympanogram shape rather than its peak pressure or admittance. This shape is sometimes referred to as the tympanometric gradient or width; it measures the degree of roundness or "peakedness" of the tympanogram. The more rounded the peak (or "flat" in an absent peak), the higher is the probability that an effusion is present (Fig. 630–6 *B*). It is important to know which instrument is used, as some compute gradient automatically but others do not.

Acoustic Reflex Test (ART). This is also part of the immittance test battery. With a properly functioning middle-ear system, admittance at the TM changes on activation of the stapedius and tensor tympani muscles. In healthy ears, the stapedial reflex occurs after exposure to loud sounds. Admittance instruments are designed to present reflex activating signals (pure tones of various frequencies or noise), either to the same or the contralateral ear, while monitoring admittance. Very small admittance changes that are time locked to presentations of the signal are considered to be a result of middle-ear muscle reflexes. Absence of admittance changes can occur when the hearing loss is sufficient to prevent the signal from reaching the loudness level necessary to elicit the reflex or when a middle-ear condition affects the ability to monitor a small admittance change. Reflexes are usually absent in those with CHL due to the presence of an abnormal transfer system; thus, the ART is useful in the differential diagnosis of hearing impairment. ART also is used in the assessment of SNHL and the integrity of the neurologic components of the reflex arc, including cranial nerves VII and VIII.

AUDITORY BRAINSTEM RESPONSE.

The ABR test is used for newborn hearing screening, to confirm hearing loss in young children, to obtain ear-specific information in young children, and to test children who cannot, for whatever reason, cooperate with behavioral test methods. It is also important in the diagnosis of auditory dysfunction and of disorders of the auditory nervous system. The ABR test is a far-field recording of minute electrical discharges from numerous neurons.

TABLE 627-4 -- **Norms for Peak (Static) Admittance (in mL) Using a 226-Hz Probe Tone for Children and Adults**

		Speed of Air Pressure Sweep	
		=50 daPa/sec*	***200 daPa/sec*†**
Children (3–5 yr)	Lower limit	0.30	0.36
	Median	0.55	0.61
	Upper limit	0.90	1.06
Adults	Lower limit	0.56	0.27
	Median	0.85	0.72
	Upper limit	1.36	1.38

* *Ear canal volume measurement based on admittance at lowest tail of tympanogram.*
† *Ear canal measurement based on admittance at lowest tail of tympanogram for children and at +200 daPa for adults. daPa = decaPascals.*

The stimulus, therefore, must be able to cause simultaneous discharge of the large numbers of neurons involved. Stimuli with very rapid onset, such as clicks or tone bursts, must be used. Unfortunately, the rapid onset required to create a measurable ABR also causes energy to be spread in the frequency domain, reducing the frequency-specificity of the response.

The ABR result is not affected by sedation or general anesthesia. Infants and children from about 4 mo-4 yr of age are routinely sedated to minimize electrical interference caused by muscle activity during testing. The ABR also can be performed in the operating room when a child is anesthetized for another procedure.

The ABR is recorded as 5–7 waves. Waves I, III, and V can be obtained consistently in all age groups; Waves II and IV appear less consistently. The latency of each wave (time of occurrence of the wave peak after stimulus onset) increases, and the amplitude decreases with reductions in stimulus intensity or loudness; latency also decreases with increasing age, with the earliest waves reaching mature latency values earlier in life than the later waves.

The ABR test has two major uses in a pediatric setting. As an audiometric test, it provides information on the ability of the peripheral auditory system to transmit information to the auditory nerve and beyond. It is used also in the differential diagnosis or monitoring of central nervous system pathology. For audiometry, the goal is to find the minimum stimulus intensity that yields an observable ABR. Plotting latency versus intensity for various waves also aids in the differential diagnosis of hearing impairment. A major advantage of auditory assessment using the ABR test is that ear-specific threshold estimates can be obtained on infants or difficult-to-test patients. ABR thresholds using click stimuli correlate best with behavioral hearing thresholds in the higher frequencies (1,000–4,000?Hz); responsivity in the low frequencies requires different stimuli (tone bursts or filtered clicks) or the use of masking, neither of which isolates the low-frequency region of the cochlea in all cases, and this may affect interpretation.

The ABR test does not assess "hearing." It reflects auditory neuronal electric

responses that can be correlated to behavioral hearing thresholds, but a normal ABR result only suggests that the auditory system, up to the level of the midbrain, is responsive to the stimulus used. Conversely, a failure to elicit an ABR indicates an impairment of the system's synchronous response but does not necessarily mean that there is no “hearing.” The behavioral response to sound is sometimes normal when no ABR can be elicited, such as in neurologic demyelinating disease. The ABR test may be used to infer whether and at what level of the auditory system an impairment exists.

Hearing losses that are sudden, progressive, or unilateral are indications for ABR testing. Although it is believed that the different waves of the ABR reflect activity in increasingly rostral levels of the auditory system, the neural generators of the response have not been precisely determined. Each ABR wave beyond the earliest waves is probably the result of neural firing at many levels of the system, and each level of the system probably contributes to several ABR waves. High-intensity click stimuli are used for the neurologic application. The morphology of the response and wave and interwave latencies are examined in respect to age-appropriate forms. Delayed or missing waves in the ABR result often have diagnostic significance.

The ABR and other electrical responses are extremely complex and difficult to interpret. A number of factors, including instrumentation design and settings, environment, degree and configuration of hearing loss, and patient characteristics, may influence the quality of the recording. Therefore, testing and interpretation of electrophysiologic activity as it possibly relates to hearing should be carried out by trained audiologists to avoid the risk that unreliable or erroneous conclusions will affect a patient's care.

OTOACOUSTIC EMISSIONS.

During normal hearing, OAEs originate from the hair cells in the cochlea and are detected by sensitive amplifying processes. They travel from the cochlea through the middle ear to the external auditory canal, where they can be detected using miniature microphones. Transient evoked OAEs (TEOAEs) may be used to check the integrity of the cochlea. In the neonatal period, detection of OAEs can be accomplished during natural sleep, and TEOAEs can be used as screening tests in infants and children for hearing at the 30?dB level of hearing loss. They are less time consuming and elaborate than ABR and are more sensitive than behavioral tests in young children. TEOAEs are reduced or absent owing to various dysfunctions in the middle and inner ears. They are absent in patients with more than 30?dB of hearing loss and are not used to determine hearing threshold; rather, they provide a screen for whether hearing is present at greater than 30–40?dB. Diseases such as OM or congenitally abnormal middle ear structures reduce the transfer of TEOAEs and may incorrectly indicate a cochlear hearing disorder. If a hearing loss is suspected by the absence of OAE, the ears should be examined for evidence of pathology, and then ABR testing should be used for confirmation and identification of the type, degree, and laterality of hearing loss.

ACOUSTIC REFLECTOMETRY.

In this test, a hand-held instrument is placed next to the opening of a child's ear canal and 80-dB sound is delivered that varies in frequency from 2,000–4,500?Hz in a 100-msec period. The instrument measures the total level of reflected and transmitted sound. Some physicians have found this device useful to help gauge the presence or absence of middle-ear fluid, and a commercial version is being marketed to parents as a way to monitor ear fluid. The instrument does not provide any information about hearing; if the presence of chronic fluid is suggested, audiometric evaluation should be obtained.

Treatment.

Once a hearing loss is identified, a full developmental and speech and language evaluation is needed. Parental counseling and involvement is required in all stages of the evaluation and treatment or rehabilitation. A conductive hearing loss can often be corrected through treatment of a middle-ear effusion (ear tube placement) or surgical correction of the abnormal sound-conducting mechanism. Children with SNHL should be evaluated for possible hearing aid use by a pediatric audiologist. Hearing aids may be fitted for children as young as 2 mo. Compelling evidence from the hearing screening program in Colorado shows that identification and amplification before age 6 mo makes a very significant difference in the speech and language abilities of affected children, compared with those cases identified and amplified after the age of 6 mo. In these children, repeat audiologic testing is needed to reliably identify the degree of hearing loss and to fine-tune the use of hearing aids.

The best educational approach to children with significant hearing loss is a subject of ongoing controversy. Because we live in a predominantly speaking world, some have advocated a pure auditory and oral approach to hearing therapy. However, because affected children often are slow to develop communication skills, many advocate a total communication approach; depending on the individual child's needs, this technique uses a mixture of sign language, lip-reading, hearing aids, and speech. The appropriate program for each child depends on the patient, family, and available resources.

The use of a surgically placed cochlear implant in children with severe to profound hearing loss and little or no help from conventional hearing aids improves the development of communication skills. The device is currently approved for use in the United States in children age 2 yr and older. However, because of a possible increased risk of pneumococcal meningitis, children with implants should receive age-appropriate vaccination against pneumococcal disease. Some members of the hearing-impaired

community have objected to its use in children who have no decision in the matter; they argue that the child may develop excellent communication abilities using more conventional therapeutic strategies.

Chapter 628 - Congenital Malformations

Joseph Haddad Jr.

The external and middle ears, derived from the 1st and 2nd branchial arches and grooves, grow throughout puberty, but the inner ear, which develops from the otocyst, reaches adult size and shape by mid-fetal development. The ossicles are derived from the 1st and 2nd arches (malleus and incus), and the stapes arises from the 2nd arch and the otic capsule. The ossicles achieve adult size and shape by the 15th wk of gestation for the malleus and incus and 18th wk for the stapes. Although the pinna, ear canal, and tympanic membrane (TM) continue to grow after birth, congenital abnormalities of these structures develop during the 1st half of gestation. Malformed external and middle ears may be associated with serious renal anomalies, mandibulofacial dysostosis, hemifacial microsomia, and other craniofacial malformations. Facial nerve abnormalities may be associated with any of the congenital abnormalities of the ear and temporal bone. Malformations of the external and middle ears may also be associated with abnormalities of the inner ear and both conductive (CHL) and sensorineural hearing loss (SNHL). Any child born with an abnormality of the pinna, external auditory canal, or TM should have a complete audiologic evaluation in the neonatal period.

Pinna Malformations.

Severe malformations of the external ear are rare, but minor deformities are common. Isolated abnormalities of the external ear occur in approximately 1% of children. A *pit*-like depression just in front of the helix and above the tragus may represent a cyst or an epidermis-lined fistulous tract; these are common, with an incidence of approximately 8/1,000 children, and may be unilateral or bilateral and familial. The pits only require surgical removal if there is recurrent infection. Accessory *skin tags*, with an incidence of 1–2/1,000, can be removed for cosmetic reasons by simple ligation if they are attached by a narrow pedicle; if the pedicle is broad-based or contains cartilage, the defect should be corrected surgically. An unusually prominent or *“lop” ear* results from lack of bending of the cartilage that creates the antihelix. It may be improved cosmetically in the neonatal period by applying a firm framework (sometimes soldering wire is used) attached by Steri-Strips to the pinna and worn continuously for weeks to months. Otoplasty for cosmetic correction can be considered in children age 5 yr or older; by this time, the pinna has reached about 80% of its adult size.

The term *microtia* may indicate subtle abnormalities of the size, shape, and location of the pinna and ear canal, or major abnormalities with only small nubbins of skin and cartilage and absence of the ear canal opening; *anotia* indicates complete absence of the pinna and ear canal. Microtic ears are often more anterior and inferior in placement than normal auricles; the facial nerve location and function may be abnormal. Surgery to correct microtia is considered for both cosmetic and functional reasons; children who have some pinna can wear regular glasses, a hearing aid, and earrings and feel more normal in appearance. If the microtia is severe, some patients may opt for creation and attachment of a prosthetic ear, which cosmetically closely resembles a real ear. Surgery to correct severe microtia may involve a multistage procedure including carving and transplantation of autogenous cartilage rib grafts, and local soft tissue flaps. Cosmetic reconstruction of the auricle is customarily done between ages 5 and 7 and is performed before canal atresia repair in the child deemed appropriate for this surgery (see later discussion).

Congenital External Auditory Canal Stenosis/Atresia.

Stenosis or atresia of the ear canal often occurs in association with malformation of the auricle and middle ear; minor stenoses may occur in isolation. In some genetic syndromes, such as trisomy 21, ear canals are narrow. Audiometric evaluation of these children should be undertaken as early in life as possible. Most children with significant CHL secondary to bilateral atresia wear bone conduction hearing aids for the first several years of life. Diagnosis, evaluation, and surgical planning are often aided by computed tomography (CT), and sometimes magnetic resonance imaging (MRI), of the temporal bone. Mild cases of ear canal stenosis do not require surgical enlargement unless the patient develops chronic external otitis or severe cerumen impaction that affects hearing.

Reconstructive ear canal and middle-ear surgery for atresia is generally considered for patients older than 5 yr with bilateral deformities resulting in a significant CHL. The aim of reconstructive surgery is to improve hearing to a point where the child may not need a hearing aid or to provide an ear canal and pinna so that the child can derive improved benefit from an air conduction hearing aid. CT evidence of an adequate middle-ear cleft and mastoid is required to perform the surgery; the position of the facial nerve, which is frequently in an abnormal location in these children, also needs to be considered. The use of bone-anchored hearing aids may provide an option for some of these children when they are older.

Congenital Middle-Ear Malformations.

Children may have congenital abnormalities of the middle ear as an isolated defect or in association with other abnormalities of the temporal bone, especially the ear canal and pinna, or as part of a syndrome. Affected children usually have CHL but may have mixed CHL and SNHL. Most malformations involve the ossicles, with the incus being the most commonly affected. Other less common abnormalities of the middle ear include persistent stapedial artery, high-riding jugular bulb, and abnormalities of the shape and volume of the aerated portion of the middle ear and mastoid; all present problems for a surgeon. Depending on the type of abnormality and the presence of other anomalies, surgery may be considered to improve hearing.

Congenital Inner Ear Malformations.

Congenital inner ear malformations have been identified and classified as a result of improvements in imaging modalities, especially CT and MRI. As many as 20% of children with SNHL may have anatomic abnormalities identified on CT or MRI. Congenital malformations of the inner ear are usually associated with SNHL of various degrees from mild to profound. These malformations may occur as isolated anomalies or in association with other syndromes, genetic abnormalities, or structural abnormalities of the head and neck. Enlarged vestibular aqueducts have been identified on imaging studies in association with SNHL; although no therapy exists for this condition, it may be associated with progressive SNHL in some children, and, therefore, diagnosis may have some prognostic value.

Congenital perilymphatic fistula (PLF) of the oval or round window membrane may present as a rapid-onset, fluctuating, or progressive SNHL with or without vertigo and is often associated with congenital inner ear abnormalities. Middle ear exploration may need to be performed to confirm this diagnosis, inasmuch as no reliable nonoperative diagnostic test exists. PLFs may need to be repaired to prevent possible spread of infection from the middle ear to the labyrinth, to stabilize hearing loss, and to improve vertigo when present.

Congenital Cholesteatoma.

A congenital cholesteatoma usually appears as a white, round, cystlike structure medial to an intact TM; cysts are most commonly seen in the anterior-superior portion of the middle ear, although they can present in other locations and within the TM or in the skin of the ear canal. Affected children frequently have no prior history of otitis media (OM). A common theory for pathogenesis is that the cyst derives from a congenital rest of epithelial tissue that persists beyond 33 wk of gestation, when it would ordinarily disappear. Other theories include squamous metaplasia of the middle ear, entrance of squamous epithelium through a nonintact eardrum into the middle ear, ectodermal implants between the 1st and 2nd branchial arch remnants, and residual amniotic fluid squamous debris. Congenital or acquired cholesteatoma should be suspected when deep retraction pockets, keratin debris, chronic drainage, aural granulation tissue, or a mass behind or involving the TM is present. Besides acting as a benign tumor causing local bone destruction, the keratinaceous debris of a cholesteatoma is a good culture medium and may become a focus of infection for chronic OM. Complications include ossicular erosion with hearing loss, bone erosion into the inner ear with dizziness, or exposure of the dura with consequent meningitis or a brain abscess. Cholesteatoma should be removed surgically after CT scan and hearing evaluation, and appropriate antibiotic therapy.

Chapter 629 - Diseases of the External Ear

Joseph Haddad Jr.

EXTERNAL OTITIS (OTITIS EXTERNA)

In an infant, the outer two thirds of the ear canal is cartilaginous and the inner third is bony, whereas in an older child and adult only the outer third is cartilaginous. In the bony portion the epithelium is thinner than in the cartilaginous portion, there is no subcutaneous tissue, and epithelium is tightly applied to the underlying periosteum; hair follicles, sebaceous glands, and apocrine glands are scarce or absent. The skin in the cartilaginous area has well-developed dermis and subcutaneous tissue and contains hair follicles, sebaceous glands, and apocrine glands. The highly viscid secretions of the sebaceous glands and the watery, pigmented secretions of the apocrine glands in the outer portion of the canal combine with exfoliated surface cells of the skin to form a protective, waxy, water-repellent coating (cerumen).

The normal flora of the external canal consists mainly of aerobic bacteria and includes coagulase-negative staphylococci, *Corynebacterium* (diphtheroids), *Micrococcus* species, and occasionally *Staphylococcus aureus*, viridans streptococci, and *Pseudomonas aeruginosa*. Excessive wetness (swimming, bathing, or increased environmental humidity), dryness (dry canal skin and lack of cerumen), and the presence of other skin pathology (previous infection, eczema or other forms of dermatitis) and trauma (digital or foreign body) make the skin of the canal vulnerable to infection by the normal flora or exogenous bacteria.

Etiology.

External otitis (also called “swimmer's ear,” although it can occur without swimming) is most commonly caused by *P. aeruginosa*, but *S. aureus*, *Enterobacter aerogenes*, *Proteus mirabilis*, *Klebsiella pneumoniae*, streptococci, coagulase-negative staphylococci, diphtheroids, and fungi such as *Candida* and *Aspergillus* may also be isolated. External otitis results from chronic irritation and maceration from excessive moisture in the canal; loss of protective cerumen may play a role, but cerumen impaction with trapping of water can also cause infection. Inflammation of the ear canal due to herpesvirus, varicella-zoster, other skin exanthems, and eczema may also predispose to external otitis.

Clinical Manifestations.

The predominant symptom is ear pain, often severe, accentuated by manipulation of the pinna or by pressure on the tragus. The severity of the pain and tenderness may be disproportionate to the degree of inflammation, because the skin of the external ear canal is closely adherent to the underlying perichondrium and periosteum. Itching is a frequent precursor of pain and is usually characteristic of chronic inflammation of the canal or resolving acute otitis externa. Conductive hearing loss may result from edema of the skin and tympanic membrane (TM), serous or purulent secretions, or the canal skin thickening associated with chronic external otitis.

Edema of the ear canal, erythema, and thick, clumpy otorrhea are prominent signs of the acute disease. The cerumen is usually white and soft in consistency, as opposed to its usual yellow color and firmer consistency. The canal frequently is so tender and swollen that the entire ear canal and TM cannot be adequately visualized, and complete otoscopic examination may be delayed until the acute swelling subsides. If the TM can be visualized, it may appear either normal or opaque; TM mobility may be normal or, if thickened, reduced in response to positive and negative pressure.

Other physical findings may include palpable and tender lymph nodes in the periauricular region, and erythema and swelling of the pinna and periauricular skin. Rarely, facial paralysis, other cranial nerve abnormalities, vertigo, and/or sensorineural hearing loss are present. If these occur, *necrotizing (malignant) external otitis* is probable. This invasive infection of the temporal bone and skull base requires immediate culture, intravenous antibiotics, and imaging studies to evaluate the extent of the disease. Surgical intervention to obtain cultures or debride devitalized tissue may be necessary. *P. aeruginosa* is the most common causative organism of necrotizing otitis externa; fortunately, this disease is rare in children and is seen only in association with immunocompromise or severe malnourishment.

Diagnosis.

Diffuse external otitis may be confused with furunculosis, otitis media (OM), and mastoiditis. Furuncles occur in the lateral hair-bearing part of the ear canal; furunculosis usually causes a localized swelling of the canal limited to one quadrant, whereas external otitis is associated with concentric swelling and involves the entire ear canal. In OM, the TM may be perforated, severely retracted, or bulging and immobile; hearing is usually impaired. If the middle ear is draining through a perforated TM or tympanostomy tube, secondary external otitis may occur; if the TM is not visible owing to drainage or ear canal swelling, it may be difficult to distinguish acute OM with drainage from an acute external otitis. Pain on manipulation of the auricle and significant lymphadenitis are not common features of OM, and these findings assist in the differential diagnosis. In some patients with external otitis, the periauricular edema is so extensive that the auricle is pushed forward, creating a condition that may be confused with acute mastoiditis and a subperiosteal abscess; in mastoiditis, the postauricular fold is obliterated, whereas in external otitis the fold is usually better preserved. In acute mastoiditis, a history of OM and hearing loss is usual; tenderness is noted over the mastoid and not on movement of the auricle; and otoscopic examination may show sagging of the posterior canal wall.

Treatment.

Topical otic preparations containing neomycin (active against gram-positive organisms and some gram-negative organisms, notably *Proteus* species) with either colistin or polymyxin

---

(active against gram-negative bacilli, notably *Pseudomonas* species) and corticosteroids are effective in treating most forms of acute external otitis. Newer preparations of ear drops are available that do not contain potentially ototoxic antibiotics. If canal edema is marked, a wick should be inserted into the ear canal and the topical drops applied to the wick 3 times a day for 24–48?hr; the wick can be removed after this time and topical antibiotic is continued. After 2 or 3 days of this treatment, the edema of the ear canal is usually markedly improved and the ear canal and TM are better seen. When the pain is severe, oral analgesics (ibuprofen, codeine) may be necessary.

As the inflammatory process subsides, cleaning the canal with a suction or cotton-tipped applicator to remove the debris enhances the effectiveness of the topical medications. In subacute and chronic infections, periodic cleansing of the canal is essential. In severe, acute external otitis associated with fever and lymphadenitis, oral or parenteral antibiotics may be indicated; an ear canal culture should be done, and empiric antibiotic treatment can then be modified if necessary, based on susceptibility of the organism cultured. A fungal infection (otomycosis) of the external auditory canal is characterized by fluffy white debris, sometimes with black spores seen; treatment includes cleaning and application of antifungal solutions such as clotrimazole or nystatin; other antifungal agents include *m*-cresyl acetate 25%, gentian violet 2%, and thimerosal 1:1,000.

Prevention.

Preventing external otitis may be necessary for individuals susceptible to recurrences, especially children who swim. The most effective prophylaxis is instillation of dilute alcohol or acetic acid (2%) immediately after swimming or bathing. During an acute episode of otitis externa, patients should not swim and the ears should be protected from water during bathing.

OTHER DISEASES OF THE EXTERNAL EAR

Furunculosis.

This is caused by *S. aureus* and affects only the hair-containing outer third of the ear canal. Mild forms are treated with oral antibiotics active against *S. aureus*; if an abscess develops, incision and drainage may be necessary.

Acute Cellulitis.

Acute cellulitis of the auricle and external auditory canal is usually caused by group A *Streptococcus* and occasionally by *S. aureus*. The skin is red, hot, and indurated, without a sharply defined border. Fever may be present with little or no exudate in the canal. Parenteral administration of penicillin G or a penicillinase-resistant penicillin is the therapy of choice.

Perichondritis/Chondritis.

Perichondritis is an infection involving the skin and perichondrium of the auricular cartilage; extension of infection to the cartilage is termed *chondritis*. The ear canal, especially the lateral aspect, may also be involved. Early perichondritis may be difficult to differentiate from cellulitis because both are characterized by skin that is red, edematous, and tender. The main cause of perichondritis/chondritis and cellulitis is trauma (accidental or iatrogenic, laceration or contusion), including ear piercing (especially through the cartilage). The most commonly isolated organism in perichondritis/ chondritis is *P. aeruginosa*, although other gram-negative and occasionally gram-positive organisms may be found. Treatment involves systemic, often parenteral, antibiotics; surgery to drain an abscess or remove nonviable skin or cartilage may also be needed. Removal of all ear jewelry is mandatory in the presence of infection.

Dermatoses.

Various dermatoses (seborrheic, contact, infectious eczematoid, or neurodermatoid) are common causes of inflammation of the external canal; acute external otitis in these conditions is caused by scratching and the introduction of infecting organisms.

Seborrheic dermatitis is characterized by greasy scales that flake and crumble as they are detached from the epidermis; associated changes in the scalp, forehead, cheeks, brow, postauricular areas, and concha are usual.

Contact dermatitis of the auricle or canal may be caused by earrings, or by topical otic medications such as neomycin, which may produce erythema, vesiculation, edema, and weeping. Poison ivy, oak, and sumac may also produce contact dermatitis. Hair care products have been implicated in sensitive individuals.

Infectious eczematoid dermatitis is caused by a purulent infection of the external canal, middle ear, or mastoid; the purulent drainage infects the skin of the canal, auricle, or both. The lesion is weeping, erythematous, or crusted.

Atopic dermatitis occurs in children with a familial or personal history of allergy; the auricle, particularly the postauricular fold, becomes thickened, scaly, and excoriated.

Neurodermatitis is recognized by the intense itching and erythematous, thickened epidermis localized to the concha and orifice of the meatus.

Treatment of these dermatoses depends on the type but should include application of an appropriate topical medication, elimination of the source of infection or contact when identified, and management of any underlying dermatologic problem. In addition to topical antibiotics (or antifungals), topical steroids are helpful if contact dermatitis, atopic dermatitis, or eczematoid dermatitis is suspected.

Herpes Simplex.

This may appear as vesicles on the auricle and lips. The lesions eventually become encrusted and dry and may be confused with impetigo. Topical application of a 10% solution of carbamide peroxide in anhydrous glycerol is symptomatically helpful. The **Ramsay Hunt syndrome** (herpes zoster oticus) may present with herpes vesicles in the ear canal and on the pinna and with facial paralysis and pain. Other cranial nerves may be affected as well, especially the 8th nerve. The current recommended treatment of herpes zoster oticus includes systemic antiviral agents, such as acyclovir, and corticosteroids. As many as 50% of patients with Ramsay Hunt syndrome do not have complete recovery of their facial nerve function.

Bullous Myringitis.

Commonly associated with an acute upper respiratory tract infection, this condition presents as an ear infection with more severe pain than usual. On examination, hemorrhagic or serous blisters (bullas) may be seen on the TM. The disease is sometimes difficult to differentiate from acute OM, because a large bulla may be confused with a bulging TM. The organisms involved are the same as those causing acute OM, including both bacteria and viruses. Treatment consists of empiric antibiotic therapy and pain medications; in addition to ibuprofen or codeine for severe pain, a topical anesthetic eardrop may also provide some relief. Incision of the bullae, although not necessary, promptly relieves the pain.

Exostoses and Osteomas.

Exostoses represent benign hyperplasia of the perichondrium and underlying bone of the external ear canal and are frequently found in people who swim often in cold water. Exostoses are broad based, often multiple and bilateral. Osteomas are benign bony growths in the ear canal; their cause is uncertain. They are usually solitary and attached by a narrow pedicle to the tympanosquamous or tympanomastoid suture line. Both are more common in males; exostoses are more common than osteomas. Surgical treatment is recommended when large masses cause cerumen impaction, ear canal obstruction, or hearing loss.

Chapter 630 - Otitis Media

Jack L. Paradise

General Considerations.

Next to the common cold, otitis media is the most commonly diagnosed and probably the most prevalent illness of children in the United States, with peak incidence and prevalence from 6–20 mo of age. Otitis media figures importantly in the differential diagnosis of fever, is the most common reason for prescribing antimicrobial drugs to children, and often serves as the sole or the main basis for undertaking the most frequently performed operations in infants and young children, namely, myringotomy with insertion of tympanostomy tubes, adenoidectomy, and adenotonsillectomy. An important characteristic of otitis media is its propensity to become chronic and recur. Generally, the earlier in life a child experiences a first episode, the greater the degree of subsequent difficulty as measured by frequency of recurrence, severity, and persistence of middle-ear effusion.

Otitis media challenges the clinician in a number of ways. Accurate diagnosis in infants and young children is often difficult. Symptoms may be absent or inapparent, especially in early infancy and in chronic stages of the disease. The eardrum may be obscured by cerumen, removal of which may be arduous and time-consuming. Abnormalities of the eardrum may be subtle and difficult to appreciate. In the face of these difficulties, both underdiagnosis and overdiagnosis occur commonly. Once a diagnosis of otitis media has been established—whatever the type of the disease—its significance to the child's health and well-being and its optimal method of management remain open to question and the subjects of continuing controversy. Underlying the uncertainties are incomplete knowledge and lack of consensus among authorities concerning benefit-risk ratios of available medical and surgical treatments and the likelihood of long-term consequences of otitis media. These include possible direct effects in the form of middle-ear damage, inner-ear damage, and hearing impairment, and possible indirect effects in the form of lasting impairments of speech, language, cognitive, and psychosocial development. Whether developmental effects actually occur remains the subject of ongoing investigation.

The spectrum of middle-ear disease subsumed under the term otitis media has two main components: infection, which is termed **suppurative or acute otitis media (AOM)**; and usually noninfective inflammation accompanied by effusion, termed **nonsuppurative or secretory otitis media,** or **otitis media with effusion (OME)**. These two main types of otitis media are interrelated: Infection usually is succeeded by residual, noninfective inflammation and effusion that, in turn, predispose children to recurrent infection. In one study, infants monitored closely during the first year of life commonly developed OME de novo, often followed by the development of AOM. These findings suggest that, most commonly, OME may be the form of otitis media that young infants first develop. Middle-ear effusion (MEE) is a feature both of AOM and of OME, and, in both conditions, is an expression of the underlying middle-ear mucosal inflammation. In children with otitis media, mucosal inflammation is generally also present in the mastoid air cells, which are in continuity with the middle-ear cavity.

Otitis media is accompanied by a variable degree of conductive hearing loss ranging from none to as much as 50 decibels hearing level (dB HL). Losses of 21–30?dB HL are usual. Although most individual episodes of otitis media subside within several weeks, middle-ear effusion persists for 3 mo or longer in approximately 10–25% of cases.

Epidemiology.

Many studies of the epidemiology of otitis media have been conducted, varying widely in design, methodology, outcome measures, scope, and generalizability. Their findings also have varied. The differences in findings may have been attributable to population or secular differences, or to differences in the intensity of surveillance, in the accuracy of disease detection, or to combinations of these factors. Factors known or believed to affect the occurrence of otitis media include age, sex, race, genetic background, socioeconomic status, type of milk used in infant feeding, degree of exposure to tobacco smoke, degree of exposure to other children, presence or absence of respiratory allergy, and season of the year. Children with certain types of congenital craniofacial anomalies are particularly prone to otitis media.

AGE.

Most prospective studies of the prevalence of otitis media in infants have involved those from families of low socioeconomic status largely or exclusively. In these studies, one or more episodes of otitis media reportedly developed in 61–73% of infants by the age of 6 mo, in 77–85% by 1 yr, and in 77–99% by 2 yr; the median cumulative proportions of days with MEE ranged from 12–27% during the first year of life and from 15–18% during the second year of life. Reported rates in infants from middle-class families have been somewhat lower: one or more episodes of otitis media in 36–46% by the age of 6 mo, 63–77% by 1 yr, and 66–90% by 2 yr. The median cumulative proportions of days with MEE in these infants ranged from 5% to 15% during the first year of life and from 6% to 11% during the second year of life. Across groups, rates were highest during 6–20 mo of age. After the age of 2 yr, the incidence and prevalence of otitis media decline progressively, although the disease remains relatively common into the early school-age years. Possible reasons for the

higher rates in infants and younger children include less well-developed immunologic defenses, more abundant nasopharyngeal lymphoid tissue, less favorable eustachian tubal factors involving both the structure and function of the tube, and greater proportions of time spent in the horizontal position.

SEX.

Although some studies have found no sex-related differences in the occurrence of otitis media, other, more convincing studies have found the incidence greater in boys than in girls. In a large Pittsburgh child development/otitis media study involving close monitoring in a sociodemographically diverse population, male infants consistently had higher mean cumulative proportions of days with MEE than female infants, even after controlling for confounding variables, but the differences were not large. Supporting a greater predilection for the disease in boys, and also suggesting greater severity in boys, are the facts that boys have predominated in most reported studies of the treatment of otitis media, and, compared with girls, consistently had higher rates of operations aimed at relieving the effects or reducing the occurrence of otitis media, namely, tympanostomy tube insertion, tympanoplasty, and adenoidectomy.

RACE.

Otitis media is especially prevalent and severe among Native American, Inuit, and Indigenous Australian children. Studies comparing the occurrence of otitis media in white children and black children have given conflicting results: Most of the studies have reported higher rates in white children. However, in the Pittsburgh study, at the practice sites that included substantial numbers of both black infants and white infants, the cumulative proportion of days with MEE during the first year of life was higher in black infants; during the second year of life the values in black and in white infants were identical. Overall, findings suggesting race-based differences in occurrence rates seem most likely attributable to differences in socioeconomic status and related factors, in access to or utilization of care, in intensity of surveillance or accuracy of diagnosis, or to combinations of these factors.

GENETIC BACKGROUND.

That middle-ear disease tends to “run in families” is a commonplace observation, and a number of studies have suggested that otitis media has a heritable component. The strongest supporting evidence to date is provided

by the finding that the degree of concordance for the occurrence of otitis media is much greater among monozygotic than among dizygotic twins.

SOCIOECONOMIC STATUS.

Poverty has long been considered an important contributing factor to both the development and the severity of otitis media. Although study results in the past have been divided on whether associations exist, recent evidence suggests strongly that low socioeconomic status is one of the most important, if not the most important, identifiable risk factor for the disease. Various component elements contributing to this relationship can be surmised to include crowding, limited hygienic facilities, suboptimal nutritional status, limited access to medical care, and limited resources for complying with prescribed medical regimens.

BREAST MILK VS FORMULA FEEDING.

Most studies examining this question have found a protective effect of breast milk feeding against otitis media. The effect is probably limited at best, but may be greater in socioeconomically disadvantaged than in more advantaged children. That the protective effect is attributable to the milk itself rather than to the mechanics of breastfeeding was shown in a study of infants with cleft palate to whom all feeding—whether of breast milk or formula—was delivered via an artificial, compressible nurser.

EXPOSURE TO TOBACCO SMOKE.

A positive relation between the occurrence of otitis media and household exposure to tobacco smoke has been found in some studies but not others. In these studies generally, measures used to estimate the degree of exposure have been problematic. Additionally, because household smoking correlates inversely with socioeconomic status, possible confounding by socioeconomic factors further complicates valid assessment of risk. Despite the uncertainty, it seems prudent at present to include exposure to tobacco smoke on the list of accepted risk factors.

EXPOSURE TO OTHER CHILDREN.

Many studies have established that a strong, positive relationship exists between the occurrence of otitis media and the extent of repeated exposure to other children—measured mainly by the number of other children involved—whether at home or in out-of-home group daycare. Together, but independently, family socioeconomic status and the extent of exposure to other children appear to constitute the two most important identifiable risk factors for developing otitis media.

SEASON.

In temperate climates, in keeping with the pattern of occurrence of upper respiratory tract infections in general, highest rates of occurrence of otitis media are observed during cold weather months and lowest rates during the heat of summer.

CONGENITAL ANOMALIES.

Otitis media is virtually universal among infants with unrepaired palatal clefts, and is also highly prevalent among children with submucous cleft palate, other craniofacial anomalies, and Down syndrome. The presence of submucous cleft palate should be suspected in children with hypernasal speech, a bifid uvula, or a history of nasal regurgitation during feeding.

OTHER FACTORS.

A reported study suggesting that restricting pacifier use results in a reduction in the occurrence of otitis media cannot be considered conclusive. Neither maternal age nor birthweight nor season of birth appears to influence the occurrence of otitis media once other demographic factors are taken into account.

Etiology

ACUTE OTITIS MEDIA.

Pathogenic bacteria can be isolated from middle-ear exudate in approximately 65–75% of cases of well-documented AOM; in the remaining cases bacterial culture shows either no growth or the presence of organisms generally considered nonpathogenic. Three pathogens predominate: *Streptococcus pneumoniae* is found in approximately 40% of cases, nontypable *Haemophilus influenzae* in approximately 25–30%, and *Moraxella catarrhalis* in approximately 10–15%. Other pathogens that, together, account for approximately 5% of cases include group A *Streptococcus, Staphylococcus aureus*, and Gram-negative organisms such as *Pseudomonas aeruginosa. S. aureus* and Gram-negative organisms are found most commonly in neonates and very young infants who are hospitalized; in outpatient settings, the distribution of pathogens in these young infants is similar to that in older infants. Evidence suggests that *H. influenzae* more commonly causes recurrent episodes than initial episodes of AOM.

Respiratory viruses (or virus-derived RNA) may also be found in middle-ear exudates of children with AOM, either alone or, more commonly, in association with pathogenic bacteria. Of these viruses, rhinovirus and respiratory syncytial virus (RSV) are found most often. AOM is a usual complication in children who develop bronchiolitis; however, middle-ear aspirates in such children regularly contain bacterial pathogens, suggesting that RSV is rarely, if ever, the sole cause of their AOM. It remains uncertain whether viruses alone can cause AOM under any circumstances, or whether, as discussed earlier, their role is limited to setting the stage for bacterial invasion, and perhaps also to amplifying the inflammatory process and interfering with resolution of the bacterial infection. Finally, it is possible that, in cases of AOM from which bacterial pathogens cannot be recovered, pathogens had nonetheless been present initially but were rendered nonviable as a result of host reaction, or were lost because of problems in collection, handling, or laboratory methods.

OTITIS MEDIA WITH EFFUSION.

Middle-ear fluid cultures from children with OME are usually sterile, but the pathogens typically found in AOM are recoverable also in approximately 30% of children with OME. In addition, in various studies of children with OME involving polymerase chain reaction (PCR) assay, middle-ear fluids have been found to contain bacterial DNA and/or viral RNA in much larger proportions of the children. In studies using special techniques, *Chlamydia pneumoniae* and *Alloiococcus otitidis* have also been identified in the effusions of children with OME. The significance of these various positive identifications is debatable; it is not clear that the organisms or materials found are indicative of actual current or past infection.

Pathogenesis.

AOM is usually caused by bacterial pathogens and may also be caused by viruses. However, central to an understanding of how otitis media develops is consideration of the eustachian tube. Under usual circumstances the tube is passively closed and is opened by contraction of the tensor veli palatini muscle. In relation to the middle ear, the tube appears to have three main functions: ventilation, protection, and clearance. The most important appears to be ventilation. The middle-ear mucosa depends on a continuing supply of air from the nasopharynx delivered by way of the eustachian tube. Interruption of this ventilatory process by tubal obstruction initiates a complex inflammatory response that includes secretory metaplasia, compromise of the mucociliary transport system, and effusion of liquid into the tympanic cavity. Impaired middle-ear ventilation probably underlies all cases of OME and at least contributes to the development of most cases of AOM. Whether middle-ear infection, as distinct from sterile inflammation, can develop in the absence of pre-existing eustachian tube obstruction is uncertain; if so, the infection would undoubtedly lead quickly to tubal obstruction as a consequence of both inflammatory edema and the accumulation of middle-ear secretions.

It seems likely that tubal obstruction might result in a number of ways: extraluminally, from hypertrophied nasopharyngeal lymphoid tissue, or tumor; or intraluminally, from inflammatory edema of the tubal mucosa, most commonly as a consequence of upper respiratory tract infection; or intramurally, from impairment of the opening mechanism of the tube, attributable in turn to abnormal tubal muscular function, or excessive

---

tubal wall compliance, or both. Progressive reduction in tubal wall compliance with increasing age may help explain the progressive decline in the occurrence of otitis media as children grow older. The protection and clearance functions of the eustachian tube may also be involved in the pathogenesis of otitis media. Thus, if the tubes are patulous or excessively compliant, they may fail to protect the middle ear from reflux of infective nasopharyngeal secretions, whereas impairment of the mucociliary clearance function of the tube might contribute to both the establishment and persistence of infection. The shorter and more horizontal orientation of the tube in infants and young children may increase the likelihood of reflux from the nasopharynx, but on the other hand may facilitate the ventilatory function of the tube.

Although otitis media may develop and certainly may persist in the absence of apparent respiratory tract infection, many if not most episodes are initiated by viral or bacterial upper respiratory tract infection. In a study of children in group daycare, AOM was observed in approximately 30–40% of children with respiratory illness caused by RSV, influenza viruses, or adenoviruses, and in approximately 10–15% of children with respiratory illness caused by parainfluenza viruses, rhinoviruses, or enteroviruses. Viral infection of the upper respiratory tract results in release of cytokines and inflammatory mediators, some of which may cause eustachian tubal dysfunction. Respiratory viruses also may enhance nasopharyngeal bacterial

colonization and adherence and impair host immune defenses against bacterial infection. In children with bacterial infection of the middle ear, evidence is mixed as to whether viruses, if present, may amplify the inflammatory process or interfere with resolution of the infection.

IgA deficiency is found in some children with recurrent AOM but the significance is questionable, inasmuch as IgA deficiency is also found not infrequently in children without recurrent AOM. Selective IgG subclass deficiencies (despite normal total serum IgG) may be found in children with recurrent AOM in association with recurrent sinopulmonary infection, which probably underlie the susceptibility to infection. Children with recurrent otitis media that is not associated with recurrent infection at other sites rarely have a readily identifiable immunologic deficiency. Nonetheless, evidence that subtle immune deficits play a role in the pathogenesis of recurrent AOM is provided by studies involving antibody responses to various types of infection and immunization; by the observation that breast milk feeding, as opposed to formula feeding, confers limited protection against the occurrence of otitis media in infants with cleft palate; and by studies in which young children with recurrent AOM achieved a measure of protection from intramuscularly administered bacterial polysaccharide immune globulin or intravenously administered polyclonal immunoglobulin.

In children with cleft palate, the main factor underlying the chronic middle-ear inflammation appears to be impairment of the opening mechanism of the eustachian tube, due perhaps to greater-than-normal compliance of the tubal wall. Another possible factor is defective velopharyngeal valving, which may result in disturbed aerodynamic and hydrodynamic relationships in the nasopharynx and proximal portions of the eustachian tubes. Finally, as noted earlier, infection and related immunologic factors appear to play a role. In children with other craniofacial anomalies and with Down syndrome, the high prevalence of otitis media is presumably attributable to structural and/or functional eustachian tubal abnormalities. No convincing evidence exists that respiratory allergy plays a role in the pathogenesis of otitis media; however, in children with both conditions it seems possible that the otitis is aggravated by the allergy.

Clinical Manifestations.

Symptoms and signs of AOM are highly variable, especially in infants and young children. There may be rupture of the tympanic membrane with purulent otorrhea, or evidence of ear pain, often manifested by holding or tugging at the ear, or fever, irritability, or other systemic symptoms, or there may be no symptoms, the disease having been discovered at a routine health examination. OME is usually not accompanied by apparent symptoms, and the associated conductive hearing loss usually goes undetected, especially in younger children. Older children may complain of mild discomfort or a sense of fullness in the ear. Also see Chapter 626 .

EXAMINATION OF THE EARDRUM

Otoscopy. For clinicians other than otolaryngologists, who may use an operating microscope, the eardrum is ordinarily viewed by means of an otoscope. Two types of otoscope heads are available: **surgical or operating**, and **diagnostic or pneumatic** (Fig. 630–1). The surgical head embodies a lens that can swivel over a wide arc and an unenclosed light source, thus providing ready access of the examiner's instruments to the external auditory canal and tympanic membrane. A suitable instrument is the Welch Allyn (Skaneateles Falls, NY) model 21700. Use of the surgical head is optimal for removing cerumen or debris from the canal under direct observation, and is necessary for satisfactorily performing tympanocentesis or myringotomy. The diagnostic head incorporates a larger lens, an enclosed light source, and a nipple for the attachment of a rubber bulb and tubing. When an attached speculum is fitted snugly into the external auditory canal, an airtight chamber is created comprising the vault of the otoscope head, the bulb and tubing, the speculum, and the proximal portion of the external canal. A suitable instrument is the Welch Allyn model 20200. Reusable specula such as those supplied with the otoscope afford less discomfort to the patient than thinner, sharper-edged disposable specula, and using a rubber-tipped speculum or adding a small sleeve of rubber tubing to the tip of the plastic speculum may serve to minimize patient discomfort and enhance the ability to achieve a proper fit and an airtight seal. By observing as the bulb is alternately squeezed gently and released, the degree of tympanic membrane mobility in response to both positive and negative pressure can be estimated. With both types of otoscope heads, bright illumination is critical to adequate visualization of the tympanic membrane.

Clearing the External Auditory Canal. If the tympanic membrane is obscured by cerumen, the cerumen may be removed under direct observation through the surgical head of

Figure 630-1 Otoscope types. *Left*: Otoscope embodying surgical or operating head. *Right*: Otoscope embodying diagnostic head, with rubber bulb attachment for pneumatic otoscopy.

the otoscope, using a Buck curette (N-400-0, Storz Instrument Co) (Fig. 630–2). Remaining bits can then be wiped away using a Farrell applicator (N-2001A, Storz Instrument Co) (Fig. 630–2), with its tip (triangular in cross section) wrapped with a bit of dry or alcohol-moistened cotton to create a dry or wet “mop.” Alternatively, gentle suction may be applied, using a No. 7 French ear suction tube. During this procedure it may be most advantageous to restrain the infant or young child in the prone position, turning the child's head to the left or right as each ear is cleared. One adult, usually a parent, can place one hand on each of the child's buttocks and brace the child's hips against the examining table, using his or her own weight for additional bracing if necessary. Another adult can restrain the child's head with one hand and the child's free arm with the other, changing hands for the opposite ear. In children old enough to cooperate, usually beginning at about 5 yr of age, clearing of the external canal can often be achieved more easily and safely and less traumatically by lavage than by mechanical removal, provided one can be certain that a tympanic membrane perforation is not present. A convenient device for accomplishing lavage is the Welch-Allyn Ear Wash System (Model 29300).

Tympanic Membrane Findings. Important characteristics of the tympanic membrane consist of contour, color, translucence, structural changes if any, and mobility. Normally the contour of the membrane is **slightly concave**; abnormalities consist of fullness or bulging, or conversely, extreme retraction. The normal color of

the tympanic membrane is **pearly gray**. Erythema may be a sign of inflammation, but unless intense, erythema alone may result from crying or vascular flushing. Abnormal whiteness of the membrane may result from either scarring or the presence of liquid in the middle-ear cavity; liquid also may impart an amber, pale yellow, or (rarely) bluish color. Normally, the membrane is translucent, although some degree of opacity may be normal in the first few months of life; later, opacification denotes either scarring, or more commonly, underlying effusion. Structural changes include scars, perforations, and retraction pockets. Of all the visible characteristics of the tympanic

Figure 630-2 *Top*: Buck curette. Note the narrow caliber of the metal forming the end loop. *Center*: Farrell applicator. Its tip is triangular in cross-section. *Bottom*: Tympanocentesis aspirator.

membrane, mobility is the most sensitive and specific in determining the presence or absence of MEE. Importantly, mobility is not an all-or-none phenomenon; although total absence of mobility (in the absence of a tympanic membrane perforation) is virtually always indicative of MEE, substantial impairment of mobility is the more common finding.

Diagnosis.

Distinguishing between AOM and OME on clinical grounds is straightforward in most cases, but because each condition may evolve into the other without any clearly differentiating physical findings, any schema for distinguishing between them is to some extent arbitrary. Nonetheless, in an era of increasing bacterial resistance, distinguishing between AOM and OME has become increasingly important in determining treatment. Obviously, purulent otorrhea of recent onset is indicative of AOM; thus, difficulty in distinguishing clinically between AOM and OME is limited to circumstances in which purulent otorrhea is not present. Both AOM without otorrhea and OME are accompanied by physical signs of MEE, namely, the presence of at least two of three tympanic membrane abnormalities: white, yellow, amber, or (rarely) blue discoloration; opacification other than that due to scarring; and decreased or absent mobility. Alternatively in OME, either air-fluid levels or air bubbles outlined by small amounts of fluid may be visible behind the tympanic membrane, a condition often indicative of impending resolution.

To support a diagnosis of AOM in a child with MEE, distinct fullness or bulging of the tympanic membrane should also be present, with or without accompanying erythema, or, at minimum, MEE should be accompanied by ear pain that appears clinically important. Unless intense, erythema alone is insufficient; erythema without other abnormalities may result from crying or vascular flushing. The malleus may be obscured, and the tympanic membrane may resemble a bagel without a hole but with a central depression (Fig. 630–3), or may be obscured by surface bullae, or may have a cobblestone appearance. **Bullous myringitis** is a physical manifestation of AOM and not an etiologically discrete entity. Within days after onset, fullness

Figure 630-3 Tympanic membrane in acute otitis media (AOM).

of the membrane may diminish, even though infection may still be present. Exceptionally, early in the course of AOM, effusion may not yet have become evident, in which case ear pain and intense erythema of the tympanic membrane are the only localizing clinical manifestations.

In OME, fullness of the tympanic membrane is absent or slight or the membrane may be retracted (Fig. 630–4); erythema also is absent or slight, but may increase with crying or with superficial trauma to the external auditory canal incurred in clearing the canal of cerumen or during otoscopic examination. In children with MEE but without tympanic membrane fullness or bulging, the presence of unequivocal ear pain is usually indicative of AOM, but a diagnosis of AOM is not justified by the associated presence of only nonspecific symptoms such as fever, irritability, anorexia, vomiting, and diarrhea. A simplified differentiating schema calls for a diagnosis of AOM when, in addition to having MEE, a child gives evidence of recent, clinically important ear pain or the tympanic membrane

Figure 630-4 Tympanic membrane in otitis media with effusion (OME).

shows marked redness or distinct fullness or bulging (Fig. 630–5).

Commonly, both before and after episodes of otitis media and also in the absence of otitis media, the tympanic membrane may be retracted as a consequence of negative middle-ear air pressure. Presumably, the cause is more rapid diffusion of air from the middle-ear cavity than its replacement via the eustachian tube. Mild retraction cannot be considered pathologic, although in some children it is accompanied by mild conductive hearing loss. More extreme retraction, however, is of concern, as discussed later in the section on sequelae of otitis media.

TYMPANOMETRY.

Tympanometry, also termed **acoustic immittance testing**, is a simple, rapid, atraumatic test that offers objective evidence of the presence or absence of MEE. The tympanogram provides information about tympanic membrane compliance in electroacoustic terms that can be thought of as roughly equivalent to tympanic membrane mobility as perceived visually during pneumatic otoscopy. The test depends on the facts that the absorption of sound by the tympanic membrane varies inversely with its stiffness and that the stiffness of the membrane is least, and accordingly its compliance is greatest, when the air pressures impinging on each of its surfaces—middle-ear air pressure and external canal air pressure—are equal. Anything tending to stiffen the tympanic membrane—for example, stretching (if the pressures on the two surfaces become unequal), scarring (of either the membrane or its attachments), or an accumulation of middle-ear liquid—increases its acoustic impedance, or stated reciprocally, reduces its acoustic **admittance**, which was formerly termed **compliance**.

Tympanograms may be grouped into one of three categories:

1. Tracings characterized by high admittance (measured by the height of the

peak), relatively steep gradient (i.e., sharp-angled peak), and middle-ear air pressure (location of the peak in terms of air pressure) that approximates atmospheric pressure (Fig. 630–6*A*). Such tracings are generally assumed to indicate normal middle-ear status.
2. Tracings characterized by low admittance and by negative or indeterminate middle-ear air pressure, and often termed *flat* (Fig. 630–6*B*). Such tracings are generally assumed to indicate the presence of a middle-ear abnormality that is causing heightened impedance. By far the most common such abnormality in infants and children is MEE.
3. Tracings characterized by intermediate findings—somewhat low admittance, often in association with a gradual gradient (obtuse-angled peak) or negative middle-ear air pressure, or combinations of these features (Fig. 630–6*C*). Such tracings may or may not be associated with MEE, and must be considered nondiagnostic or equivocal. In general, the lower the admittance, the more gradual the gradient, and the more negative the middle-ear air pressure, the greater the likelihood of MEE.

In addition to providing information concerning middle-ear status, the tympanometer also measures and records the volume of the external auditory canal, and if a tympanic membrane perforation or a patent tympanostomy tube is present, the volume of the middle ear and mastoid air cells as well. A volume reading in excess of 1.0?mL, particularly if associated with a flat tracing, should suggest the presence of either a perforation or a patent tympanostomy tube.

Although tympanometry is quite sensitive in detecting MEE, its positive predictive value is limited. Accordingly, abnormal or questionable tympanograms are not infrequently found in association with normal middle-ear status, especially in infants. On the other hand, the tympanogram is sometimes normal early in the course of AOM. Use of tympanometry may be helpful in office screening, by obviating the need for routine otoscopic examination in difficult-to-examine patients whose tympanic membranes have been visualized previously, who are asymptomatic, and whose tympanograms are classified as normal, and

Figure 630-5 Algorithm for distinguishing between acute otitis media (AOM) and otitis media with effusion (OME). (TM = tympanic membrane.)

by identifying patients who require further attention because their tympanograms are abnormal. Tympanometry also may be used to help confirm, refine, or clarify questionable otoscopic findings; to objectify the follow-up evaluation of patients with known middle-ear disease; and to serve as validators (or invalidators) of otoscopic diagnoses of MEE. Importantly, even though tympanometry can predict the probability of MEE, it cannot distinguish the effusion of OME from that of AOM.

SPECTRAL GRADIENT ACOUSTIC REFLECTOMETRY (SGAR).

Reflectometry is a more newly developed acoustic test that estimates the condition of the middle ear by assessing the response of the tympanic membrane to a sound stimulus (also see Chapter 627). The instrument analyzes the reflectance of sound waves with respect to frequency and presents results as spectral gradient angles that correlate with the likelihood that MEE is present. An angle of greater than 95 degrees indicates a low risk of

Figure 630-6 Tympanograms obtained with a Grason-Stadler GSI 33 Middle Ear Analyzer, exhibiting (*A*) high admittance, steep gradient (i.e., sharp-angled peak), and middle ear air pressure approximating atmospheric pressure (zero decaPascals [daPa]); (*B*) low admittance and indeterminate middle-ear air pressure; and (*C*) somewhat low admittance, gradual gradient, and markedly negative middle-ear air pressure.

MEE, and an angle of less than 49 degrees indicates a high risk of MEE. The instrument is small and portable, and gives readings rapidly. However, the information provided concerning middle-ear status is more limited than that provided by tympanometry. Results regarding the accuracy of reflectometry as compared with that of tympanometry in predicting the presence or absence of MEE have been mixed. As in the case of tympanometry, SGAR cannot distinguish the effusion of OME from that of AOM.

Treatment.

The management of otitis media is based on the diagnosis of the illness as either AOM or OME.

MANAGEMENT OF ACUTE OTITIS MEDIA.

Individual episodes of AOM have customarily been treated with antimicrobial drugs. However, concern about increases in bacterial resistance has prompted some authors to recommend withholding antimicrobial treatment in some or most cases unless

symptoms persist for 2 or 3 days, or worsen. This recommendation must be viewed in light of the fact that much of the use of antimicrobials for otitis media has been directed not at treating individual episodes of AOM but, instead, at treating OME or at attempting to prevent recurrent episodes of AOM. Avoidance of inappropriate antimicrobial use for these latter purposes should go far toward reducing antimicrobial use for otitis media generally.

Three factors argue in favor of routinely treating children who have bona fide AOM with an antimicrobial drug. First, pathogenic bacteria cause a large majority of cases. Second, symptomatic improvement and resolution of infection occur more promptly and more consistently with antimicrobial treatment than without (even though most untreated cases eventually also resolve). Third, prompt and adequate antimicrobial treatment may prevent the development of suppurative complications. The sharp decline in such complications during the last half-century seems likely attributable, at least in part, to the widespread routine use of antimicrobials for AOM. In the Netherlands, where initial antibiotic treatment is routinely withheld from most children

older than 6 mo of age, and where only approximately 30% of children with AOM currently receive antibiotics at all, the incidence of acute mastoiditis, although low (in children < 14 yr, 3.8 per 100,000 person years), is substantially higher than rates in the United States and in many other countries with higher antibiotic prescription rates. It is also the case that follow-up of children in the Netherlands is generally more assiduous than is customary in the United States, where failure to improve or worsening might not be detected as promptly. Accordingly, it seems advisable to continue the present policy of routine antimicrobial treatment for AOM. In particular, antimicrobials should not be withheld initially from children with AOM who are younger than 2 yr of age, or who are ill systemically or appear to have severe infections, or who have recent histories of recurrent AOM, or in whom satisfactory follow-up cannot be assured. Admittedly, the policy of withholding treatment initially in milder cases in children at lower risk will deserve further consideration if the prevalence of bacterial resistance continues to escalate.

Bacterial Resistance. Bacteria have a remarkable ability to develop resistance to antimicrobial drugs. Adaptive mechanisms include mutations in their ß-lactamases that enable these enzymes to inactivate new ß-lactam drugs, development of an intracellular pump that removes antibiotics before they can act upon the bacteria, changes in their cell wall proteins that serve to keep antibiotics out, and development of substitute proteins that are not targeted by antibiotics. Bacterial resistance in general has been an increasing problem in the past decade. Children at greatest risk of harboring resistant bacteria are those who are younger than 2 yr of age, in regular contact with large groups of other children, or have recently received antimicrobial treatment. Bacterial resistance is a problem in relation particularly to otitis media on two counts. First, both the development of resistant bacterial strains and their rapid spread have been fostered and facilitated by selective pressure resulting from extensive use of antimicrobial drugs, the most common target of which, in children, is otitis media. Second, many strains of each of the pathogenic bacteria that commonly cause AOM are resistant to certain commonly used antimicrobial drugs.

Currently, approximately 40% of strains of nontypable *H. influenzae* and almost all strains of *M. catarrhalis* are resistant to aminopenicillins (ampicillin and amoxicillin). In most cases the resistance is attributable to production of ß-lactamase, and can be overcome by combining amoxicillin with a ß-lactamase inhibitor, namely, clavulanate, or by using a ß-lactamase-stable antibiotic such as cefixime. However, occasional strains of nontypable *H. influenzae* that do not produce ß-lactamase are resistant to aminopenicillins and other ß-lactam antibiotics by virtue of alterations in their penicillin-binding proteins.

Currently also, approximately 50% of strains of *S. pneumoniae* are penicillin-nonsusceptible, divided approximately equally between penicillin-intermediate and penicillin-resistant strains. Resistance by *S. pneumoniae* to the penicillins and other ß-lactam antibiotics is mediated not by ß-lactamase production, but by alterations in penicillin-binding proteins. There are at least six known penicillin-binding proteins, and the greater the number of alterations in these proteins the greater the degree of resistance. This mechanism of resistance can be overcome, however, if higher concentrations of ß-lactam antibiotics at the site of infection can be achieved for a sufficient time interval. Many penicillin-resistant strains of *S. pneumoniae* are also resistant to other antimicrobial drugs, including sulfonamides, macrolides, and the newer cephalosporins. In general, as penicillin resistance increases, so also does resistance to other antimicrobial classes.

Resistance to macrolides by *S. pneumoniae* has been increasing rapidly; approximately 30% of strains are currently macrolide-resistant. Two mechanisms of macrolide resistance have been identified: one, mediated by the mef(A) gene, involves an efflux pump that decreases intracellular accumulation of macrolides and results in low-level resistance; the other mechanism, mediated by the erm(B) gene, involves production of ribosomal methylases that modify ribosomal RNA and result in high-level resistance. The latter mechanism also results in resistance to clindamycin, which otherwise is generally effective against resistant strains of *S. pneumoniae*. Unlike resistance to ß-lactam antibiotics, macrolide resistance cannot be overcome by increasing the dose. Currently, the only antimicrobial to which resistance by *S. pneumoniae* has not been reported is vancomycin.

First-Line Antimicrobial Treatment. Currently, amoxicillin remains the drug of first choice for uncomplicated AOM under most circumstances because of its excellent record of safety, relative efficacy, palatability, and low cost. In particular, amoxicillin is the most efficacious of available oral antimicrobial drugs against both penicillin-susceptible and penicillin-nonsusceptible strains of *S. pneumoniae*. Increasing the dose from the traditional 40?mg/kg/24?hr to 80–100?mg/kg/24?hr will generally provide efficacy against penicillin-intermediate and some penicillin-resistant strains. This higher dose should be used particularly in children younger than 2 yr old, in children who have recently received treatment with ß-lactam drugs, and in children who are exposed to large numbers of other children, because, as noted earlier, it is in these children that the prevalence of nonsusceptible strains of *S. pneumoniae* is highest. A limitation of amoxicillin is that it may be inactivated by the ß-lactamases produced by many strains of nontypable *H. influenzae* and most strains of *M. catarrhalis*. Fortunately, episodes of AOM caused by these pathogens often, although by no means always, resolve spontaneously. For children who are allergic to ß-lactams, or in whom palatability or convenience of administration are of overriding importance, azithromycin, which also has an excellent safety record, is an appropriate alternative first-line drug. Resistance to trimethoprim-sulfamethoxazole (TMP-SMZ) by many strains of both *H. influenzae* and *S. pneumoniae* and a reported high clinical failure rate in children with AOM treated initially with TMP-SMZ argue against its use as first-line treatment.

Duration of Treatment. The duration of treatment of AOM has often been set at 10 days, in an apparent extrapolation from the optimal duration of treatment of streptococcal pharyngitis with penicillin. However, 10 days may be unduly long for some children while not long enough for others. Studies comparing shorter with longer durations of treatment suggest that short-course treatment will often prove inadequate in children younger than 6 yr of age, and particularly in children younger than 2 yr. Thus, for most episodes in most children, treatment that provides tissue concentrations of an antimicrobial for at least 10 days would seem advisable. Treatment for shorter periods, of 3–5 days, may be appropriate for older children with mild episodes who improve quickly, whereas treatment for longer than 10 days will often be required for children who are very

young or are having severe episodes or whose previous experience with otitis media has been problematic.

Follow-Up. The principal goals of follow-up are to assess the outcome of treatment and to differentiate between inadequate response to treatment and early recurrence. Accordingly, the appropriate interval for follow-up should be individualized. Follow-up within days is advisable in the young infant with a severe episode or in a child of any age with continuing pain. Follow-up within 2 wk is appropriate for the infant or young child who has apparently been having frequent recurrences. At that point, the tympanic membrane is not likely to have returned to normal, but substantial improvement in its appearance should be evident. In the child with only a sporadic episode of AOM and prompt symptomatic improvement, follow-up 1 mo after initial examination is early enough, or in older children, no follow-up may be necessary. Importantly, the continuing presence of MEE alone following an episode of AOM is not an indication for additional or second-line antimicrobial treatment.

Unsatisfactory Response to First-Line Treatment. AOM is essentially a closed-space infection and its resolution depends both on eradication of the offending organism and restoration of middle-ear ventilation. Factors contributing to unsatisfactory response to first-line treatment, in addition to inadequate antimicrobial efficacy, include poor compliance with treatment regimens, concurrent or intercurrent viral infection, persistent eustachian tube dysfunction and middle-ear under-aeration, reinfection from other sites or from outside sources, and immature or impaired host defenses. Despite these many potential factors, switching to an alternative or second-line drug would seem reasonable when there has been inadequate improvement in symptoms or in middle-ear status as reflected in the appearance of the tympanic membrane, or when the persistence of purulent nasal discharge suggests that the antimicrobial drug being used has less than optimal efficacy. Second-line drugs may also appropriately be used when AOM develops in a child already receiving antimicrobial prophylaxis, or in an immunocompromised child, or in a child with severe symptoms whose previous experience with otitis media has been problematic.

Second-Line Treatment. When treatment of AOM with a first-line antimicrobial drug has proven inadequate, a number of second-line alternatives are available. As recently emphasized by the Drug-resistant *Streptococcus pneumoniae* Therapeutic Working Group of the U.S. Centers for Disease Control and Prevention (CDC), drugs chosen for second-line treatment should be effective against ß-lactamase-producing strains of *H. influenzae* and *M. catarrhalis* and against susceptible and most nonsusceptible strains of *S. pneumoniae*. Based on available evidence, the CDC Working Group concluded that only three drugs had been clearly shown to meet that requirement: amoxicillin-clavulanate, cefuroxime axetil, and intramuscular ceftriaxone. Because high-dose amoxicillin is effective against most strains of *S. pneumoniae* and because the addition of clavulanate extends the effective antibacterial spectrum of amoxicillin to include ß-lactamase-producing bacteria, high-dose amoxicillin-clavulanate is particularly well-suited as a second-line drug for treating AOM. The 14:1 amoxicillin-clavulanate formulation contains twice as much amoxicillin as the previously available 7:1 formulation. Diarrhea, especially in infants and young children, is a common adverse effect, but may perhaps be ameliorated in some cases by feeding yogurt, and usually is not severe enough to require cessation of treatment. Unfortunately, amoxicillin-clavulanate is quite expensive. The two other drugs identified by the CDC Working Group have important limitations for use in young children. The currently available suspension of cefuroxime axetil is not palatable and its acceptance is low. Ceftriaxone treatment entails both the pain of intramuscular injection and substantial cost, and the injection may need to be repeated once or twice at 2- or 3-day intervals to achieve the desired degree of effectiveness. Nonetheless, use of ceftriaxone is appropriate in severe cases of AOM when oral treatment is not feasible, or in highly selected cases after treatment failure using orally administered second-line antimicrobials (i.e., amoxicillin-clavulanate or cefuroxime axetil), or when highly resistant *S. pneumoniae* is found in aspirates obtained from diagnostic tympanocentesis.

In cases of treatment failure specifically, the clinical effectiveness of the various available drugs has not been tested in appropriately designed studies. The newer macrolides, clarithromycin and azithromycin, have only limited activity against nonsusceptible strains of *S. pneumoniae* and against ß-lactamase-producing strains of *H. influenzae*. Macrolide use also appears to be a major factor in causing increases in rates of resistance to macrolides by group A *Streptococcus* and *S. pneumoniae*. Of the cephalosporins other than cefuroxime axetil, cefpodoxime and cefdinir seem most promising, with antibacterial spectrums similar to those of cefuroxime axetil. The liquid preparation of cefdinir is quite palatable, but that of cefpodoxime is not. Cefprozil possesses somewhat less ß-lactamase stability than either cefuroxime or cefpodoxime. Cefaclor and loracarbef have limited activity against ß-lactamase-producing bacteria and nonsusceptible pneumococci, and cefaclor may occasionally cause serum sickness. Cefixime has excellent activity against ß-lactamase-producing bacteria but limited activity against even penicillin-susceptible pneumococci. All of the cephalosporins are expensive. TMP-SMZ is relatively inexpensive, but its efficacy is limited and its use for treating AOM is not recommended. Additionally, this drug rarely may cause severe reactions such as bone-marrow suppression or Stevens-Johnson syndrome. Erythromycin-sulfisoxazole also may cause such reactions and is not active against penicillin-nonsusceptible pneumococci. Clindamycin is active against most strains of *S. pneumoniae*, including resistant strains, but is not active against *H. influenzae* or *M. catarrhalis*. It should therefore be reserved for patients known to have infection caused by penicillin-nonsusceptible pneumococci.

Because comparative studies of antibiotics in children who have experienced treatment failure are lacking, the choice of drugs to use in such cases should be guided by the limited clinical evidence available concerning the efficacy of individual drugs; by available in vitro, pharmacokinetic, and pharmacodynamic data; and, because bacterial resistance patterns vary geographically, by personal clinical experience.

Myringotomy and Tympanocentesis. Myringotomy is a time-honored treatment for AOM but is rarely necessary in children receiving antimicrobials initially. In a clinical trial limited to children with severe AOM, those who received amoxicillin plus myringotomy fared no better overall than those who received amoxicillin only, but the study population was not large enough to have excluded the possibility that myringotomy had been marginally beneficial. Indications for myringotomy in children with AOM include severe, refractory pain; hyperpyrexia; complications of AOM such as facial paralysis, mastoiditis, labyrinthitis, or central nervous system infection; and immunologic compromise from any source. In children with AOM in whom clinical response to vigorous, second-line treatment has been unsatisfactory, either diagnostic tympanocentesis or myringotomy is indicated to enable identification of the offending organism and its sensitivity profile. Either procedure, but more reliably, myringotomy, may be additionally helpful in effecting relief of pain. Tympanocentesis

with culture of the middle-ear aspirate is also indicated as part of the sepsis work-up in very young infants with AOM who show systemic signs of illness such as fever, vomiting, or lethargy, and whose illness accordingly cannot be presumed to be limited to infection of the middle ear. “In an era of increasing antimicrobial resistance,” the CDC Working Group wrote, “clinicians treating children with AOM should consider developing the capacity to perform tympanocentesis themselves or establish ready referral mechanisms to a clinician with this capacity.” Performing tympanocentesis is

much facilitated by use of a specially designed tympanocentesis aspirator (No. 91-19010, Xomed Surgical Products, Jacksonville, FL) (see Fig. 630–2).

Early Recurrence After Treatment. Recurrence of AOM after apparent resolution may be due either to incomplete eradication of infection in the middle ear or upper respiratory tract or to reinfection by the same or a different bacterium or bacterial strain. Recurrence within several days is usually caused by the same organism, and thus treatment may be best guided by the response to treatment of the antecedent episode: if it had seemed to respond to a first-line antimicrobial, that drug would again be appropriate; if it had failed to respond to a first-line drug but seemed to respond to a second-line drug, use of a second-line drug from the outset might be advisable. Recurrence developing 2 wk or more after a treated episode of AOM is usually caused by a different organism; accordingly, use of a first-line antimicrobial irrespective of previous responses to treatment is usually appropriate.

Tube Otorrhea. Otorrhea through a previously inserted tympanostomy tube must be considered evidence of middle-ear infection, although in some cases it may result from reflux of secretions from the nasopharynx via the eustachian tube. When accompanied by pain or fever, tube otorrhea should be treated as described earlier for AOM because the causative organisms tend to be the same as those that cause AOM. However, in many cases, especially those that become persistent, *Pseudomonas aeruginosa* is the main offending pathogen; in such cases the drugs commonly used for AOM are not effective. When tube otorrhea develops without associated pain or fever, ototopical treatment may suffice. Currently, ofloxacin otic solution is the only preparation approved for use in the middle ear because of its lack of ototoxicity. Polymixin B-neomycin-hydrocortisone otic suspension is also relatively effective, but carries a theoretical risk in humans of ototoxicity. Prompt adjunctive treatment of tube otorrhea with a short course of oral prednisolone has recently been reported to result in more rapid resolution. In all cases, attention to aural toilet, that is, cleansing the external auditory canal of secretions, is important. When children with tube otorrhea fail to improve satisfactorily with conventional outpatient management, they may require tube removal, or hospitalization to receive parenteral antibiotic treatment, or both.

MANAGEMENT OF OTITIS MEDIA WITH EFFUSION.

To determine the course of an episode of OME, and to distinguish between persistence and recurrence, examination should be conducted monthly until resolution, and hearing should be assessed if effusion has been present for 3 mo or more. Rational management of OME depends in considerable degree on an understanding of its natural history and its possible complications and sequelae. Unfortunately, information in each of these areas is limited. Most cases of OME resolve with or without treatment within 3 mo; however, virtually no data are available concerning the subsequent long-term course of children in whom resolution does not occur within that time frame and who do not receive surgical intervention.

Except in the few children who are troubled by the variable accompanying conductive hearing loss, the occasional mild discomfort, or the unusual tinnitus or disturbance of balance, the main rationale for treating OME is to prevent possible complications and sequelae. These have been thought to include, variously, a heightened risk of developing AOM; pathologic middle-ear changes, namely, atelectasis of the tympanic membrane and retraction pocket, adhesive otitis media, ossicular discontinuity, and cholesteatoma; conductive and sensorineural hearing loss; and long-term adverse effects on speech, language, cognitive, and psychosocial development.

Many uncertainties remain about the extent to which these constitute risks of OME under most circumstances. Physical damage, when it occurs, is more often a consequence of repeated or chronic infection than of OME. Whether persistent early-life MEE during the first few years of life results in later developmental impairment has been addressed in many studies over more than 3 decades. Specifically at issue has been whether the mild-to-moderate hearing impairment commonly associated with MEE, occurring during supposedly “critical” or “sensitive” developmental periods, leaves in its wake what might be thought of as developmental scars, persisting into later childhood long after both otitis media and hearing loss have been resolved. Impairments of development associated with persistent early-life otitis media have been reported in four domains: speech, language, cognition, and psychosocial development.

Most of the reported studies of developmental outcomes of early-life otitis media have had important limitations, and as a group, their results have been inconclusive and contradictory. Moreover, because of the studies' uniformly associational designs, they have been unsuited to address the question of causality. Results from a more recent study incorporating a randomized clinical trial suggest that in otherwise healthy children, effusion developing at common levels of frequency and duration (e.g., up to 9 mo continuously in both ears) during the first 3 yr of life poses no developmental risks measurable at 3 and 4 yr of age. At present writing, all results in the study children at age 6 yr are not yet available, and few of the children have reached 9 yr of age, when another battery of tests will be administered. Whether adverse developmental consequences will emerge or become apparent at later ages, or whether there are adverse consequences of more prolonged periods of effusion, remains uncertain.

Variables Influencing OME Management Decisions. In deciding whether to intervene in individual cases of OME, and if so, how vigorously, it may be useful to take into account a number of variables. Patient-related variables include the child's age; the frequency and severity of previous episodes of AOM and the interval since the last episode; the child's language development; the presence or absence of a history of adverse drug reactions, concurrent medical problems, or risk factors such as daycare attendance or other exposure to infectious disease; and the parents' wishes. Disease-related variables include whether the effusion is unilateral or

bilateral; the apparent quantity of effusion; the duration, if known; the degree of hearing impairment; the presence or absence of other possibly related symptoms, such as tinnitus, vertigo, or disturbance of balance; and the presence or absence of mucopurulent or purulent rhinorrhea, which, if sustained for 2 wk or more, would suggest that concurrent nasopharyngeal or paranasal sinus infection is contributing to continuing compromise of middle-ear ventilation.

Medical Treatment. Antimicrobials have definite but limited efficacy in resolving OME, presumably because they help eradicate nasopharyngeal infection or inapparent middle-ear infection or both. However, mainly because of the short-term nature of their benefit and because of the contribution of antimicrobial usage to the development of bacterial resistance, routine antimicrobial treatment of OME, previously recommended by some authorities, no longer seems reasonable. Instead, treatment should be limited to cases in which there is evidence of associated bacterial upper respiratory tract infection, or in which chronicity and/or troubling hearing loss are prompting consideration of tympanostomy tube insertion. In the latter circumstance, a 2–4-wk course of antimicrobial treatment may bring about resolution of OME and thereby avert surgery. For this purpose, the most broadly effective drug available should be used as recommended for AOM.

The efficacy of corticosteroids in the treatment of OME remains debatable and is probably short-term at best. Antihistamine-decongestant combinations are not effective in treating children in general with OME, but their efficacy has not been tested in allergic children specifically. Antihistamines alone, decongestants alone, and mucolytic agents are unlikely to be effective. Allergic

management might prove helpful in children with problematic OME who also have evidence of upper respiratory allergy, but supporting data are lacking. In children without such evidence, allergy testing is not indicated. Inflation of the eustachian tubes by the Valsalva maneuver or other means has no proven long-term efficacy.

Myringotomy and Insertion of Tympanostomy Tubes. When OME persists despite both adequate antimicrobial treatment and an ample period of watchful waiting, the question arises as to surgical intervention. Myringotomy alone, without tympanostomy tube insertion, permits evacuation of middle-ear effusion and may sometimes be effective, but often, because the incision heals before eustachian tube ventilatory function has been restored, effusion soon reaccumulates. Adding tube insertion offers the likelihood that middle-ear ventilation will be sustained for at least as long as the tube remains in place and functional, about 12 mo on average. However, tube placement is not consistently innocuous. Common complications include obstruction of the tube lumen, premature extrusion, and tube otorrhea. Sequelae following tubal extrusion include residual perforation of the eardrum, tympanosclerosis, localized or diffuse atrophic scarring of the eardrum that may predispose to the development of atelectasis or a retraction pocket or both, residual conductive hearing loss, and cholesteatoma. Fortunately, the more serious of these sequelae are the exception rather than the rule. Recurrence of middle-ear effusion following the extrusion of tubes develops not infrequently, especially in younger children.

Given the uncertainties concerning possible consequences of long-standing OME, and given the risks and cost of tube insertion, the point at which tube insertion should be considered remains debatable. A reasonable approach is to consider myringotomy with tube insertion after 6–12 mo of continuous bilateral OME or after 9–18 mo of continuous unilateral OME. Importantly, because even previously persistent OME usually clears spontaneously during the summer months, watchful waiting through at least one summer season is advisable in all children with OME who are otherwise well.

Complications.

Most complications of AOM consist of the spread of infection to adjoining or nearby structures or the development of chronicity, or both. Suppurative complications are relatively uncommon in children in developed countries, but occur not infrequently in disadvantaged children whose medical care is limited or nonexistent. The complications of AOM may be classified as either intratemporal or intracranial.

INTRATEMPORAL COMPLICATIONS.

Direct but limited extension of otitis media leads to complications within the temporal bone.

Infectious Eczematoid Dermatitis. This is an infection of the skin of the external auditory canal resulting from contamination by purulent discharge from the middle ear. The skin is often erythematous, edematous, and tender. Management consists of proper hygiene combined with systemic antimicrobials and ototopical drops as appropriate for treating AOM and tube otorrhea. Also see Chapter 629 .

Chronic Suppurative Otitis Media. This consists of persistent middle-ear infection with discharge through a tympanic membrane perforation. The disease is initiated by an episode of AOM with rupture of the membrane. The mastoid air cells are invariably involved. The most common etiologic organisms are *P. aeruginosa* and *S. aureus*. Treatment is guided by the results of microbiologic investigation. If an associated cholesteatoma is not present, parenteral antimicrobial treatment combined with assiduous aural cleansing is likely to be successful in clearing the infection, but in refractory cases, tympanomastoidectomy is required.

Acute Mastoiditis. All cases of AOM are technically accompanied by mastoiditis by virtue of the associated inflammation of the mastoid air cells. However, early in the course of the disease, no signs or symptoms of mastoid infection are present, and the inflammatory process usually is readily reversible, along with the AOM, in response to antimicrobial treatment. Spread of the infection to the overlying periosteum, but without involvement of bone, constitutes **acute mastoiditis with periosteitis**. In such cases, signs of mastoiditis are usually present, namely, inflammation in the postauricular area, often with displacement of the pinna inferiorly and anteriorly. If instituted promptly, treatment with myringotomy and parenteral antibiotics usually results in satisfactory resolution. In **acute mastoid osteitis**, infection has progressed further to cause destruction of the bony trabeculae of the mastoid. Frank signs and symptoms of mastoiditis are usually, but not always,

present. If, as is often the case, an associated subperiosteal abscess has also developed, fluctuation at the site or a fistula from the mastoid to the postauricular area may be present. In **acute petrositis**, infection has extended further to involve the petrous portion of the temporal bone. Eye pain is a prominent symptom, due to irritation of the ophthalmic branch of the fifth cranial nerve, and later, sixth nerve palsy develops. **Gradenigo syndrome** is the triad of suppurative otitis media, paralysis of the external rectus muscle, and pain in the ipsilateral orbit. Rarely, mastoid infection spreads to the neck muscles that attach to the mastoid tip, resulting in an abscess in the neck, termed a **Bezold abscess**.

When mastoiditis is suspected or diagnosed clinically, computed tomography (CT) scan of the temporal bone should be carried out to further clarify the nature and extent of the disease. Bony destruction of the mastoid must be differentiated from the simple clouding of mastoid air cells that is found often in uncomplicated cases of otitis media. The most common causative organisms in all variants of acute mastoiditis are *S. pneumoniae*, nontypable *H. influenzae*, and *P. aeruginosa*. Children with acute mastoid osteitis require intravenous antimicrobial treatment and mastoidectomy, with the extent of the surgery dependent on the extent of the disease process. Insofar as possible, choice of the antimicrobial regimen should be guided by the findings of microbiologic examination.

Each of the variants of mastoiditis may also occur in subacute or chronic form. Symptoms are correspondingly less prominent. **Chronic mastoiditis** is always accompanied by chronic suppurative otitis media, and occasionally will respond to the conservative regimen recommended for that condition. In most cases, however, mastoidectomy also will be required.

Facial Paralysis. The facial nerve, as it traverses the middle ear and mastoid bone, may be affected by adjacent infection. Facial paralysis occurring as a complication of AOM is uncommon, and usually resolves rapidly after myringotomy and parenteral antibiotic treatment. However, if facial paralysis develops in a child with mastoid osteitis or with chronic suppurative otitis media, mastoidectomy should be undertaken urgently.

Acquired Cholesteatoma. Cholesteatoma is a cyst-like growth within the middle ear or other pneumatized portions of the temporal bone, lined by keratinized, stratified squamous epithelium and containing desquamated epithelium and/or keratin. Acquired, as distinct from congenital (Chapter 628), cholesteatoma develops most often as a complication of long-standing chronic otitis media. However, the condition also may develop from a deep retraction pocket of the tympanic membrane or as a consequence of epithelial implantation in the middle-ear cavity from traumatic perforation of the tympanic membrane or insertion of a tympanostomy tube. Cholesteatomas tend to expand progressively, causing bony resorption, and may extend intracranially with potentially life-threatening consequences. Cholesteatoma should be suspected if otoscopy shows a discrete, whitish opacity of the eardrum or a polyp protruding through a defect in the eardrum; or a white, caseous debris persistently overlies the eardrum, especially its superior portion; or

persistent malodorous aural discharge is present. When cholesteatoma is suspected, CT scan of the temporal bone should be carried out to define the presence and extent of the disease. The required treatment for cholesteatoma is tympanomastoid surgery.

Labyrinthitis. This occurs uncommonly as a result of the spread of infection from the middle ear and/or mastoid to the inner ear. Cholesteatoma or chronic suppurative otitis media is the usual source. Symptoms and signs include vertigo, tinnitus, nausea, vomiting, hearing loss, nystagmus, and clumsiness. Treatment is directed at the underlying condition and must be undertaken promptly to preserve inner ear function and prevent the spread of infection. Also see Chapter 631 .

INTRACRANIAL COMPLICATIONS.

Meningitis, epidural abscess, subdural abscess, focal encephalitis, brain abscess, and lateral sinus thrombosis each may develop as a complication of acute or chronic middle-ear or mastoid infection, through direct extension, hematogenous spread, or thrombophlebitis. Bony destruction adjacent to the dura is often involved, and a cholesteatoma may be present. In a child with middle-ear or mastoid infection, the presence of any systemic symptom, such as fever, headache, or lethargy, of extreme degree, or a finding of meningismus or of any central nervous system sign on physical examination, should prompt suspicion of an intracranial complication.

When an intracranial complication is suspected, lumbar puncture should be performed only after imaging studies establish that there is no evidence of mass effect or hydrocephalus. In addition to examination of the cerebrospinal fluid, culture of middle ear exudate obtained via tympanocentesis may identify the causative organism, thereby helping guide the choice of antimicrobial drugs, and myringotomy should be performed to permit middle-ear drainage. Lateral sinus thrombosis, diagnosis of which is facilitated through imaging studies, may be complicated by dissemination of infected thrombi with resultant development of septic infarcts in various organs. Intravenous antibiotic treatment of all intracranial complications, and surgical drainage of any abscess, are urgently required. If mastoiditis is present, mastoidectomy should be undertaken as soon as feasible. When meningitis develops as a complication of AOM, investigation should be directed at the possible presence of a perilymphatic fistula.

Otitic Hydrocephalus. This condition, also termed **benign intracranial hypertension**, consists of increased intracranial pressure without dilatation of the cerebral ventricles, occurring in association with acute or chronic otitis media or mastoiditis. The pathogenesis is uncertain, but the condition is commonly also associated with lateral sinus thrombosis, and the pathophysiology may involve obstruction by thrombus of intracranial venous drainage into the neck, producing a rise in cerebral venous pressure and a consequent increase in cerebrospinal fluid pressure. Symptoms are those of increased intracranial pressure. Signs may include, in addition to evidence of otitis media, paralysis of one or both lateral rectus muscles and papilledema. The diagnosis is confirmed by magnetic resonance imaging (MRI) scan. Treatment measures include the use of antimicrobials and drugs such as acetazolamide or furosemide to reduce intracranial pressure, mastoidectomy, repeated lumbar puncture, lumboperitoneal shunt, and ventriculoperitoneal shunt. If left untreated, otitic hydrocephalus may result in loss of

vision secondary to optic atrophy.

PHYSICAL SEQUELAE.

Physical sequelae of otitis media consist of structural middle-ear abnormalities resulting from long-standing middle-ear inflammation. In most instances, these sequelae are consequences of severe and/or chronic infection, but some may also result from the presumably noninfective inflammation of long-standing OME. The various sequelae may occur singly, or interrelatedly in various combinations.

Tympanosclerosis consists of whitish plaques in the tympanic membrane and nodular deposits in the submucosal layers of the middle ear. The changes involve hyalinization with deposition of calcium and phosphate crystals. Uncommonly, there may be associated conductive hearing loss. In developed countries, probably the most common cause of tympanosclerosis is tympanostomy tube insertion.

Atelectasis of the tympanic membrane is a descriptive term applied to either severe retraction of the tympanic membrane caused by high negative middle-ear pressure or loss of stiffness and medial prolapse of the membrane, presumably as a consequence of long-standing retraction or severe or chronic inflammation. A **retraction pocket** is a localized area of atelectasis. Atelectasis is often transient and usually unaccompanied by symptoms, but a deep retraction pocket may lead to erosion of the ossicles and adhesive otitis, and may serve as the nidus of a cholesteatoma. For a deep retraction pocket, and for the unusual instance in which atelectasis is accompanied by symptoms such as otalgia, tinnitus, or conductive hearing loss, the required treatment is tympanostomy tube insertion.

Adhesive otitis media consists of proliferation of fibrous tissue in the middle-ear mucosa, which may in turn result in impaired movement of the ossicles, rarefying osteitis and **ossicular discontinuity**, conductive hearing loss, and cholesteatoma. The hearing loss may be amenable to surgical correction.

Cholesterol granuloma is an uncommon condition in which the tympanic membrane appears to be dark blue, reflecting the presence of thick, granulomatous material in the middle-ear cavity. The condition appears to result more often from long-standing OME than from frank middle-ear infection. Tympanostomy tube insertion alone does not provide satisfactory relief, and the required treatment is middle-ear and mastoid surgery.

Chronic perforation may develop after spontaneous rupture of the tympanic membrane during an episode of AOM or as a sequela of chronic suppurative otitis media. In developed countries, however, probably the most common cause is tympanostomy tube insertion (see earlier). A chronic perforation may be amenable to surgical repair, usually after the child has been free of otitis media for an extended period.

Permanent **conductive hearing loss** may result from any of the conditions just described. Rarely, permanent **sensorineural hearing loss** may occur in association with acute or chronic otitis media, presumably from the spread of infection or products of inflammation through the round window membrane, or as a consequence of suppurative labyrinthitis.

POSSIBLE DEVELOPMENTAL SEQUELAE.

Continuous, bilateral MEE for up to 9 mo during the first 3 yr of life poses no measurable developmental risk by 4 yr of age. However, it remains possible that effects not measurable by then will become apparent at older ages. In addition, it seems reasonable to assume that substantially longer periods of effusion or a sustained degree of hearing loss greater than the usual mild-to-moderate level might indeed have adverse effects. Fortunately, such circumstances are not common.

Prevention.

General measures to prevent otitis media consist of breast milk feeding; avoidance, insofar as possible, of exposure to individuals with respiratory infection; and, probably, avoidance of environmental tobacco smoke. The administration of xylitol, a natural sugar, in chewing gum or syrup has been reported to provide a measure of protection against AOM by inhibiting the growth of *S. pneumoniae*, but the studies have had important limitations. Moreover, the current unavailablility of xylitol-containing products in the United States, the required frequency and duration of administration, and the absence of adequate safety data concerning the high doses of xylitol required preclude its general use.

IMMUNOPROPHYLAXIS.

Pneumococcal polysaccharide vaccine is relatively ineffective in protecting against otitis media in children younger than 2 yr of age, and provides only limited protection in older children. The newer heptavalent pneumococcal conjugate vaccine was found in one study to effect a 7% overall reduction in the number of episodes of AOM, but reductions of 9–23% in children with histories of frequent episodes and a 20% reduction in the number of children undergoing tympanostomy tube insertion. In another study, the same vaccine effected a 57% reduction in serotype-specific episodes, but a reduction of only 6% in the number of overall episodes of AOM. The further development of vaccines against the pathogens that cause AOM offers promise of improved overall protection. Influenza vaccine may also provide a measure of protection against otitis media, but further studies are necessary to clarify its degree of efficacy. Passive immunization by exogenously administered immunoglobulin is not practicable because of the discomfort, risks, cost, and inconvenience entailed.

ANTIMICROBIAL PROPHYLAXIS.

In children who have developed frequent episodes of AOM, antimicrobial prophylaxis with subtherapeutic doses of an aminopenicillin or a sulfonamide offers variable protection against recurrences of AOM (although not of OME). However, because of the contribution of antimicrobial usage to bacterial resistance, the risks of sustained antimicrobial prophylaxis now appear, in general, to outweigh the likely benefits,

particularly for children in daycare who in any case are at increased risk of colonization with multiply resistant *S. pneumoniae*. Prophylaxis may, nonetheless, be an appropriate option for the child with recurrent AOM who is cared for at home and usually away from other young children.

MYRINGOTOMY AND INSERTION OF TYMPANOSTOMY TUBES.

In children with persistent OME, several studies have shown tympanostomy tube insertion to be effective in reducing the children's subsequent proportion of time with MEE and also their recurrence rate of AOM. In the one study in children who had recurrent AOM but not persistent MEE, tube insertion was effective in reducing time with MEE, but a reduction in the recurrence rate of symptomatic episodes of AOM was offset by the occurrence of episodes of tube otorrhea. However, anecdotal evidence and personal clinical experience suggest that in children more severely affected than those enrolled in the study, tube insertion offers a greater degree of benefit than that reported.

How best to manage the individual child who is severely affected with recurrent AOM must remain a matter of individual judgment, with the alternatives to prophylaxis being either continued reliance on episodic treatment alone, which seems preferable where feasible, or referral for tympanostomy tube insertion with its attendant risks.

ADENOIDECTOMY.

In children who have undergone tube insertion and in whom, after extrusion of tubes, otitis media continues to be a problem, adenoidectomy is efficacious to some extent in reducing the risk of subsequent recurrences both of AOM and of OME. Efficacy appears to be independent of adenoid size, and probably derives from removal of a focus of infection. On the other hand, in children with recurrent AOM who have not previously undergone tube insertion, the benefit of adenoidectomy is quite limited. In such children, if the burden of illness becomes intolerable, tube insertion alone is the preferred first surgical recourse.

Chapter 631 - The Inner Ear and Diseases of the Bony Labyrinth

Joseph Haddad Jr.

The function and anatomy of the inner ear may be affected by infectious organisms, including viruses, bacteria, and protozoa. Genetic abnormalities may also be responsible for abnormal anatomy and function. Other acquired diseases of the labyrinthine capsule include otosclerosis, osteopetrosis, Langerhans cell histiocytosis, fibrous dysplasia, and other types of bony dysplasia. All of these can cause hearing loss, both conductive and sensorineural, as well as vestibular dysfunction.

Viruses.

Viral causes of sensorineural hearing loss (SNHL) include congenital rubella and congenital cytomegalovirus (CMV), as well as mumps, postnatal rubella, and rubeola (measles). Fifth disease, caused by parvovirus B19, is an infrequent cause of SNHL. Many other viruses are occasionally associated with SNHL. The most common cause of congenital viral sensorineural hearing loss is CMV (Chapter 627). In as many as 50%, hearing loss, which is usually bilateral though often asymmetric, progresses and worsens over weeks to years. Stabilization or improvement in the hearing loss may be possible by using ganciclovir in very young infants with congenital CMV (Chapter 234).

Before the introduction of an effective vaccine, rubella was responsible for as many as 60% of the newly identified cases of childhood SNHL. Vaccination in most developed countries has reduced the rate of rubella by more than 97%. Similarly, measles and mumps are now uncommon causes of SNHL in the United States because of successful vaccination programs.

Herpes simplex encephalitis may also be associated with SNHL; the hearing loss is more common in those children with congenital herpesvirus infection. Acyclovir and other antiviral agents may help the hearing loss and other central nervous system manifestations (Chapter 231).

Toxoplasmosis.

Toxoplasma gondii is a protozoan that may cause congenital SNHL. About 3,000 children are born in the United States yearly with congenital toxoplasmosis; approximately 25% of untreated patients have SNHL. If infection is documented during the fetal period, medical therapy may be able to prevent some of the clinical manifestations, including SNHL (Chapter 266).

Bacterial Meningitis.

Since the introduction of the Hib vaccine, *Streptococcus pneumoniae* and *Neisseria meningitidis* have become the leading causes of bacterial meningitis in children in the United States. Hearing loss occurs more commonly with *S. pneumoniae*,

with an estimated incidence of 15–20%. Approximately 60% of those hearing losses are bilateral, though often asymmetric. If the hearing loss is present at the time of presentation with meningitis, and especially if it is severe to profound, the likelihood of significant improvement is small. However, if the hearing loss develops after admission for treatment and is not severe, stabilization or improvement is possible. Late progression of SNHL has also been noted in some children years after meningitis. In the United States and many other developed countries, bacterial meningitis is one of the major causes of profound deafness leading to cochlear implantation in children. The introduction of pneumococcal conjugate vaccine is expected to lead to a reduction in SNHL due to pneumococcal meningitis.

Studies have shown favorable trends in the course and outcome after administration of dexamethasone for hearing loss and other neurologic deficits associated with bacterial meningitis (Chapter 594.1), although the effectiveness, especially for *S. pneumoniae* and *N. meningitidis* meningitis, generally has not reached statistical significance because of the small number of cases in the trials. A meta-analysis of 11 studies conducted from 1988 to 1996 showed dexamethasone reduced severe hearing loss associated with *H. influenzae* type b meningitis regardless of the timing of administration of dexamethasone (before or with antibiotics vs. later) or of the antibiotic used. For pneumococcal meningitis, the meta-analysis showed a benefit of dexamethasone only when given early and only for protection against severe hearing loss. Too few cases of meningococcal meningitis were included to assess the effect of dexamethasone on this entity.

Syphilis.

Congenital syphilis may cause SNHL in 3–38% of children; the exact incidence is difficult to ascertain, because the hearing loss may not occur until adolescence or even adulthood. When the condition is identified, treatment with antibiotics and steroids may improve the hearing loss.

Other Diseases of the Inner Ear.

Labyrinthitis may be a complication of direct spread of infection from acute or chronic

otitis media (OM) or mastoiditis but may also complicate bacterial meningitis as a result of organisms entering the labyrinth through the internal auditory meatus, endolymphatic duct, perilymphatic duct, vascular channels, or hematogenous spread. Clinical manifestations of labyrinthitis may include vertigo, disequilibrium, deep-seated ear pain, nausea, vomiting, nystagmus, and SNHL. Acute suppurative labyrinthitis, characterized by abrupt, severe onset of these symptoms, requires intensive antimicrobial therapy. If it is secondary to OM, it may require otologic surgery to remove underlying cholesteatoma or drain the middle ear and mastoid, in addition to antibiotics. Acute serous labyrinthitis, with milder symptoms of vertigo and hearing loss, may occur secondary to middle-ear infection as well. It usually responds well to antibiotics and steroids, with improvement in both the vertigo and hearing. Chronic labyrinthitis, most commonly associated with cholesteatoma, presents with SNHL and vestibular dysfunction that develops over time; surgery is required to remove the cholesteatoma. Chronic labyrinthitis may also uncommonly occur secondary to long-standing OM, with the slow development of SNHL, usually starting in the higher frequencies, and possibly with vestibular dysfunction. Additionally, and more commonly, children with chronic middle-ear fluid are often unsteady or off balance, a situation that immediately improves when the fluid resolves.

Otosclerosis, an autosomal dominant disease that affects only the temporal bones, causes abnormal bone growth that can result in fixation of the stapes in the oval window, leading to progressive hearing loss. The hearing loss is usually conductive at first, but SNHL may develop. White females are affected most commonly, with onset of otosclerosis in teenagers or young adults, often associated with pregnancy. Corrective surgery to replace the stapes with a mobile prosthesis is often successful.

Osteogenesis imperfecta (OI) is a systemic disease that may involve both the middle and inner ears (Chapter 689). Hearing loss occurs in about 20% of young children and as many as 90% of adults with this disease. The hearing loss is most commonly conductive because of abnormalities of the ossicles, but SNHL may occur if other areas of the otic capsule become affected. If the hearing loss is severe enough, a hearing aid may be a preferable alternative to surgical correction of the fixed stapes, because stapedectomy in children with OI can be technically very difficult, and the disease and the hearing loss may be progressive.

Osteopetrosis, a very uncommon skeletal dysplasia, may involve the temporal bone, including the middle ear and ossicles, resulting in a moderate to severe, usually conductive hearing loss. Recurrent facial nerve paralysis may also occur as a result of excess bone deposition; each time it occurs, less facial function may return (Chapter 687).

Chapter 632 - Traumatic Injuries of the Ear and Temporal Bone

Joseph Haddad Jr.

Auricle and External Auditory Canal.

Hematoma, an accumulation of blood between the perichondrium and the cartilage, may follow trauma to the pinna; this is a common sports injury in teenagers related to wrestling or boxing. Immediate needle aspiration or, when the hematoma is extensive or recurrent, incision and drainage and a pressure dressing are necessary to prevent perichondritis, which can result in a cauliflower ear deformity.

Frostbite of the auricle should be managed by rapidly rewarming the exposed pinna with warm irrigation or warm compresses.

Foreign bodies in the external canal are common in childhood. These can often be removed without general anesthesia if the child is informed about the procedure (if old enough to understand it) and is properly restrained; if an adequate headlight, surgical head otoscope, or otomicroscope is used for visualizing the object; and if appropriate instruments, such as alligator forceps, wire loops or a blunt cerumen curette, or suction are used, depending on the shape of the object. Gentle irrigation of the ear canal with body temperature water or saline may be used to remove very small objects, but only if the tympanic membrane (TM) is intact. Attempted removal of an object from a struggling child, or with poor visualization and inadequate tools, results in a terrified child with a swollen and bleeding ear canal and may then mandate general anesthesia for removal of the object. More difficult foreign bodies, especially those that are large, deeply embedded or associated with canal swelling, are best removed under general anesthesia. Disk batteries are removed emergently because they leach a basic fluid that can cause severe tissue destruction. Insects in the canal are first killed with mineral oil or lidocaine, and are then removed under otomicroscopic examination.

After a foreign body is removed from the external canal, the TM should be carefully inspected for possible traumatic perforation or for a pre-existing middle-ear effusion. If a foreign body has resulted in acute inflammation of the canal, treatment as described for acute external otitis should be instituted.

Tympanic Membrane and Middle Ear.

Traumatic perforation of the TM usually occurs as a result of a sudden external compression

(a slap) or penetration by a foreign object (a stick or cotton-tipped applicator). The perforation may be linear or stellate and is most frequently in the anterior portion of the pars tensa when it is caused by compression; it may be in any quadrant of the TM when caused by a foreign object. Systemic antibiotics and topical otic medications are not required unless suppurative otorrhea is present. Close follow-up examination is necessary to ensure that spontaneous healing occurs. If the TM does not heal within several months, surgical graft repair should be considered. As long as the perforation is present, otorrhea may occur from water entering the middle ear from the ear canal, which can occur during swimming or bathing; appropriate precautions should be taken. Perforations resulting from penetrating foreign bodies are less likely to heal than those caused by compression. Audiometric examination reveals a conductive hearing loss (CHL), with larger air-bone gaps seen in larger perforations. Immediate surgical exploration is indicated if the injury is accompanied by one or more of the following: vertigo, nystagmus, severe tinnitus, moderate to severe hearing loss, or cerebrospinal fluid (CSF) otorrhea. At the time of exploration, it is necessary to inspect the ossicles, especially the stapes, because they may have been dislocated or fractured; examination also is made for sharp objects that may have penetrated the oval or round windows. If the stapes has been subluxed or dislocated into the oval window or if either the oval or round window has been penetrated, sensorineural hearing loss (SNHL) results.

Perilymphatic fistula (PLF) may occur after sudden barotrauma or an increase in CSF pressure. This condition is suspected in a child who develops a sudden SNHL or vertigo after physical exertion, deep water diving, air travel, playing a wind instrument, or significant head trauma. The leak characteristically is at the oval or the round window and may be associated with congenital abnormalities of these structures or an anatomic abnormality of the cochlea or semicircular canals. PLFs occasionally close spontaneously, but immediate surgical repair of the fistula is recommended to control vertigo and to stop any progression of the SNHL; even timely surgery does not usually restore the SNHL. No reliable test is known for PLF, so middle-ear exploration is required for diagnosis and treatment.

Temporal Bone Fractures.

Children are particularly prone to basilar skull fractures, which usually involve the temporal bone. From 70% to 80% of temporal bone fractures are longitudinal and are commonly manifested by bleeding from a laceration of the external canal or tympanic membrane; postauricular ecchymosis (**Battle sign**); hemotympanum (blood behind an intact TM); CHL resulting from TM perforation, hemotympanum, or ossicular injury; delayed onset of facial paralysis (which usually improves spontaneously); and temporary CSF otorrhea or rhinorrhea (from CSF running down the eustachian tube). Transverse fractures of the temporal bone have a graver

prognosis than longitudinal fractures and are often associated with immediate facial paralysis. Facial paralysis may improve if caused by edema, but surgical decompression of the nerve is often recommended, if there is no evidence of clinical recovery and facial nerve studies are unfavorable. If the facial nerve has been transected, surgical decompression and anastomosis offer the possibility of some functional recovery. Transverse fractures are also associated with severe SNHL, vertigo, nystagmus, tinnitus, nausea, and vomiting associated with loss of cochlear and vestibular function; hemotympanum; rarely, external canal bleeding; and CSF otorrhea, either in the external auditory canal or behind the TM, which may exit the nose via the eustachian tube.

If temporal bone fracture is suspected or seen on radiographs, gentle examination of the pinna and ear canal is indicated; lacerations or avulsion of soft tissue is common with temporal bone fractures. Vigorous removal of external auditory canal blood clots or tympanocentesis is not indicated, because clot removal may further dislodge the ossicles or reopen CSF leaks. Some have advocated prophylactic parenteral administration of antibiotics when CSF otorrhea or rhinorrhea is present, but this is controversial. If a patient is afebrile and the drainage is not cloudy, watchful waiting without antibiotics is indicated. Surgical intervention is reserved for children who require repair of a nonhealing TM perforation, who have suffered dislocation of the ossicular chain, or who need decompression of the facial nerve. SNHL can also follow a blow to the head without an obvious fracture of the temporal bone (labyrinthine concussion).

Acoustic Trauma.

This results from exposure to high-intensity sound (fireworks, gunfire, rock music, heavy machinery) and is initially manifested by a temporary decrease in hearing threshold, most commonly at 4,000?Hz on an audiometric examination, and tinnitus. If the sound exceeds 85?dB but is less than 140?dB, the loss is usually temporary (after a rock concert), but both the hearing loss and the tinnitus may become permanent with chronic noise exposure; the frequencies from 3,000 to 6,000?Hz are most often involved. Sudden, extremely loud (>140?dB), short-duration noises with loud peak components (gunfire, bombs) may cause permanent hearing loss after a single exposure. Ear protection and avoidance of chronic exposure to loud noise are preventive measures. Hearing loss due to chronic noise exposure should be entirely preventable.

Chapter 633 - Tumors of the Ear and Temporal Bone

Joseph Haddad Jr.

Benign tumors of the external canal include *osteomas* and *monostotic* and *polyostotic fibrous dysplasia*. Osteomas present as bony masses in the canal and require removal only if hearing is impaired or external otitis results; osteomas may be confused clinically with exostoses.

Eosinophilic granuloma, which may occur in isolation or as part of the systemic Langerhans cell histiocytosis, should be suspected in patients with otalgia, otorrhea (sometimes bloody), hearing loss, abnormal tissue within the middle ear or ear canal, and roentgenographic findings of a sharply delineated destructive lesion of the temporal bone. Definitive diagnosis is made by biopsy. Treatment depends on the site of the lesion and whether it is “eosinophilic granuloma,” a unifocal or multifocal lesion of the bone that has a more benign course. Depending on the site, it may be treated by surgical excision, curettage, or local radiation (Chapter 499). If the lesion is part of a systemic presentation of Langerhans cell histiocytosis, chemotherapy in addition to local therapy (surgery with or without radiation) is indicated. Long-term follow-up is necessary whether the temporal bone lesion is a single isolated one or part of a multisystem disease.

Symptoms and signs of *rhabdomyosarcoma* originating in the middle ear or ear canal include a mass or polyp in the middle ear or ear canal, bleeding from the ear, otorrhea, otalgia, facial paralysis, and hearing loss. Other cranial nerves also may be involved. Diagnosis is based on biopsy, but the extent of disease is determined by both CT and MRI of the temporal bone, skull base, and brain. Classification is generally according to the stage as outlined in the current International Rhabdomyosarcoma Study group system. Management usually involves a combination of chemotherapy, radiation, and surgery (Chapter 492.1).

Non-Hodgkin lymphoma and *leukemia* may also present in the temporal bone, although it is rare as the initial presentation in

these diseases. Although primary neoplasms of the middle ear are very uncommon

in children, they include adenoid cystic carcinoma, adenocarcinoma, and squamous cell carcinoma. Benign tumors of the temporal bone include glomus tumors. The initial signs and symptoms of the more common nasopharyngeal neoplasms (angiofibroma, rhabdomyosarcoma, epidermoid carcinoma) may be associated with insidious onset of chronic otitis media with effusion (often unilateral); a high index of suspicion is needed for diagnosing these tumors accurately. **REFERENCES**

Part 30 - The Skin

Chapter 634 - Morphology of the Skin

Epidermis.

The mature epidermis is a stratified epithelial tissue composed predominantly of *keratinocytes*. The lowest keratinocyte layer, the basal cell layer, is constantly renewing the epidermis by mitotic division of the basal cells. Keratinocyte stem cells originate from hair follicles. Individual keratinocytes mature through a process of epidermal differentiation that results in the barrier portion of the epidermis, the stratum corneum. When composed of mature, differentiated keratinocytes, the stratum corneum is 10–50?µm thick. Damage to the stratum corneum increases skin permeability and may increase the potential for skin or systemic infection or systemic toxicity to topically applied medications or chemicals.

The continuous renewal of the surface keratinocytes of the epidermis normally proceeds in an orderly fashion as the cells of the basal cell layer move upward to the stratum corneum. The total life span from mitotic division of the basal cell until loss from the stratum corneum is approximately 28 days. In hyperproliferative diseases such as psoriasis, the movement of the cells is more rapid. The newly arrived keratinocytes in the stratum corneum are not fully differentiated and form a defective barrier. Keratinocytes are joined together by attachment plaques, the desmosomes. Cytoplasmic tonofibrils project to the desmosome and aid in cell attachment. Autoantibodies to various desmosomal adhesion molecules cause acantholysis (detachment of joined keratinocytes with bullae formation).

In addition to keratinocytes, the epidermis contains three additional cell types. The *melanocytes* are pigment-forming cells, which are responsible for skin color. Melanocytes produce melanosomes containing melanin. Epidermal melanocytes are derived from the neural crest and migrate to the skin during embryonic life. They reside in the interfollicular epidermis and in the hair follicles and increase in number in the epidermis by mitosis or migration of additional cells into the epidermis. *Merkel cells* are nerve-associated epidermal cells that may be important in the sensation of

touch and in skin development. *Langerhans cells* are dendritic cells of the mononuclear phagocyte system. They contain a specific organelle, the Birbeck granule. These cells are derived from bone marrow and participate in immune reactions in the skin, playing an active part in antigen presentation and processing.

Dermis.

The dermis forms a tough, pliable, fibrous supporting structure between the epidermis and the subcutaneous fat. It consists of collagen and elastic and reticulin fibers embedded in an amorphous ground substance; it contains blood vessels, lymphatics, neural structures, eccrine and apocrine sweat glands, hair follicles, sebaceous glands, and smooth muscle. Morphologically, the dermis can be divided into two layers: the superficial papillary layer that interdigitates with the rete ridges of the epidermis and the deeper reticular layer that lies beneath the papillary dermis. The papillary layer is less dense and more cellular, whereas the reticular layer appears more compact because of the coarse network of interlaced collagen and elastic fibers.

The junction of the epidermis and dermis is the *basement membrane zone*. This complex structure is a result of contributions from both epidermal and mesenchymal cells. The dermoepidermal junction extends from the basal cell plasma membrane to the uppermost region of the dermis. Ultrastructurally, the basement membrane appears as a trilaminar structure, consisting of a *lamina lucida* immediately adjacent to the basal cell plasma membrane, a central *lamina densa*, and the *subbasal lamina* on the dermal side of the lamina densa. Several structures within this zone act to anchor the epidermis to the dermis. The plasma membrane of basal cells contains electron-dense plates known as hemidesmosomes; tonofilaments course within basal cells to insert at these sites. Anchoring filaments originate in the plasma membrane, primarily near the hemidesmosomes, and insert into the lamina densa. Anchoring fibrils, composed predominantly of type VII collagen, extend from the lamina densa into the uppermost dermis where they insert into anchoring plaques. The composition of the basement membrane as well as its role in skin disease, particularly the vesiculobullous disorders, is the subject of intensive investigation. Molecular defects in basement membrane components have been shown to underlie several of the blistering diseases (see Chapter 644).

The predominant dermal cell is a spindle-shaped *fibroblast* that is responsible for the synthesis of collagen, elastic fibers, and mucopolysaccharides. Phagocytic histiocytes, mast cells, and motile leukocytes are also present. The gelatinous ground substance serves as a supporting medium for the fibrillar and cellular components and as a storage place for a substantial portion of body water. Nutrients are supplied to both epidermis and dermis by the dermal blood vessels.

Subcutaneous Tissue.

Panniculus, or subcutaneous tissue, consists of fat cells and fibrous septa that divide it into lobules and anchor it to the underlying fascia and periosteum. Blood vessels and nerves are also present in this layer, which serves as a storage depot for lipid, an insulator to conserve body heat, and a protective cushion against trauma.

Appendageal Structures.

These structures are derived from aggregates of epidermal cells that become specialized during early embryonic development. Small buds (primary epithelial germs) appear during the 3rd fetal mo and give rise to hair follicles, sebaceous and apocrine glands, and the attachment bulges for the arrector pili muscles. Eccrine sweat glands are derived from separate epidermal downgrowths that arise during the 2nd fetal mo and are completely formed by the 5th mo. Formation of nails is initiated during the 3rd intrauterine mo.

Hair Follicles.

The hair follicle is the most prominent structure in the pilary complex, which includes the sebaceous gland, the arrector pili muscle, and, in areas such as the axillae, an apocrine gland. Hair follicles are distributed throughout the skin, except in the palms, soles, lips, and glans penis; if destroyed, they cannot regenerate. Individual follicles extend from the surface of the epidermis to the deep dermis, where the matrix cells

---

with the dermal papilla form a bulbous hair root. The growing hair consists of a bulb and a matrix from which the keratinized hair shaft is generated; the shaft consists of an inner medulla, a cortex, and an outer cuticular layer.

Human hair growth is cyclic, with alternate periods of growth (anagen) and rest (telogen). The length of the anagen phase varies from months to years. At birth, all hairs are in the anagen phase. Subsequent generative activity lacks synchrony, so that an overall random pattern of growth and shedding prevails. Scalp hair usually grows about 1?cm/mo.

The types of hair are fetal lanugo, terminal, and vellus. *Lanugo* hair is thin and short; this hair is shed before term and is replaced by vellus hair by 36–40 wk of gestation. *Terminal hair* is long and coarse and is found on the scalp, beard, eyebrows, eyelashes, and axillary and pubic areas. *Vellus hair* is short, soft, and frequently unpigmented and is distributed over the rest of the body. During puberty, androgenic hormone stimulation causes pubic, axillary, and beard hair to change from vellus hair to terminal hair.

Sebaceous Glands.

These glands occur in all areas except the palms of the hands and soles and dorsa of the feet, but they are most numerous on the face, upper chest, and back. Their ducts open into the hair follicles except on the lips, prepuce, and labia minora, where they emerge directly onto the mucosal surface. These holocrine glands are saccular structures that are often branched and lobulated and consist of a proliferative basal layer of small flat cells peripheral to the central mass of lipidized cells. The latter cells disintegrate as they move toward the duct and form the lipid secretion known as sebum, which consists of cellular debris, triglycerides, phospholipids, and cholesterol

esters. Sebaceous glands depend on hormonal stimulation and are activated by androgens at puberty. Fetal sebaceous glands are stimulated by maternal androgens, and their lipid secretion, together with desquamated stratum corneum cells, constitutes the vernix caseosa.

Apocrine Glands.

The apocrine glands are located in the axillae, areolae, perianal and genital areas, and the periumbilical region. These large, coiled, tubular structures continuously secrete an odorless milky fluid that is discharged in response to adrenergic stimuli, usually a result of emotional stress. Bacterial decomposition of apocrine sweat accounts for the unpleasant odor associated with perspiration. Apocrine glands remain dormant until puberty, when they enlarge and secretion begins in response to androgenic activity. The secretory coil of the gland consists of a single layer of cells enclosed by a layer of contractile myoepithelial cells. The duct is lined with a double layer of cuboidal cells and opens into the pilosebaceous complex. Although apocrine glands do not function in thermoregulation, they are involved in certain disease processes.

Eccrine Sweat Glands.

These glands are distributed over the entire body surface, including the palms and soles, where they are most abundant. Those on the hairy skin respond to thermal stimuli and serve to regulate body temperature by delivering water to the skin surface for evaporation; in contrast, sweat glands on the palms and soles respond mainly to psychophysiologic stimuli.

Each eccrine gland consists of a secretory coil located in the reticular dermis or subcutaneous fat and a secretory duct that opens onto the skin surface. Sweat pores can be identified on the epidermal ridges of the palm and fingers with a magnifying lens but are not readily visualized elsewhere. Two types of cells compose the single-layered secretory coil: small dark cells and large clear cells; these rest on a layer of contractile myoepithelial cells and a basement membrane. The glands are supplied by sympathetic nerve fibers, but the pharmacologic mediator of sweating is acetylcholine rather than epinephrine. Sweat consists of water, sodium, potassium, calcium, chloride, phosphorus, lactate, and small quantities of iron, glucose, and protein. The composition varies with the rate of sweating but is always hypotonic in normal children.

Nails.

Nails are specialized protective epidermal structures that form convex, translucent, tight-fitting plates on the distal dorsal surfaces of the fingers and toes. The nail plate, which is derived from a metabolically active matrix of multiplying cells situated beneath the posterior nail fold, grows forward at a rate of approximately 1?cm every 3 mo. The nail plate is bounded by the lateral and posterior nail folds; a thin eponychium (the cuticle) protrudes from the posterior fold over a crescent-shaped white area called the lunula. The pink color reflects the underlying vascular bed.

Chapter 635 - Evaluation of the Patient

History and Physical Examination.

Although many skin disorders are easily recognized by simple inspection, the history and physical examination are often necessary for accurate assessment. The entire body surface, mucous membranes, conjunctiva, hair, and nails should always be examined thoroughly under adequate illumination. The color, turgor, texture, temperature, and moisture of the skin and the growth, texture, caliber, and luster of the hair and nails should be noted. Skin lesions should be palpated, inspected, and classified on the bases of morphology, size, color, texture, firmness, configuration, location, and distribution. One must also decide whether the changes are those of the primary lesion itself or whether the clinical pattern has been altered by a secondary factor such as infection, trauma, or therapy.

Primary lesions are classified as macules, papules, patches, plaques, nodules, tumors, vesicles, bullae, pustules, wheals, and cysts. A *macule* represents an alteration in skin color but cannot be felt. When the lesion is larger than 1?cm, the term *patch* is used. *Papules* are palpable solid lesions smaller than 0.5–1?cm, whereas *nodules* are larger in diameter. *Tumors* are usually larger than nodules and vary considerably in mobility and consistency. *Vesicles* are raised, fluid-filled lesions less than 0.5?cm in diameter; when larger, they are called *bullae*. *Pustules* contain purulent material. *Wheals* are flat-topped, palpable lesions of variable size, duration, and configuration that represent dermal collections of edema fluid. *Cysts* are circumscribed, thick-walled lesions that are located deep in the skin; they are covered by a normal epidermis and contain fluid or semisolid material. Aggregations of papules and pustules are referred to as *plaques*.

Primary lesions may change into secondary lesions, or secondary lesions may develop over time where no primary lesion existed. Primary lesions are usually more helpful for diagnostic purposes than secondary lesions. Secondary lesions include scales, ulcers, erosions, excoriations, fissures, crusts, and scars. *Scales* consist of compressed layers of stratum corneum cells that are retained on the skin surface. *Erosions* involve focal loss of the epidermis, and they heal without scarring. *Ulcers* extend into the dermis and tend to heal with scarring. Ulcerated lesions inflicted by scratching are often linear or angular in configuration and are called *excoriations*. *Fissures* are caused by splitting or cracking;

they usually occur in diseased skin. *Crusts* consist of matted, retained accumulations of blood, serum, pus, and epithelial debris on the surface of a weeping lesion. *Scars* are end-stage lesions that can be thin, depressed and atrophic, raised and hypertrophic, or flat and pliable; they are composed of fibrous connective tissue. *Lichenification* is a thickening of skin with accentuation of normal skin lines that is caused by chronic irritation (rubbing, scratching) or inflammation.

If the diagnosis is not clear after a thorough examination, one or more diagnostic procedures may be indicated. Besides those discussed here, others are identified in appropriate subsections (e.g., biopsies or scrapings of scabies lesions and smears, cultures of vesicles and pustules for detection of virus or bacteria).

Biopsy of Skin.

Biopsy of skin is required for diagnosis in children only occasionally. *Punch biopsy* is a simple, relatively painless procedure and usually provides adequate tissue for examination if the appropriate lesion is sampled. The selection of a fresh, well-developed primary lesion is extremely important to obtain an accurate diagnosis. The site of the biopsy should have relatively low risk for damage to underlying dermal structures. The skin is anesthetized by application of EMLA cream and/or intradermal injection of 1–2% lidocaine (Xylocaine), with or without epinephrine, with a 27- or 30-gauge needle after cleansing of the site. A punch, 3 or 4?mm in diameter, is pressed firmly against the skin and rotated until it sinks to the proper depth. All three layers (epidermis, dermis, subcutis) should be contained in the plug. The plug should be lifted gently with forceps or extracted with a needle and separated from the underlying tissue with an iris scissors. Bleeding abates with firm pressure and with suturing. The biopsy specimen should be placed in 10% formaldehyde solution (Formalin) for appropriate processing.

Wood Lamp.

The Wood lamp transmits ultraviolet light mainly in a wavelength of 365?nm. The examination, which is performed in a darkened room, is useful in detecting hypopigmented macules and certain superficial fungal infections of the scalp. Blue-green fluorescence is detectable at the base of each infected hair shaft in ectothrix and in some endothrix infections. Scales and crusts may appear pale yellow, but this is not evidence of a fungal infection. Dermatophyte lesions of the skin (tinea corporis) do not fluoresce; macules of tinea versicolor, however, have a golden fluorescence under a Wood lamp. *Erythrasma*, an intertriginous infection caused by *Corynebacterium minutissimum*, may fluoresce pink-orange, whereas *Pseudomonas aeruginosa* is yellow-green under a Wood lamp. Discrete areas of altered pigment can often be visualized more clearly by using a Wood lamp, particularly if the pigmentary change is epidermal. Hyperpigmented lesions appear darker, and hypopigmented lesions (as in tuberous sclerosis) lighter than the surrounding skin.

Potassium Hydroxide (KOH) Preparation.

This provides a rapid and reliable method for detecting fungal elements of both yeasts and dermatophytes. Scaly lesions should be scraped at the active border for optimal recovery of mycelia and spores. Vesicles should be unroofed, and the blister

top should be clipped and placed on a slide for examination. In tinea capitis, infected hairs must be plucked from the follicle; scales from the scalp do not usually contain mycelia. A few drops of 20% KOH are added to the specimen, which is then gently heated over an alcohol lamp until it begins to bubble; alternatively, ample time (approximately 10–20?min) can be allowed for dissolution of the keratin. Alternatively, dimethyl sulfoxide (DMSO) can be included in the KOH solution. The preparation is examined under low-intensity light for fungal elements.

Tzanck Smear.

This is useful in the diagnosis of some viral infections (herpes simplex, varicella, herpes zoster, eczema herpeticum) and for the detection of acantholytic cells in pemphigus. An intact, fresh blister should be ruptured and drained of fluid. The base of the blister is then scraped with a dull-edged instrument, taking care to avoid drawing a significant amount of blood; the material is smeared on a clear glass slide and air dried. Staining with Giemsa stain is preferable, but Wright stain is acceptable. Balloon cells and multinucleated giant cells are diagnostic of herpesvirus infection; acantholytic epidermal cells are characteristic of pemphigus.

The *direct fluorescent assay* is more sensitive and specific. The keratinocytes are scraped from the base of the blister as described earlier. The laboratory stains the slide with labeled antibodies specific for varicella-zoster virus or herpes simplex virus. Observation of the slide with a fluorescence microscope documents the presence of the specific virus within the cells.

Immunofluorescence Studies.

Immunofluorescence studies of skin can be used to detect tissue-fixed antibodies to skin components and complement; characteristic staining patterns are specific for certain skin disorders. Serum can be used for identifying circulating antibodies. Skin biopsy specimens for direct immunofluorescence preparations should be obtained from involved sites except in those diseases for which perilesional skin or uninvolved skin is required (Table 635–1). A punch biopsy sample is obtained, and the tissue is placed in a special transport medium or immediately frozen in liquid nitrogen for transport or storage. Thin cryostat sections of the specimen are incubated with fluorescein-conjugated antibodies to the specific antigens.

Serum of patients can be examined by indirect immunofluorescence techniques using sections of normal human skin, guinea pig lip, or monkey esophagus as substrate. The substrate is incubated with fresh or thawed frozen serum and then with fluorescein-conjugated antihuman globulin. If the serum contains antibody to epithelial components, its specific staining pattern can be seen on fluorescence microscopy. By serial dilution, the titer of circulating antibody can be estimated.

635.1 Cutaneous Manifestations of Systemic Diseases

Selected diseases have signature skin findings, often as the presenting sign of illness, which can facilitate the assessment of complex medical patients (Table 635–2).

CONNECTIVE TISSUE DISEASES

Lupus Erythematosus.

Lupus erythematosus (LE) (see Chapter 148) is an idiopathic autoimmune inflammatory disease that may be multisystemic or confined to the skin.

SYSTEMIC LUPUS ERYTHEMATOSUS.

Systemic LE (SLE) is a multisystem disease but may present with erythematous patches in a photo distribution. The classic malar or "butterfly" rash of SLE may be the initial presentation and must be distinguished from other causes of a "red face," most notably seborrheic dermatitis, atopic dermatitis, and rosacea. Other cutaneous findings may help confirm the diagnosis of SLE including purpuric lesions, livedo reticularis, mucosal ulcerations, Raynaud phenomena, and nonscarring alopecia. The degree of cutaneous involvement often reflects the activity of underlying disease.

Histologically, cutaneous LE demonstrates varying degrees of epidermal atrophy, plugging of hair follicles, and a vacuolar alteration at an inflamed dermoepidermal junction. Immunoglobulin (IgM, IgG) and complement deposition in lesional skin may help confirm the diagnosis (see Table 635–1). Immune deposits in nonlesional sun-exposed skin are found in the majority of patients with SLE (lupus band test). Treatment of skin lesions includes sun protection and low-potency topical corticosteroids.

TABLE 635.1-1 -- **Immunofluorescent Findings in Immune-Mediated Cutaneous Diseases**

Disease	Involved Skin	Uninvolved Skin	Direct IF	Indirect IF	Circulating Antibodies
Dermatitis herpetiformis	Negative	Positive	Granular IgA ± C in papillary dermis	None	IgA antireticulum in 20–70%. Antiendomysial (IgA, IgG) and transglutaminase antibodies with celiac disease
Bullous pemphigoid	Positive	Positive	Linear IgG and C band in BMZ, occasionally IgM, IgA, IgE	IgG to BMZ in 70%	None
Pemphigus (all variants)	Positive	Positive	IgG in intercellular spaces of epidermis between keratinocytes	IgG to intercellular space	None
Pemphigus foliaceus	Positive	Positive	IgG to desmosomal glycoprotein, desmoglein1	Same as direct IF	None
Herpes gestationis	Positive	Positive	C3 at BMZ, occasionally IgG	IgG anti-BMZ	None
Linear IgA bullous dermatosis (chronic bullous dermatosis of childhood)	Positive	Positive	Linear IgA at BMZ, occasionally C	Low titer, rare IgA, anti-BMZ	None
Discoid lupus erythematosus	Positive	Negative	Linear IgG, IgM, IgA, and C3 at BMZ (lupus band)	None	ANA negative
Systemic lupus erythematosus	Positive	Variable; exposed to sun, 30–50%; nonexposed, 10–30%	Linear IgG, IgM, C3 at BMZ (lupus band)	None	ANA Anti-Ro (SSA) Anti-RNP Anti-DNA Anti-Sm
Henoch-Schönlein purpura	Positive	Negative	IgA around vessel walls	None	IgA rheumatoid factor, occasionally

C = complement; IF = immunofluorescent findings; Ig = immunoglobulin; ANA = antinuclear antibody; BMZ = basement membrane zone at the dermoepidermal junction.

NEONATAL LUPUS ERYTHEMATOSUS.

Neonatal LE (NLE) (see Chapter 148) presents during the first weeks to months of life as annular, erythematous, scaly plaques typically on the head, neck, and upper trunk. Ultraviolet light, including phototherapy for hyperbilirubinemia, may exacerbate or initiate cutaneous lesions. NLE is often misdiagnosed as infantile eczema, seborrheic dermatitis, or tinea corporis. Passive transfer of maternal IgG (e.g., anti-Ro) antibodies cause the transient skin lesions; antibody levels wane by 6 mo, generally resulting in clearance of the rash. Congenital heart block occurs in 50% of affected infants, but only 10% of affected infants have both skin and cardiac abnormalities. Noncardiac extracutaneous manifestations such as anemia, thrombocytopenia, and cholestatic liver disease are uncommon; later progression to SLE is rare. Maternal antibody (ANA) testing is indicated.

DISCOID LUPUS ERYTHEMATOSUS.

Discoid LE (DLE) is uncommon in early childhood and presents in late adolescence. The signature skin findings in DLE are chronic, erythematous, scaly, atrophic, telangiectatic plaques on sun-exposed skin that frequently heal with scarring and dyspigmentation. Extracutaneous features may include involvement of the nasal and oral mucosa, eyes, and nails. The differential diagnosis includes other photo dermatoses such as polymorphous light eruption, juvenile springtime eruption, and juvenile dermatomyositis. There is a distinct overlap between SLE and DLE with common histopathologic features and photo exacerbation; most patients with DLE have normal laboratory studies and do not progress to systemic disease. Topical sunscreens and steroids may be helpful; intralesional steroids and oral antimalarials (e.g., hydroxychloroquine) are used with severe disease.

Juvenile Dermatomyositis.

Characteristic skin findings are often the presenting sign of juvenile dermatomyositis (JDMS) (see Chapter 149). An ill-defined, erythematous to violaceous scaly, minimally pruritic eruption occurs in photo-distributed areas such as the face, upper trunk, and extensor extremities. Circumscribed periocular involvement of this “heliotrope” rash may take the appearance of “raccoon eyes,” particularly in young children. Distinctive papules overlying the knuckles (Gottron papules) are helpful in suggesting the diagnosis in the absence of associated muscle weakness. Other cutaneous features include nail fold and gingival margin telangiectasia, palmar hyperkeratosis (or “mechanic's hands”), and a poikilodermatous (dyspigmentation and telangiectasia) eruption over the shoulder girdle (“shawl sign”). Cutaneous features may precede the systemic illness, reflecting disease activity. The differential diagnosis includes atopic dermatitis, other connective tissue diseases, lichen planus, medication reactions, and infectious exanthems. The paucity of itch in JDMS may help eliminate some considerations. Histologically, lesional skin demonstrates epidermal atrophy and vacuolar degeneration at the dermoepidermal junction. JDMS is distinct from adult dermatomyositis in both presentation and prognosis. Pediatric patients have more difficulty with gastrointestinal vasculopathy and cutaneous calcifications, but are not at increased risk of malignancy.

Treatment includes both steroidal and nonsteroidal immunosuppressants, and photoprotection is vital to prevent skin flares.

Scleroderma.

Scleroderma (see Chapter 150) is an inflammatory disorder of unknown etiology that, like LE, can be either localized to the skin or affect multiple organ systems. Localized scleroderma, or *morphea*, has several distinctive presentations. The most common is a solitary circumscribed patch of erythema that evolves into an indurated, sclerotic, atrophic plaque, later healing, or “burning out” with pigment change. Morphea can affect any area of skin, but when confined to the frontal scalp, forehead, and midface in a linear band, is referred to as linear scleroderma or “en coup de sabre.” This form of morphea carries a poorer prognosis because of the associated underlying musculoskeletal atrophy that can be cosmetically disfiguring. The differential diagnosis includes granuloma annulare, necrobiosis lipoidica, lichen sclerosis et atrophicus, and late stage Lyme disease (acrodermatitis chronica atrophicans). Histology is characterized by thickening or sclerosis of the dermis with collagen degeneration. Morphea tends to persist with gradual outward expansion on the skin until spontaneous or induced cessation of the inflammatory phase after months to years. Topical steroids

---

TABLE 635.1-2 -- Characteristics of Cutaneous Signs of Syster

Disease	Age of Onset	Skin Lesions	Distribution	Diagnostic Evaluations
Systemic lupus erythematosus	Any	Erythematous patches; palpable purpura; livedo reticularis; Raynaud phenomenon; thrombocytopenic and non-thrombocytopenic purpura	Photodistribution; “malar” face	ANA panel Anti-Double stranded DNA Leukopenia/ lymphopenia Thrombocytopenia Complement levels Urinalysis
Discoid lupus	Adolescents	Annular, scaly plaques; atrophy; dyspigmentation	Photodistribution	ANA
Neonatal lupus	Newborn To 6 mo	Annular, erythematous, scaly plaques	Photodistribution; head/neck	ANA Anti-ro
Juvenile dermatomyositis	Any	Erythematous to violaceous scaly, macules; discrete papules overlying knuckles	Periocular face; shoulder girdle; extensor extremities; knuckles; palms	ANA Jo-1 Ab Aldolase CK LDH

Henoch-Schönlein purpura	Children and adolescents	Purpuric papules and plaques	Buttocks; lower extremities	Urinalysis Bun/Cr Skin biopsy
Kawasaki disease	Infants, children	Erythematous maculopapular to urticarial plaques; acral and groin erythema, edema, desquamation	Diffuse	Leukocytosis ESR CRP Thrombocytosis
Inflammatory bowel disease	Children and adolescents	Aphthae; erythema nodosum; pyoderma gangrenosum; thrombophlebitis	Oral ulcers; perianal fissures	ESR Thrombocytosis Radiographic abnormalities
Sweet syndrome	Any	Infiltrated erythematous, edematous plaques	Diffuse	Skin biopsy Leukocytosis ESR
Graft versus host disease	Any	Acute: erythema, papules, vesicles, bulla	Head and neck; palms/soles; diffuse	Skin biopsy Liver function
Hypersensitivity reaction	Any	Erythema; urticarial macules and plaques	Diffuse	Liver function Eosinophilia Atypical lymphocytosis
Serum sickness-like reaction	Any	Edematous, purpuric plaques	Acral; diffuse	ESR

ESR = erythrocyte sedimentation rate; ANA = antinuclear antibodies; LDH = lactate dehydrogenas protein.

may help shorten the disease course; however, significant postinflammatory pigment alteration often persists.

Systemic scleroderma frequently presents with acral (e.g., sclerodactyly, ulceration, nail fold telangiectasia, or Raynaud phenomena) and other cutaneous changes (e.g., pinched nose, furrowed perioral skin, or "scleroderma facies") (see Chapter 150). Overlap syndromes such as CREST and mixed connective tissue disease may include some physical and laboratory features of scleroderma.

VASCULITIDES

The vasculitides (see Chapter 157) encompass a broad group of disorders having considerable overlap with connective tissue diseases. Immune-mediated inflammation of blood vessels of varying size may be caused by an underlying inflammatory state, infection, medication, or malignancy. Common clinical features include palpable nonthrombocytopenic purpuric skin lesions, arthritis, fever, myalgia, fatigue, and weight loss, as well as an elevated erythrocyte sedimentation rate. Extracutaneous organ involvement includes the joints, lungs, kidneys, and central nervous system.

Henoch-Schönlein Purpura.

Henoch-Schönlein purpura (HSP) is a vasculitis that presents with purpuric lesions prominently on the buttocks and lower extremities of school-aged children. Infantile hemorrhagic edema (IHE) shares some clinical features with HSP but appears in infants and toddlers. IHE is characterized by circumscribed purpuric papules and plaques on the trunk and extremities, but unlike HSP, commonly affects the face and lacks systemic signs or symptoms. HSP must also be differentiated from infectious causes of purpuric skin lesions such as meningococcemia, Rocky Mountain spotted fever, and purpuric viral exanthems such as those caused by enteroviruses, as well as from juvenile rheumatoid arthritis and other vasculitides.

Kawasaki Disease.

Kawasaki disease (KD), (see Chapter 156), is a clinical diagnosis based on both cutaneous and extracutaneous features. The skin eruption of KD may be polymorphic, presenting variously with urticarial, maculopapular, or morbilliform patches and plaques on the trunk and extremities, but early involvement in the groin region may be an initial clue to the diagnosis. Acral edema and desquamation also are prominent features, but typically occur later. Conjunctivitis, often with

sparing of the limbus, and lingual plaques ("white strawberry tongue") that shed to produce denuded, erythematous patches with prominent papilla ("strawberry tongue") are classic mucocutaneous features. Histopathologic findings in the skin are nonspecific and generally do not assist in distinguishing other differential considerations such as a viral or bacterial exanthem or medication reaction.

Behçet Disease.

Behçet disease (see Chapter 151) is multisystemic disease that includes oral and genital ulceration and ocular disease (uveitis, relapsing iridocyclitis). Recurrent aphthous stomatitis is present in up to 98% of patients, and is commonly the presenting symptom. Genital ulcerations may resemble aphthae and can occur on the penis or scrotum, and may be particularly painful in females. Additional skin findings may include folliculitis, purpuric lesions, erythema nodosum, and pustule formation after venipuncture or skin trauma ("pathergy"). Differential diagnosis of oral lesions includes recurrent aphthous stomatitis, herpes simplex, and less common oculocutaneous syndromes (e.g., MAGIC syndrome: mouth and genital ulcers with inflamed cartilage). Skin biopsy demonstrates either leukocytoclastic or lymphocytic vasculitis. Oral lesions may respond to swish and spit/swallow preparations variably including corticosteroids, antihistamines, antibiotics, and analgesics.

GASTOINTESTINAL DISEASES

Inflammatory Bowel Disease.

Ulcerative colitis (see Chapter 317) presents with cutaneous manifestations in up to 30% of patients. Aphthous ulcers are common and seem to worsen with gastrointestinal symptoms. Erythema nodosum, occurring in up to 10%, presents as warm, erythematous plaques often on the distal, lower extremities. Pyoderma gangrenosum is a focal, ulcerative process that has distinctive, inflamed, “undermined” borders and a purulent, boggy center. Thrombophlebitis also occurs at an increased rate in patients with ulcerative colitis. In most cases, treatment of the underlying disease state improves the cutaneous sequelae.

Crohn disease, or regional enteritis (see Chapter 317), classically presents with perianal fissures, abscesses, sinuses, and fistulas, and these features may be presenting signs of illness. Like ulcerative colitis, aphthae, erythema nodosum, and pyoderma gangrenosum occur at increased frequency and may improve with treatment of underlying disease. Noncaseating granulomatous inflammation is seen on routine histopathology, and when found in skin not contiguous with the intestinal tract, is labeled “metastatic Crohn disease.” Metastatic lesions may present as solitary or multiple, localized, plaques or nodules and may be on perianal, perioral, or other cutaneous surfaces, including scars or ileostomy sites. Standard therapy includes immunosuppressive medications, nutritional support, and surgery for complications.

CUTANEOUS MANIFESTATIONS OF MALIGNANCY

Internal malignancies may find cutaneous expression by several mechanisms. Cutaneous metastases may present as firm nodules at any cutaneous site, including the scalp. Distinctive paraneoplastic reaction patterns may result in sometimes striking rashes. Some genetic syndromes have increased malignancy risk that may be suggested initially by cutaneous signs.

Sweet Syndrome.

Also known as acute febrile neutrophilic dermatosis, Sweet syndrome (see Chapter 157) presents abruptly with tender, erythematous, edematous plaques or nodules on any area of the skin, often accompanied by fever, anemia, and leukocytosis. Diagnosis is confirmed by the presence of a dense neutrophilic infiltrate without evidence of vasculitis. The differential diagnosis includes pyoderma gangrenosum, cellulites, erythema multiforme, Behçet syndrome, and erythema nodosum. The etiology of Sweet syndrome is unknown but may be due to a hypersensitivity reaction to a bacterial, viral, or tumor antigen, and may occur in association with Behçet disease. Even though Sweet syndrome may occur without an identifiable etiology, investigation for infection or malignancy is warranted. In children, Sweet syndrome has been associated with otitis media, osteomyelitis, aseptic meningitis, HIV, and leukemia. In adults, 15% of patients have an associated malignancy, most commonly hematologic. Sweet syndrome is sensitive to oral corticosteroids.

Necrolytic Migratory Erythema.

Necrolytic migratory erythema (NME), or glucagonoma syndrome, is a distinctive migratory erythema that may signal an underlying neoplasm, such as an alpha-cell pancreatic tumor underlying the eruption of NME. Polycyclic erythematous patches and plaques on the trunk, extremities, and groin occur in association with glossitis, and cheilitis. Elevated glucagon levels, glucose intolerance, and hypoaminoacidemia confirm the diagnosis, and tumor resection leads to resolution of the rash.

Other cutaneous findings that may signal an underlying malignancy include pruritus, ichthyosis, acanthosis nigricans, urticaria, pemphigus, and erythroderma.

CUTANEOUS REACTIONS IN THE SETTING OF IMMUNOSUPPRESSION

Rashes in immunosuppressed patients are a diagnostic challenge. Medication reactions, infectious etiologies, and graft vs host disease (GVHD) are included in the differential diagnosis; cutaneous and histologic similarities can be confounding. The majority of medication reactions are mild morbilliform or exanthematous eruptions of little clinical consequence. Identifying the suspect medication may be difficult owing to the typically lengthy medication lists in this population. Features that may help identify suspect medications include rash onset relative to exposure, character of distribution and spread, associated symptoms, and laboratory data. Medication eruptions begin on the trunk 7–10 days after exposure, spread peripherally, and are associated with pruritus, and less commonly fever, arthralgia, and lymphadenopathy. Eosinophilia may support a diagnosis of drug eruption, but may be absent in the setting of bone marrow suppression. Antibiotics including penicillins, sulfa drugs, cephalosporins, nonsteroidal anti-inflammatory agents, anticonvulsants and, on occasion, aminoglycoside, are common offenders. Medication eruptions may resolve despite continued use of the offending agent, or they may progress to more severe involvement. A careful drug history, elimination of all nonessential suspect medications or change to medications of dissimilar class, and treatment of pruritus with emollients, topical steroids, antihistamines, and antipruritics are indicated. Skin biopsies are rarely useful in distinguishing medication eruptions from infectious exanthems, although GVHD, if sufficiently advanced, may have signature histopathologic findings.

Graft vs Host Disease.

GVHD (see Chapter 127) may have florid cutaneous expression in addition to characteristic extracutaneous features such as fever, mucositis, diarrhea, and hepatitis. Acute GVHD may be mistaken for a medication reaction or infectious exanthem based on the nonspecific erythematous maculopapular eruption that often starts focally and generalizes. Features that may suggest GVHD include timing of eruption (typically 1–3 wk post-transplant at the time of hematopoietic reconstitution), initial involvement of the head and neck including the ears, and subsequent spread to the trunk, extremities, and palms and soles. Chronic GVHD, which occurs in approximately 20% of long-term transplant survivors, is seen most often in patients who have previously experienced acute disease. Cutaneous manifestations of chronic GVHD are distinctive, with sclerotic, dyspigmented scaly plaques and

lichenoid papules predominating. Treatment includes systemic

immunosuppression supplemented by topical steroids, antihistamines, antipruritics, and emollients. Chronic disease may also respond to photochemotherapy (e.g., PUVA), plasmapheresis, and thalidomide. Topical immunomodulators such as tacrolimus may offer new avenues of therapy for this difficult condition. The pediatrician should also be mindful of GVHD in susceptible nontransplant settings, such as in the severely immunosuppressed neonate or infant in response to therapeutic transfusion of blood products, the fetus with congenital immunodeficiency secondary to transplacental passage of maternal lymphocytes, and the older child with malignancy who has received nonirradiated blood products.

MULTISYSTEMIC MEDICATION REACTIONS (see Chapter 139)

Most cutaneous reactions that result from the use of systemic medications are confined to the skin and resolve without sequelae after discontinuation of the offending agent. More severe drug eruptions may be life threatening, making rapid recognition vital. (See *Stevens-Johnson syndrome* and *toxic epidermal necrolysis*.)

Hypersensitivity Syndrome.

This syndrome is classically seen 1–4 wk after initial exposure to an aromatic anticonvulsant and often presents with the triad of fever, rash, and hepatitis. The skin rash is characterized by a pruritic, diffuse, erythematous to urticarial eruption of coalescing plaques. Prominent periocular edema, cervical lymphadenopathy, pharyngitis, and malaise accompany this dramatic cutaneous eruption. Eosinophilia occurs in up to 30% of patients; atypical lymphocytosis is common. Hepatitis ranging from mild transaminitis to frank hepatic failure may be accompanied by interstitial nephritis, pneumonitis, and encephalitis. Late-onset (several months) thyroiditis and hypothyroidism may occur as a result of antimicrosomal antibodies directed against thyroid peroxidases involved in drug metabolism. A heritable defect in the epoxide hydrolase pathway, in the case of anticonvulsants, leads to accumulation of toxic metabolites, which react with lymphocytes. Anticonvulsants having the distinctive aromatic structure (carbamazepine, phenobarbital, Dilantin) have a high risk of triggering hypersensitivity syndrome in susceptible individuals and their first-degree relatives. The differential diagnosis includes Stevens-Johnson syndrome, into which some of these cases can evolve, viral exanthem, or GVHD in the appropriate clinical setting. In addition to anticonvulsants, sulfonamides may cause a similar constellation of symptoms on first exposure due to abnormalities in glutathione transferase pathways.

Withdrawal of the medication is the primary therapeutic intervention, with symptomatic treatment of itch and/or pain being universal. The use of corticosteroids is controversial in Stevens-Johnson syndrome, but it is useful in the setting of rapidly evolving hepatic or renal involvement in hypersensitivity syndrome. The role of intravenous immunoglobulin in hypersensitivity syndrome is unclear. Counseling regarding increased risk with like medications and sibling risk is important. Hypersensitivity reaction can flare, both in the skin and other organ systems, well after the medication has been withdrawn and initial improvement achieved, necessitating close follow-up for several months.

Serum Sickness–Like Reaction.

Serum sickness–like reaction (SSLR) presents with urticarial to purpuric, sharply marginated coalescing plaques and acral erythema/edema, often in association with arthritis, lymphadenopathy, and fever. Unlike true serum sickness, laboratory evidence of circulating immune complexes and multisystem involvement of vasculitis are typically absent. The differential diagnosis includes Kawasaki disease, connective tissue diseases, and hypersensitivity syndrome. SSLR is most commonly seen following exposure to cefaclor. The cause is unknown but a toxic metabolite is suspected. In contrast to hypersensitivity reaction, SSLR typically occurs after repeated drug exposures. Symptomatic treatment and medication withdrawal are recommended.

Chapter 636 - Principles of Therapy

Competent skin care requires a specific diagnosis, knowledge of the natural course of the disease, and appreciation of primary versus secondary lesions. If the diagnosis is uncertain, it is better to err on the side of less rather than more aggressive treatment. Even when the diagnosis is clear, an acute dermatitis may require gentle and bland therapy initially.

In the use of topical medication, consideration of vehicle is as important as the specific therapeutic agent. Acute weeping lesions respond best to wet compresses, followed by lotions or creams. For dry, thickened, scaly skin or when treating a contact-allergic reaction possibly due to a component of a topical medication, an ointment base is preferable. Gels and solutions are most useful for the scalp and other hairy areas. The site of involvement is of considerable importance because the most desirable vehicle may not be cosmetically or functionally appropriate, such as an ointment on the face or hands. A patient's preference should also play a part in the choice of vehicle because compliance is poor if a medication is not acceptable to a patient.

Most *lotions* are mixtures of water and oil that can be poured. After the water evaporates, the small amount of remaining oil covers the skin. Some *shake lotions* are a suspension of water and insoluble powder; as the water evaporates, cooling the skin, a thin film of powder covers the skin. *Creams* are emulsions of oil and water that are viscous and do not pour (more oil than in lotions). *Ointments* have oils and a small amount of water or no water at all; they feel greasy, lubricate dry skin, trap water, and may be occlusive. Ointments without water usually require no preservatives because microorganisms require water to survive.

Therapy should be kept as simple as possible, and specific written instructions about the frequency and duration of application should be provided. Physicians should become familiar with one or two preparations in each category and should learn to use them appropriately. Prescribing nonspecific proprietary medications that may contain sensitizing agents should be avoided. Certain preparations such as topical antihistamines and sensitizing anesthetics are never indicated.

Wet Dressings.

These dressings decrease pruritus, burning, and stinging sensations; they are indicated for acutely inflamed moist or oozing dermatitis. Although various astringent and antiseptic substances may be added to the solution, tap water compresses are just as effective.

OPEN WET DRESSINGS.

These dressings cool and dry the skin by evaporation and cleanse by removing crusts and exudate that cause further irritation if permitted to remain. The solution should be cool or tepid and consist of tap water, isotonic saline, or aluminum acetate (Burow solution) in a 1:20 or 1:40 dilution. Potassium permanganate is messy and offers no advantage. Boric acid can be toxic if absorbed and should ***never*** be used for

---

compresses. Dressings of multiple layers of Kerlix, gauze or soft cotton material should be saturated with the solution and remoistened as often as necessary. Compresses should be applied for 10–20?min at least every 4?hr and should be continued usually for 24–48?hr.

CLOSED WET DRESSINGS.

These dressings are indicated for abscesses. The solution should be warm, and the dressings should be covered with plastic to prevent evaporation. Closed wet dressings, if prolonged, cause maceration because they prevent evaporation and heat loss.

Bath Oils, Colloids, Soaps.

Bath oil has little benefit in the treatment of children. It offers little moisturizing effect while increasing the risk of injury during a bath. Bath oil may lubricate the surface of the bathtub, causing an adult or child to fall when stepping into the tub. Tar bath solutions (Balnetar, Zetar) can be prescribed and may be helpful for psoriasis and atopic dermatitis. *Colloids* such as starch powder or colloidal oatmeal (Aveeno) are soothing and antipruritic for some patients when added to the bath water. Oilated Aveeno contains mineral oil and lanolin derivatives for lubrication if the skin is dry. These can also lubricate the bathtub surface. Ordinary toilet *soaps* may be irritating and drying if patients have dry skin or dermatitis. Examples of soaps that are usually not harmful to skin are Dove, Lowila, Aveeno, Neutrogena, Basis, Alpha Keri, and Oilatum. When skin is acutely inflamed, avoidance of soap is advised. Some patients find that lipid-free cleansers containing cetyl alcohol (Cetaphil) are soothing.

Lubricants.

Lubricants, such as lotions, creams, and ointments, can be used as emollients for dry skin and as vehicles for topical agents such as corticosteroids and keratolytics. In general, ointments are the most effective emollients. Numerous commercial preparations are available in addition to standard products such as petrolatum, cold cream, stearin-lanolin cream, and hydrophilic ointment. Some patients do not tolerate ointments, and some may be sensitized to a component of the lubricant; some preservatives of creams (most commonly parabens) are sensitizers. Useful lubricating lotions include Lubriderm, Nutraderm, and Nivea. Creams include

Eucerin, Neutrogena, Nutraderm, Purpose, Vanicream, and Complex 15. Aquaphor is a cosmetically acceptable alternative to petrolatum. These preparations can be applied several times a day if necessary. Maximal effect is achieved when they are applied *immediately* to damp skin after a bath or shower. Sarna lotion contains menthol and camphor in an emollient vehicle for control of pruritus and dryness.

Shampoos.

Special shampoos containing sulfur, salicylic acid, antiseptics, and selenium sulfide (Selsun, Exsel) are useful for conditions in which there is scaling of the scalp. Most shampoos also contain surfactants and detergents. Shampoos with sulfur or salicylic acid include Ionil, Sebulex, Fostex, and Vanseb. Those with only antiseptic agents include DHS-Zinc, Danex, and Head and Shoulders. Tar-containing shampoos such as T-Gel, Ionil-T, Sebutone, and Polytar are useful for psoriasis and severe seborrheic dermatitis. They can be used as frequently as necessary to control scaling, but use should be limited to avoid irritation. Patients should be instructed to leave the lathered shampoo in contact with the scalp for 5–10?min.

Shake Lotions.

These lotions are useful antipruritic agents; they consist of a suspension of powder in a liquid vehicle. A water-dispersible oil may be added for lubrication. Calamine lotion is acceptable but tends to cake on the skin. A prototype lotion is zinc oxide 20?g, talc 20?g, glycerin 20?g, Alpha Keri 5?g, and water to make 120?g. These preparations can be used effectively in combination with wet dressings for exudative dermatitis. Cooling occurs as the lotion evaporates and moisture is absorbed by the powder deposited on the skin.

Powders.

Powders are hygroscopic and serve as absorptive agents in areas of excessive moisture. When dry, powders decrease friction between two surfaces. They are most useful in the intertriginous areas and between the toes, where maceration and abrasion may result from friction on movement. Coarse powders may cake; therefore, they should be of fine particle size and inert unless medication has been incorporated in the formulation. Zeasorb is a bland, finely milled, general purpose powder that can be applied to any area of the body.

Pastes.

These contain a fine powder in an ointment vehicle and are not often prescribed in current dermatologic therapy; in certain situations, however, they can be used effectively to protect vulnerable or damaged skin. A stiff zinc oxide paste is bland and inert and can be applied to the diaper area to prevent further irritation due to diaper dermatitis. Zinc paste should be applied in a thick layer completely obscuring the skin and is removed more easily with mineral oil than with soap and water.

Keratolytic Agents.

Urea-containing agents are hydrophilic; they hydrate the stratum corneum and make the skin more pliable. In addition, because urea dissolves hydrogen bonds and epidermal keratin, it is effective in treating scaling disorders. Concentrations of 10–25% are available in several commercial lotions and creams (Carmol 20, Carmol 10, Nutraplus, Aquacare HP), which can be applied once or twice daily as tolerated. *Salicylic acid* is an effective keratolytic agent and can be incorporated into various vehicles in concentrations up to 6% to be applied two to three times daily. Salicylic acid preparations should not be used in treating small infants or on large surface areas or denuded skin; percutaneous absorption may result in salicylism. The a-*hydroxy acids*, particularly *lactic acid* and *glycolic acid*, are available in commercial preparations (LactiCare, LacHydrin, Aqua Glycolic) or can be incorporated in an ointment vehicle such as petrolatum or Aquaphor in concentrations up to 5%. Eucerin Plus Creme contains both urea and lactic acid. The a-hydroxy acid preparations are useful for the treatment of keratinizing disorders and may be applied once or twice daily. Some patients complain of burning; in this case, the frequency of application should be decreased.

Tar Compounds.

Tars are obtained from bituminous coal, shale, petrolatum (coal tars), and wood. They are antipruritic and astringent and appear to promote normal keratinization. They may be useful for chronic eczema and psoriasis, and their efficacy may be increased if the affected area is exposed to ultraviolet (UV) light after the tar has been removed. *Tars should not be used in acute inflammatory lesions*. Tars are often messy and unacceptable because they may stain and they have an odor. Tars may be incorporated into shampoos, bath oils, lotions, and ointments. A useful preparation for pediatric patients is liquor carbonis detergens 2–5% in a cream or ointment vehicle. Tar gels (PsoriGel, Estargel, AquaTar) and tar in a light body oil (T-Derm) are relatively pleasant cosmetic preparations that cause minimal staining of skin and fabrics. Tars can also be incorporated into a vehicle with a topical corticosteroid. The frequency of application varies from one to three times daily, according to tolerance. Many children refuse to use tar preparations because of their odor and staining characteristics.

Antifungal Agents.

These agents are available as powders, lotions, creams, and ointments for the treatment of dermatophyte and yeast infections. Nystatin, naftifine (Naftin), and amphotericin B are specific for *Candida* and are ineffective in other fungal disorders. Tolnaftate is effective against dermatophytes but not effective for yeast. The spectrum for ciclopirox olamine includes the dermatophytes, *Malassezia furfur,* and *Candida albicans*. The azoles—miconazole, clotrimazole, econazole, oxiconazole, and ketoconazole (Nizoral)—have a similar broad spectrum. Terbinafine has greater activity against dermatophytes but poorer activity against yeasts than the azoles. The topical anti-fungal

agents should be applied one to two times a day for most fungal infections. All have low sensitizing potential; however, additives such as preservatives and stabilizers in the vehicles may cause allergic contact dermatitis. Whitfield's ointment (6% benzoic

acid and 3% salicylic acid) is a potent keratolytic agent that has also been used for the treatment of dermatophyte infections. Irritant reactions are common.

Topical Antibiotics.

Topical antibiotics have been used to treat local cutaneous infections for many years, although their efficacy, with the exception of mupirocin (Bactroban), has been questioned. Ointments are the preferred vehicles, and combinations with other topical agents, such as corticosteroids, are in general inadvisable. Whenever possible, the etiologic agent should be identified and treated specifically. Antibiotics in wide use as systemic preparations should be avoided because of the risk of sensitization. The sensitizing potential of certain other antibiotics, such as neomycin and nitrofurazone (Furacin), should be kept in mind. Mupirocin is the most effective topical agent currently available and is as effective as oral erythromycin in treatment of mild to moderate impetigo. Polysporin and bacitracin are not as effective as mupirocin or oral antibiotics.

Topical Corticosteroids.

Topical corticosteroids are potent anti-inflammatory agents and effective antipruritic agents. Successful therapeutic results are achieved in a wide variety of skin conditions. Corticosteroids fall into two classes: nonfluorinated preparations, such as hydrocortisone (Hytone), desonide (Tridesilon, Des Owen), hydrocortisone butyrate (Locoid), and mometasone furoate (Elocon), and fluorinated compounds, including triamcinolone (Kenalog, Aristocort), flurandrenolide (Cordran), fluocinolone (Synalar), betamethasone (Valisone, Benisone, Flurobate), and amcinonide (Cyclocort). The nonfluorinated steroids are usually of lesser potency and may cause fewer local and systemic side effects, whereas fluorinated steroids are potentially more harmful, particularly with long-term use. Other fluorinated compounds, for example, fluorocinonide (Lidex), halcinonide (Halog), betamethasone dipropionate (Diprolene), and clobetasol propionate (Temovate), are extremely potent and should be prescribed with care. Some of these compounds are formulated in several strengths based on their clinical efficacy and degree of vasoconstriction. Physicians using topical steroids should become familiar with several preparations and with the potency of the preparations used.

All corticosteroids can be obtained in various vehicles, including creams, ointments, solutions, gels, and aerosols. Absorption is enhanced by an ointment or gel vehicle, but the vehicle should be selected on the basis of the type of disorder and the site of involvement. Frequency of application should be determined by the potency of the preparation and the severity of the eruption. Applying a *thin film* two times daily usually suffices. Adverse local effects include cutaneous atrophy, striae, telangiectasia, hypopigmentation, and increased hair growth.

In selected circumstances, corticosteroids may be administered by intralesional injection (acne cysts, keloids, psoriatic plaques, alopecia areata, persistent insect bite reactions). This method of administration should be used only by experienced physicians.

Sunscreens.

Sunscreens are of two general types: (1) those that reflect all wavelengths of UV and visible spectrums, such as zinc oxide and titanium dioxide, and (2) a heterogeneous group of chemicals that selectively absorb energy of various wavelengths within the UV spectrum. Some sunscreens permit tanning without burning; others prevent both. In addition to the spectrum of light that is blocked, other factors to be considered include cosmetic acceptance, sensitizing potential, retention on skin while swimming or sweating, required frequency of application, and cost. Effective opaque total barrier agents are zinc oxide ointment, Covermark, Dermablend, and RVPaque. Para-aminobenzoic acid (PABA)-ethanol (Pabanol, PreSun) and cinnamate-benzophenone combinations (Maxafil, Solbar, Uval) effectively prevent transmission of solar UVB and at least some UVA wavelengths. PABA esters (Eclipse, Pabafilm, Sundown) afford partial protection. Lip protectants that absorb in the UVB range (Sunstick, Blistik, PreSun) are also available for patients with photo-induced lip disorders such as recurrent herpesvirus infections. Sunscreens are designated by sun protection factor (SPF). The SPF is defined as the amount of time to develop a mild sunburn with the sunscreen compared with the amount of time without the sunscreen. A minimum SPF factor of 15 is required for most fair-skinned individuals to prevent sunburn. The higher the SPF, the better the protection is against UVB rays. Examples of sunscreens offering maximal protection are Supershade, Photoplex, and Total Eclipse. The efficacy of these agents depends on careful attention to instructions for use. PABA-containing sunscreens should be applied at least 30?min before sun exposure to permit penetration of the epidermis. Most patients with photosensitivity eruptions require protection by agents that absorb UVB wavelengths; patients with porphyria, phototoxic eruptions, and some types of solar urticaria require agents with a broader spectrum of prevention (see Chapters 136 and 646).

Although sunscreens do confer photoprotection and may decrease the development of nevi, protection is incomplete against all harmful UV light. Sun avoidance is also important during the times when the sun is most intense, such as during midday. Clothing and hats offer additional sun protection.

Chapter 637 - Diseases of the Neonate

Minor evanescent lesions of newborn infants, particularly when florid, may cause undue concern. Most neonatal rashes of the entities described in this chapter are relatively common, benign, and transient; they do not require therapy.

Sebaceous Hyperplasia.

Minute, profuse, yellow-white papules are frequently found on the forehead, nose, upper lip, and cheeks of a term infant; they represent hyperplastic sebaceous glands. These tiny papules diminish gradually in size and disappear entirely within the first few weeks of life.

Milia.

Milia are superficial epidermal inclusion cysts that contain laminated keratinized material. The lesion is a firm papule, 1–2?mm in diameter, and pearly, opalescent white. Milia may occur at any age but in neonates are most frequently scattered over the face and gingivae and on the midline of the palate, where they are called *Epstein pearls*. Milia exfoliate spontaneously in

---

most infants and may be ignored; those that appear in scars or sites of trauma in older children may be gently unroofed and the contents extracted with a fine-gauge needle.

Sucking Blisters.

Solitary or scattered superficial bullae on the upper limbs of infants at birth are presumed to be induced by vigorous sucking on the affected part in utero. Common sites are the radial aspect of the forearm, thumb, and index finger. These bullae resolve rapidly without sequelae and should be distinguished from sucking pads (calluses), which are found on the lips in the first few months and are due to combined intracellular edema and hyperkeratosis. The diagnosis can be confirmed by observing the neonate suck the affected area.

Cutis Marmorata.

When a newborn infant is exposed to low environmental temperatures, an evanescent, lacy, reticulated red and/or blue cutaneous vascular pattern appears over most of the body surface. This vascular change represents an accentuated physiologic vasomotor response that disappears with increasing age, although it is sometimes discernible even in older children. Persistent and pronounced cutis marmorata occurs in Menkes disease, familial dysautonomia, and Cornelia de Lange, Down, and trisomy 18 syndromes. *Cutis marmorata telangiectatica congenita* is clinically similar, but the lesions are more intense, may be segmental, are persistent, and may be associated with loss of dermal tissue, epidermal atrophy, and ulceration. The condition improves in the 1st yr year of life, however, with half showing decreased vascular markings. The congenital form is associated with microcephaly, micrognathia, cleft palate, dystrophic teeth, glaucoma, short stature, and skull asymmetry.

Harlequin Color Change.

This rare but dramatic vascular event occurs in the immediate newborn period and is most common in low birthweight infants. It probably reflects an imbalance in the autonomic vascular regulatory mechanism. When the infant is placed on the side, the body is bisected longitudinally into a pale upper half and a deep red dependent half. The color change lasts only for a few minutes and occasionally affects only a portion of the trunk or face. Changing the infant's position may reverse the pattern. Muscular activity causes generalized flushing and obliterates the color differential. Repeated episodes may occur but do not indicate permanent autonomic imbalance.

Salmon Patch (Nevus Simplex).

Salmon patches are small, pale pink, ill-defined, vascular macules that occur most commonly on the glabella, eyelids, upper lip, and nuchal area of 30–40% of normal newborn infants. These lesions, which represent localized vascular ectasia, persist for several months and may become more visible during crying or changes in environmental temperature. Most lesions on the face eventually fade and disappear completely, but those on the posterior neck and occipital areas often persist. The facial lesions should not be confused with a port-wine stain, which is a permanent lesion. The salmon patch is usually symmetric, with lesions on both eyelids or both sides of midline. Port-wine stains are often larger and unilateral, and they usually end along the midline (see Chapter 640).

Mongolian Spots.

These blue or slate-gray macular lesions have variably defined margins; they occur most commonly in the presacral area but may be found over the posterior thighs, legs, back, and shoulders. They may be solitary or numerous and often involve large areas. More than 80% of black, Asian, and East Indian infants have these lesions, whereas the incidence in white infants is less than 10%. The peculiar hue of these macules is due to the dermal location of melanin-containing melanocytes that are presumably arrested in their migration from neural crest to epidermis. Mongolian spots usually fade during the first few years of life but occasionally persist. Malignant degeneration does not occur. Widespread numerous lesions, particularly those in unusual sites, are unlikely to disappear. The characteristic appearance and congenital onset distinguish these spots from the bruises of child abuse.

Erythema Toxicum.

This benign, self-limited, evanescent eruption occurs in approximately 50% of full-term infants; preterm infants are affected less commonly. The lesions are firm, yellow-white, 1–2?mm papules or pustules with a surrounding erythematous flare (Fig. 637–1). At times, splotchy erythema is the only manifestation. Lesions may be sparse or numerous and clustered in several sites or widely dispersed over much of the body surface. Palms and soles are usually spared. Peak incidence occurs on the 2nd day of life, but new lesions may erupt during the first few days as the rash waxes and wanes. Onset may occasionally be delayed for a few days to weeks in premature infants. The pustules form below the stratum corneum or deeper in the epidermis and represent collections of eosinophils that also accumulate around the upper portion of the pilosebaceous follicle. The eosinophils can be demonstrated in Wright-stained smears of the intralesional contents. Cultures are sterile.

The cause of erythema toxicum is unknown. The lesions can mimic pyoderma, candidosis, herpes simplex, transient neonatal pustular melanosis, and miliaria but can be differentiated by the characteristic infiltrate of eosinophils and the absence of organisms on a stained smear. The course is brief, and no therapy is required. Incontinentia pigmenti and eosinophilic pustular folliculitis also have eosinophilic infiltration but can be distinguished by their distribution, histologic type, and chronicity.

Transient Neonatal Pustular Melanosis.

Pustular melanosis, which is more common in black than in white infants, is a transient, benign, self-limited dermatosis of unknown cause that is characterized by three types of lesions: (1) evanescent superficial pustules, (2) ruptured pustules with a collarette of fine scale, at times with a central hyperpigmented macule, and (3) hyperpigmented macules (Fig. 637–2). Lesions are present at birth, and one or all types of lesions may be found in a profuse or sparse distribution. Pustules represent the early phase of the disorder, and macules, the late phase. The pustular phase rarely lasts more than 2–3 days; hyperpigmented macules may persist for as long as 3 mo. Sites of predilection are the anterior neck, forehead, and lower back, although the scalp, trunk, limbs, palms, and soles may be affected.

The active phase shows an intracorneal or subcorneal pustule filled with polymorphonuclear leukocytes, debris, and an occasional eosinophil. The macules are characterized only by increased melanization of epidermal cells. Cultures and smears can be used to distinguish these pustules from those of erythema toxicum and pyoderma because they do not contain bacteria or dense aggregates of eosinophils. No therapy is required.

Figure 637-1 Erythema toxicum on the trunk of a newborn infant.

Figure 637-2 *A* and *B*, Transient neonatal pustular melanosis showing pustules, rings of scales, and hyperpigmented macules.

Infantile Acropustulosis.

Infantile acropustulosis generally has its onset at 2–10 mo of age; lesions are occasionally noted at birth. Black males have a predisposition for this eruption, but infants of both sexes and all races may be affected. The cause is unknown.

The lesions are initially discrete erythematous papules that become vesiculopustular within 24?hr and subsequently crust before healing. They are intensely pruritic, and a fresh outbreak is usually accompanied by fretfulness and irritability. Preferred sites are the palms of the hands and soles and sides of the feet, where the lesions may develop in profusion. A less dense eruption may be found on the dorsum of the hands and feet, ankles, and wrists. Pustules occasionally may occur elsewhere on the body. Each episode lasts 7–14 days, during which time pustules continue to appear in crops. After a 2–4 wk remission, a new outbreak follows. This cyclic pattern continues for about 2 yr; permanent resolution is often preceded by longer intervals of remission between periods of activity. Infants with acropustulosis are otherwise well.

Wright-stained smears of intralesional contents show abundant neutrophils or, occasionally, a predominance of eosinophils. Histologically, well-circumscribed, subcorneal, neutrophilic pustules, with or without eosinophils, are noted.

The *differential diagnosis* in neonates includes transient neonatal pustular melanosis, erythema toxicum, milia, cutaneous candidosis, and staphylococcal pustulosis. In older infants and toddlers, additional diagnostic considerations include scabies, and a history of previous scabies infection is common; dyshidrotic eczema; pustular psoriasis; subcorneal pustular dermatosis; and hand-foot-and-mouth disease. A therapeutic trial of a scabicide is warranted in equivocal cases.

Therapy is directed at minimizing discomfort for infants. Topical corticosteroid preparations or oral antihistamines decrease the severity of the pruritus and an infant's irritability. Dapsone 2?mg/kg/24?hr PO bid has been effective but has potentially serious side effects—notably, hemolytic anemia and methemoglobinemia—and should be used with caution.

Eosinophilic Pustular Folliculitis.

This is described as recurrent crops of pruritic, coalescing, follicular papulopustules on the face, trunk, and extremities. Fifty per cent of patients have peripheral eosinophilia exceeding 5%, and about one third (32%) have leukocytosis (>10,000/mm^3).

Infants make up less than 10% of all cases. The clinical and histologic appearance of this disorder in infants closely resembles that in immunocompetent adults, with minor exceptions. In infants, the lesions are most prominent on the scalp, although they also occur on the trunk and extremities and occasionally are found on the palms and soles. The classic annular and polycyclic appearance with centrifugal enlargement is not seen in infants. Adults have an eosinophilic infiltrate that invades sebaceous glands and the outer root sheath of hair follicles, often leading to spongiosis in the outer root sheath. The eosinophilic infiltrate in most infants, however, is perifollicular, without spongiosis in the outer root sheath. Because of the slightly different clinical findings and course in immunocompetent adults compared with infants or patients with acquired immunodeficiency syndrome, it has been proposed that eosinophilic pustular folliculitis (EPF) be subclassified into classic, human immunodeficiency virus–related, and infantile forms. The differential diagnosis includes erythema toxicum neonatorum, infantile acropustulosis, localized pustular psoriasis, pustular folliculitis, and transient neonatal pustular melanosis.

The pathogenesis of EPF is linked epidemiologically to sebaceous gland activity because lesions appear most commonly in association with hair follicles in areas of the body with a high density of sebaceous glands. Most theories on the pathogenesis of EPF invoke immunologic mechanisms in the initiation of lesions. Proposed etiologic factors in EPF include a cyclo-oxygenase–generated metabolite with chemotactic properties; an

exaggerated response to skin saprophytes or dermatophytes, leading to eosinophilic infiltration and destruction of the follicle; or autoantibodies directed against the intercellular substance of the lower epidermis or the cytoplasm of basal cells of the epidermis and the outer sheath of hair follicles.

Response of EPF to therapy is variable; no one specific treatment is the therapy of choice. Antimicrobials and medicated shampoos have been ineffective; mid-potency topical corticosteroids are modestly effective in the treatment of scalp lesions in infants.

Chapter 638 - Cutaneous Defects

Skin Dimples.

Cutaneous depressions over bony prominences and in the sacral area, at times associated with pits and creases, may occur in normal children and in association with dysmorphologic syndromes. Skin dimples may develop in utero as a result of interposition of tissue between a sharp bony point and the uterine wall, which leads to decreased subcutaneous tissue formation. A rare benign autosomal dominant anomaly presents with dimples near the acromion bilaterally in association with deletion of the long arm of chromosome 18. Dimples tend to occur over the patella in congenital rubella, over the lateral aspects of the knees and elbows in prune-belly syndrome, on the pretibial surface in camptomelic dwarfs, and in the shape of an H on the chin in whistling-face syndrome.

Sacral dimples are common, and may occur as an isolated finding or occur as part of multiple syndromes, including Bloom syndrome, Smith-Lemli-Opitz syndrome, 4p deletion syndrome, spina bifida occulta, and diastomyelia. Large size (>5?mm), increased distance from the anus (>2.5?cm), or association with a mass or other cutaneous stigmata (e.g., hair, nevus flammeus, hemangioma) should increase concern for underlying spinal dysraphism. Ultrasonography during the first 3 mo of life, before ossification of the posterior elements of the lower spine, may provide a cost-effective, noninvasive method for assessment of any associated lumbosacral abnormalities.

Redundant Skin.

Loose folds of skin must be differentiated from a congenital defect of elastic tissue or collagen such as cutis laxa, Ehlers-Danlos syndrome, or pseudoxanthoma elasticum. Redundant skin over the posterior part of the neck is common in the Turner, Noonan, Down, and Klippel-Feil syndromes; more generalized folds of skin occur in infants with trisomy 18 and short-limbed dwarfism.

Amniotic Constriction Bands.

Partial or complete constriction bands that produce defects in extremities and digits are found in 1/10,000–1/45,000 otherwise normal infants. Constrictive tissue bands are caused by primary amniotic rupture, with subsequent entanglement of fetal parts, particularly limbs, in shriveled fibrotic amniotic strands. This event is probably sporadic, with negligible risk of recurrence. Formation of constrictive tissue bands is associated with abdominal trauma, amniocentesis, and hereditary defects of collagen

such as Ehlers-Danlos syndrome or osteogenesis imperfecta. Constriction bands on the limbs may be removed by plastic surgical procedures (Chapter 97).

Adhesive bands involve the craniofacial area and are associated with severe defects such as encephalocele and facial clefts. Adhesive bands result from broad fusion between disrupted fetal parts and an intact amniotic membrane. The craniofacial defects do not appear to be caused by constrictive amniotic bands but result from a vascular disruption sequence with or without cephaloamniotic adhesion.

The *limb-body wall complex* (LBWC) involves vascular disruption early in development, affecting several embryonic structures; it includes at least two of the following three characteristics: exencephaly or encephalocele with facial clefts, thoracoschisis and/or abdominoschisis, and limb defects. Amniotic rupture may be the cause of embryonic vascular disruption, leading to the LBWC; however, LBWC has been reported in the absence of amniotic rupture.

Preauricular Sinuses and Pits.

Pits and sinus tracts anterior to the pinna may be a result of imperfect fusion of the tubercles of the first and second branchial arches. These anomalies may be unilateral or bilateral, may be familial, are more common in females and blacks, and at times are associated with other anomalies of the ears and face. Preauricular pits are present in branchio-otorenal dysplasia, an autosomal dominant disorder that consists of external ear malformations, branchial fistulas, hearing loss, and renal anomalies. When the tracts become chronically infected, retention cysts may form and drain intermittently; such lesions may require excision.

Accessory Tragi.

An accessory tragus typically appears as a single pedunculated, flesh-colored papule in the preauricular region anterior to the tragus. Less commonly, accessory tragi are multiple, are unilateral or bilateral, and may be located in the preauricular area, on the cheek along the line of the mandible, or on the lateral aspect of the neck anterior to the sternocleidomastoid muscle. In contrast to the rest of the pinna, which develops from the second branchial arch, the tragus and accessory tragi derive from the first branchial arch. Accessory tragi may occur as isolated defects or in chromosomal first branchial arch syndromes that include anomalies of the ears and face such as cleft lip, cleft palate, and mandibular hypoplasia. Accessory tragus is consistently found in *oculoauriculovertebral syndrome (Goldenhar syndrome).* Surgical excision is appropriate.

Branchial Cleft and Thyroglossal Cysts and Sinuses.

Cysts and sinuses in the neck may be formed along the course of the first, second, third, or fourth branchial clefts as a result of improper closure during embryonic life. Second branchial cleft cysts are the most common. The lesions may be unilateral or bilateral (2–3%) and may open onto the cutaneous surface or drain into the pharynx. Secondary infection is an indication for systemic antibiotic therapy. These anomalies may be inherited as autosomal dominant traits.

Thyroglossal cysts and fistulas are similar defects located in or near the midline of the neck; they may extend to the base of the tongue. A pathognomonic sign is vertical motion of the mass with swallowing and tongue protrusion. Cysts in the tongue base may be differentiated from an undescended lingual thyroid by radionuclide scanning. Unlike branchial cysts, a thyroglossal duct cyst often appears after an upper respiratory infection.

Supernumerary Nipples.

Solitary or multiple accessory nipples may occur in a unilateral or bilateral distribution along a line from the anterior axillary fold to the inguinal area. They are more common in black (3.5%) than white (0.6%) children. Accessory nipples may or may not have an areola and may be mistaken for congenital nevi. They may be excised for cosmetic reasons. Rarely, they undergo malignant change. Renal or urinary tract anomalies may occur in children with this finding.

Aplasia Cutis Congenita (Congenital Absence of Skin).

Developmental absence of skin is usually noted on the scalp as multiple or solitary (70%), noninflammatory, well-demarcated, oval or circular 1–2?cm ulcers. The appearance of lesions varies, depending on when they occurred during intrauterine development. Those that form early in gestation may heal before delivery and appear as an atrophic, fibrotic scar with associated alopecia, whereas more recent defects may present as an ulceration. Most occur at the vertex just lateral to the midline, but similar defects may also occur on the face, trunk, and limbs, where they are often symmetric. The depth of the ulcer varies. Only the epidermis and upper dermis may be involved, resulting in minimal scarring or hair loss, or the defect may extend to the deep dermis, subcutaneous tissue, and, rarely, to the periosteum, skull, and dura.

No unifying theory can account for all lesions of aplasia cutis congenita. *Diagnosis* is made on the basis of physical findings indicative of in utero disruption of skin development. Lesions are sometimes mistakenly attributed to scalp electrodes or obstetric trauma. Rather, they appear to be due to various factors, including genetic factors, teratogens, compromised vasculature to the skin, and trauma.

Although most individuals with aplasia cutis congenita have no other abnormalities, these lesions may be associated with isolated physical anomalies or with a number of malformation syndromes. Scalp lesions may be seen in association with distal limb reduction anomalies, generally with autosomal dominant inheritance, or sporadically in association with epidermal and organoid nevi. Aplasia cutis congenita may also be found in association with an overt or underlying embryologic malformation, such as meningomyelocele, gastroschisis, omphalocele, or spinal dysraphism. Aplasia cutis congenita in association with fetus papyraceus is apparently due to ischemic or thrombotic events in the placenta and fetus. Blistering or skin fragility and/or absence or deformity of nails in association with aplasia cutis congenita is a well-recognized presentation of epidermolysis bullosa. Maternal ingestion of the teratogen methimazole or intrauterine herpes simplex virus or varicella-zoster virus infection may also be associated with lesions of aplasia cutis congenita. Finally, aplasia cutis

congenita may also occur in the setting of a malformation syndrome such as several of the ectodermal dysplasias, trisomy 13 or 14, deletion of the short arm of chromosome 4, Johanson-Blizzard syndrome, focal facial dermal dysplasia, or focal dermal hypoplasia. Cutis aplasia may be confused with traumatic skin injury from monitoring devices and spontaneous atrophic patches (anetoderma) of prematurity.

Major *complications* are hemorrhage, secondary local infection, and meningitis. If the defect is small, recovery is uneventful, with gradual epithelialization and formation of a hairless atrophic scar over a period of several weeks (Fig. 638–1). Small bony defects usually close spontaneously during the 1st yr of life. Large or numerous scalp defects may require excision and primary closure if feasible, rotation of a flap to fill the defect, or the use of tissue expanders. Truncal and limb defects, despite large size, usually epithelialize and form atrophic scars, which can later be revised.

Focal Facial Ectodermal Dysplasia (Bitemporal Aplasia Cutis Congenita, Ectodermal Dysplasia of the Face).

This rare disorder is characterized by congenital atrophic scarlike lesions on the temples. Sweating is absent over the defects, the lateral one third of the eyebrows is sparse, and linear vertical wrinkles are present on the forehead. Autosomal dominant and autosomal recessive inheritance have been documented; both subgroups of patients lack associated facial anomalies. A subgroup, identified as *Setler syndrome*, is marked by full lips, coarse facies, and rugae around the lips and chin. Growth and development are generally normal.

Focal Dermal Hypoplasia (Goltz Syndrome).

This rare congenital mesoectodermal and ectodermal disorder is characterized by dysplasia

Figure 638-1 Healing solitary lesion of aplasia cutis congenita.

of connective tissue in the skin and skeleton. It presents with numerous soft tan papillomas. Other cutaneous findings include linear atrophic lesions; reticulated hypopigmentation and hyperpigmentation; telangiectasias; congenital absence of skin; angiofibromas presenting as verrucous excrescences; and papillomas of the lips, tongue, circumoral region, vulva, anus, and the inguinal, axillary, and periumbilical areas. Partial alopecia, sweating disorders, and dystrophic nails are additional less common ectodermal anomalies. The most frequent skeletal defects include syndactyly, clinodactyly, polydactyly, and scoliosis. Osteopathia striata are fine parallel vertical stripes noted on radiographs in the metaphyses of long bones; these are highly characteristic of focal dermal hypoplasia but are not pathognomonic. Many ocular abnormalities, the most common of which are colobomas, strabismus, nystagmus, and microphthalmia, are also characteristic. Small stature, dental defects, soft tissue anomalies, and peculiar dermatoglyphic patterns are also common. Mental deficiency occurs occasionally.

This familial disorder occurs principally in girls. It has been postulated that an X-linked dominant gene, lethal in hemizygous males, may account for the sex distribution. The linear pattern of skin and bone lesions may be due to random X-inactivation in females. Cases of father-daughter transmission, evidence for an autosomal locus on chromosome 9q32-qter, and the unexpectedly high (10%) proportion of males with the disorder, however, argue against X-linked dominance with lethality in males. Affected males may have an early half chromatid mutation or autosomal dominant inheritance affecting the germ line.

The primary defect may be due to a deficiency of collagen caused by a fibroblastic defect. Others suggest that the cutaneous defects represent heterotopic proliferations of fatty nevi within the dermis, resulting from dysplasia, not hypoplasia, followed by herniation of subcutaneous fat.

This disorder is often confused with incontinentia pigmenti because of the sex predilection for females, the linear distribution of skin lesions, and the initial inflammatory phase, which are features of both disorders. The cutaneous lesions may also superficially resemble epidermal nevi. *Treatment* should be directed at amelioration of specific anomalies; genetic counseling is advisable.

Dyskeratosis Congenita (Zinsser-Engman-Cole Syndrome).

This rare familial syndrome consists classically of the triad of reticulated hyperpigmentation of the skin, dystrophic nails, and mucous membrane leukoplakia. It usually affects males and is inherited most often in an X-linked recessive fashion, although autosomal recessive or dominant inheritance has been reported. The gene for the X-linked form of dyskeratosis congenita, DKC1, is on Xq28. Onset occurs during childhood, most commonly as nail dystrophy, at age 5–13 yr. The nails become atrophic and ridged longitudinally, and there is considerable loss of the nail plate. Skin changes usually appear 2–3 yr after onset of nail changes and consist of reticulated gray-brown pigmentation, atrophy, and telangiectasia, especially on the neck, face, and chest. Hyperhidrosis and hyperkeratosis of the palms and soles, acrocyanosis, and occasional bullae on the hands and feet are also characteristic. Blepharitis, ectropion, and excessive tearing as a result of atresia of the lacrimal ducts are occasional manifestations. Vesiculobullous lesions may occur on the oral mucous membranes and result in ulceration, formation of epithelial tags, atrophic changes of the tongue, and oral leukokeratosis. Oral leukokeratosis generally presents after the 3rd decade of life and may give rise to squamous cell carcinoma. Similar changes have been noted in the urethral and anal mucosae. The scalp hair, eyebrows, and lashes may become sparse. Hypoplastic anemia, at times of the Fanconi variety, may present at age 10 yr or older in up to 50% of patients. Impaired cell-mediated immunity has been noted. The primary causes of death are infections, including *Pneumocystis carinii*, and carcinoma. In one large series, approximately 12% of patients had tumors, most commonly oral and anal squamous cell carcinoma, pancreatic adenocarcinoma, or Hodgkin disease. The *differential diagnosis* includes the ectodermal dysplasias, pachyonychia congenita, poikilodermas, epidermolysis bullosa, keratoderma of the palms and soles, and lichen sclerosus et atrophicus. The abnormalities noted in skin biopsy specimens are those of poikiloderma.

Treatment includes biopsy of leukoplakic sites to identify malignancies. Etretinate may cause regression of leukoplakia, and orally administered ß-carotene has some

utility for treatment of leukoplakia and as a preventive agent for oral cancer. Aplastic anemia may be treated by administration of androgens or granulocyte-macrophage colony-stimulating factor or bone marrow transplantation.

Cutis Verticis Gyrata.

This unusual alteration of the scalp, which is more common in males, may be present from birth or may develop during adolescence. The scalp is characterized by convoluted elevated folds, 1–2?cm in thickness, usually in the fronto-occipital axis. Unlike the lax skin of other disorders, the convolutions cannot generally be flattened by traction. Primary cutis gyrata is often associated with mental retardation, ocular defects, abnormal size and shape of the head, seizures, and spasticity. Secondary cutis gyrata may be due to chronic inflammatory diseases, tumors, nevi, acromegaly, and pachydermoperiostosis, a syndrome characterized by hypertrophy of the skin and bones.

Chapter 639 - Ectodermal Dysplasias

Ectodermal dysplasia is a heterogeneous group of disorders characterized by a constellation of findings involving defects of two or more of the following: the teeth, skin, and appendageal structures, including hair, nails, and eccrine and sebaceous glands. Disturbances in tissue derived from embryologic layers other than ectoderm are common.

Hypohidrotic (Anhidrotic) Ectodermal Dysplasia.

This syndrome is manifested as a triad of defects: partial or complete absence of sweat glands, anomalous dentition, and hypotrichosis. It is usually inherited as an X-linked recessive trait, with full expression only in males; however, an autosomal recessive mode of inheritance may be operative in some families. Mutations in ectodysplasin, the protein product of the EDA or ED1 gene, cause the X-linked form of hypohidrotic ectodermal dysplasia.

Heterozygotic females may have no or variable *clinical manifestations*, including dental defects, sparse hair, and reduced sweating; because of random X-inactivation, they are mosaics of functionally normal and abnormal cells. Affected children, unable to sweat, may experience episodes of high fever in warm environments and may be mistakenly considered to have fever of unknown origin. This is particularly the case in infancy, when the facial changes are not easily appreciated. The typical facies is characterized by frontal bossing; malar hypoplasia; a flattened nasal bridge; recessed columella; thick, everted lips; wrinkled, hyperpigmented periorbital skin; and prominent, low-set ears (Fig. 639–1). The skin over the entire body is dry, finely wrinkled, and hypopigmented, often with a prominent venous pattern. Extensive peeling of the skin is a clinical clue to diagnosis in the newborn period. The paucity of sebaceous glands may account for the dry skin. The hair is sparse, unruly, and lightly pigmented, and eyebrows and lashes are sparse or absent. Anodontia or hypodontia with widely spaced, conical teeth is a consistent feature (see Fig. 639–1). Less commonly, stenotic lacrimal puncta, corneal opacity, cataracts, hypoplastic or absent mammary glands, and conductive hearing loss have been observed. The incidence of atopic diseases in these children is relatively high. Poor development of mucous glands in the respiratory and gastrointestinal tract may result in increased susceptibility to respiratory infection, purulent rhinitis, dysphonia, dysphagia, and diarrhea. Sexual development is usually normal. Approximately 30% of affected boys die during the first 2 yr of life of hyperpyrexia or respiratory infection.

The sweating deficit is a reflection of hypoplasia or absence of eccrine glands; this may be *diagnosed* by skin biopsy. The palmar skin is an appropriate site for biopsy. Reduction or absence of sweating can be documented by pilocarpine iontophoresis or by topical application of *o*-phthalaldehyde to the palmar skin. Sweat pores are not visible in the palmar ridges of affected children and are decreased in number in carrier females. Applying a 2% solution of iodine in alcohol to the back, followed by applying a suspension of cornstarch in castor oil, also allows highlighting of sweat glands by the appearance of a black dot; this test may be useful for detecting female carriers. Linkage analysis has been used for prenatal and early neonatal diagnosis.

Figure 639-1 Hypohidrotic ectodermal dysplasia is characterized by pointed ears, wispy hair, periorbital hyperpigmentation, midfacial hypoplasia, and pegged teeth.

Treatment of these children includes protecting them from exposure to high ambient temperatures. Early dental evaluation is necessary so that prostheses can be provided for cosmetic reasons and for adequate nutrition. The use of artificial tears prevents damage to the cornea in patients with defective lacrimation. Alopecia may necessitate the wearing of a wig to improve appearance.

Hidrotic Ectodermal Dysplasia (Clouston Syndrome).

Dystrophic, hypoplastic, or absent nails; sparse hair; and hyperkeratosis of the palms and soles are the salient features of this autosomal dominant disorder. The dentition is usually normal, although small teeth and numerous caries are occasionally found. Conjunctivitis and blepharitis are common. Sweating is always normal. Absence of eyebrows and lashes and hyperpigmentation over the knees, elbows, and knuckles have been noted in some affected individuals. Mutations in the GJB6 gene encoding the gap junction protein connexin 30, are responsible for this disorder.

EEC Syndrome.

Ectrodactyly (split hand and foot), ectodermal dysplasia, cleft lip and palate, and tear duct abnormalities constitute the EEC syndrome, which is probably inherited as an autosomal dominant trait of low penetrance and variable expressivity. The ectodermal dysplasia consists of dry, poorly pigmented skin; light-colored, wispy, sparse scalp hair and eyebrows; and absence of lashes. Decreased numbers of hair follicles and sebaceous glands have been demonstrated by biopsy. Nails may be dystrophic. Clinical expression of the EEC syndrome is variable; any one of these signs may be absent, except the ectodermal signs. Associated defects include anomalies of the hands and feet, nail hypoplasia, granulomatous perlèche frequently complicated by candidosis, defective dentition, deafness, ocular abnormalities (blepharophimosis, strabismus), and abnormalities of the urinary tract. Sweating usually is normal.

Chapter 640 - Vascular Disorders

Developmental vascular anomalies may occur as isolated defects or as part of a syndrome. They can be separated into two major categories: hemangiomas and vascular malformations. Hemangiomas are proliferative hamartomas of vascular endothelium that are present at birth or, more commonly, become apparent in the first few (e.g., 3–5) weeks of life, predictably enlarge, and then spontaneously involute. Hemangiomas are the most common tumor of infancy, occurring in 1–2% of newborns and 10% of white infants in the 1st yr of life. Vascular anomalies occur sporadically and occasionally have a genetic basis (Table 640–1 (Table Not Available)). Malformations are present at birth and are derived from capillaries, veins, arteries, or lymphatics or any combination thereof. Malformations do not regress but usually enlarge over time.

Port-Wine Stain (Nevus Flammeus, Port-Wine Nevus).

Port-wine stains are present at birth. These vascular malformations consist of mature dilated dermal capillaries and represent a permanent developmental defect. The lesions are macular, sharply circumscribed, pink to purple, and tremendously varied in size (Fig. 640–1). The head and neck region is the most common site of predilection, and most lesions are unilateral. The mucous membranes can be involved. As a child matures into adulthood, the port-wine stain may become darker in color and pebbly in consistency, and it may occasionally develop elevated areas that bleed spontaneously.

True port-wine stains should be distinguished from the most common vascular malformation, the salmon patch of neonates, which is, in contrast, a relatively transient lesion (see Chapter 637). Stretching the skin horizontally or placing firm pressure on a glass slide over the involved skin decreases the red color of both lesions and is not diagnostic. When a port-wine stain is localized to the trigeminal area of the face, specifically around the eyelids, the diagnosis of *Sturge-Weber syndrome* (glaucoma, leptomeningeal venous angioma, seizures, hemiparesis contralateral to the facial lesion, intracranial calcification) must be considered (see Chapter 589.3). Early screening for glaucoma is important to prevent additional damage to the eye. Port-wine stains also occur as a component of *Klippel-Trenaunay-Weber syndrome* and with moderate frequency in other syndromes, including the *Cobb* (spinal arteriovenous malformation, port-wine stain), *Proteus, Beckwith-Wiedemann*, and *Bonnet-Dechaume-Blanc* syndromes. In the absence of associated anomalies, morbidity from these lesions may include a poor self-image, hypertrophy of underlying structures, and traumatic bleeding.

The most effective treatment for port-wine stains is the flashlamp-pumped-pulsed

dye laser. This therapy is targeted at the lesion and avoids thermal injury to the surrounding normal tissue. After such treatment, the texture and pigmentation of the skin are generally normal without scarring. Therapy can begin in infancy when the surface area of involvement is smaller, although the response appears to be similar regardless of age when treated. Other therapies include masking with cosmetics (Covermark, Dermablend), cryosurgery, excision, grafting, and tattooing.

Hemangioma.

Superficial hemangiomas are bright red, protuberant, compressible, sharply demarcated lesions that may occur on any area of the body. Although sometimes present at birth, they

TABLE 640-1 -- Familial Vascular Anomalies with Identified Genetic Mutations

more often appear within the first 2 mo and are heralded by an erythematous or blue mark or an area of pallor, which subsequently develops a fine telangiectatic pattern before the phase of expansion. The presenting sign may occasionally be an ulceration of the perineum or lip. Girls are affected more often than boys. Favored sites are the face, scalp, back, and anterior chest; lesions may be solitary or multiple. Most superficial hemangiomas undergo a phase of rapid expansion, followed by a stationary period, and finally by spontaneous involution. Regression may be anticipated when the lesion develops blanched or pale gray areas that indicate fibrosis. The course of a particular lesion is unpredictable, but approximately 60% of

Figure 640-1 Widespread nevus flammeus in an infant with Klippel-Trenaunay-Weber syndrome.

these lesions involute completely by the age 5 yr, with 90–95% by age 9 yr. Spontaneous involution cannot be correlated with size or site of involvement, but lip lesions seem to persist most often. Complications include ulceration, secondary infection, and, rarely, hemorrhage. The location of a lesion may interfere with a vital function (e.g., eyelid with vision, urethra with urination). Hemangiomas in a “beard” distribution may be associated with upper airway or subglottic involvement. Respiratory symptoms should suggest a tracheobronchial lesion. Large hemangiomas may be complicated by coexistent hypothyroidism due to type-3 iodothyronine deiodinase, and symptoms may be difficult to detect in this age group (Table 640–2 (Table Not Available)).

In the usual patient who has no serious complications or extensive overgrowth that results in tissue destruction and severe disfigurement, *treatment* consists of expectant observation. Because almost all lesions resolve spontaneously, therapy is rarely indicated and may cause further harm. Parents require repeated reassurance and support. After spontaneous resolution, approximately 10% of patients are left with small cosmetic defects, such as puckering or discoloration of skin. These defects can be eliminated or minimized by judicious plastic repair if desired. In the rare case in which intervention is required, early therapy by the flashlamp-pumped-pulsed dye laser may be beneficial in decreasing growth of the hemangioma and in inducing more rapid resolution of an ulcerated hemangioma. Excision may be advisable in lesions that have remained large for several years; the extent of scarring anticipated should influence the final decision. Radiation can be hazardous and should be considered only in life-threatening situations, such as the Kasabach-Merritt syndrome (see later discussion). Elastic bandages may reduce the amount of tissue distortion resulting from rapid growth, but they are appropriate only in selected patients with large hemangiomas. Systemic or intralesional administration of corticosteroids and interferon-a (IFN-a) may be indicated for infants at risk for serious sequelae from exceptionally large or rapidly growing hemangiomas in vital areas (see later text) (Table 640–3 (Table Not Available)).

Hemangiomas that are more deeply situated appear more diffuse and ill defined than superficial hemangiomas. The lesions are cystic, firm, or compressible, and the overlying skin may appear normal in color or have a bluish hue. Mixed hemangiomas have both superficial and deep components. Deep hemangiomas progress from a growth phase to a stationary phase to a period of involution. These lesions are as likely to regress as superficial hemangiomas, and the outcome cannot be predicted from size or site of involvement. A course of expectant observation should be followed in most cases. If involvement of underlying structures is

TABLE 640-2 -- Clinical Red Flags Associated with Hemangiomas

(Not Available)
From Blei F: Vascular anomalies: From bedside to bench and back again.Curr Prob Pediatr Adolesc Health 2002;32:67–102.

suspected, appropriate radiologic studies should be performed for elucidation. Rarely, these lesions impinge on vital structures, interfere with functions such as vision or feeding (Fig. 640–2), cause grotesque disfigurement because of rapid growth, or are associated with life-threatening complications such as thrombocytopenia and hemorrhage (see Kasabach-Merritt syndrome).

If *treatment* becomes necessary, a course of prednisone (2–5?mg/kg/24?hr) is effective in some infants. Termination of growth and sometimes regression may be evident after approximately 4 wk of therapy. When a response is obtained, the dose should be decreased gradually. Alternate-day corticosteroid therapy has also been administered with success. Intralesional corticosteroid injection with the patient anesthetized can also induce rapid involution of a localized hemangioma. Pulsed dye laser therapy is also beneficial in managing complicated (cervicofacial, periorbital, parotid, lumbosacral) hemangiomas. IFN-a therapy may also be effective and may be the next therapeutic action. Spastic diplegia is a rare complication of interferon

therapy.

Syndromes associated with hemangiomas include PHACES (*p*osterior fossa defects such as Dandy-Walker malformation or cerebellar hypoplasia, large plaque-like facial *h*emangioma, *a*rterial abnormalities such as aneurysms and stroke, *c*oarctation of the aorta, *e*ye abnormalities, and *s*ternal raphe defects such as pits or scars), disseminated hemangiomatosis, Klippel-Trenaunay-Weber,

TABLE 640-3 -- **Hemangioma Complications and Their Treatment**

Gorham (cutaneous hemangiomas with massive osteolysis), and Bannayan-Riley-Ruvalcaba (macrocephaly lipomas, hemangiomas–autosomal dominant inheritance).

Disseminated Hemangiomatosis.

This is a serious condition in which numerous hemangiomas are widely distributed. The skin usually has many small red or purple papular hemangiomas, but infrequently they may be sparse or absent. The internal hemangiomas may involve any of the viscera; the liver, gastrointestinal tract, central nervous system, and lungs are the most common sites. Although involvement falls along a continuum, three entities have been described: (1) benign neonatal hemangiomatosis, with widespread cutaneous hemangiomas in the absence of apparent visceral involvement; (2) disseminated neonatal hemangiomatosis, with myriad small (2?mm–2?cm) papular hemangiomas of the skin and internal organs; and (3) hemangiomatosis of the liver. In cases of benign neonatal hemangiomatosis, spontaneous regression of the lesions without complications is probable. Multiple hemangiomas may also occur in several rare syndromes, such as macrocephaly combined with pseudopapilledema or with lipomas. Ultrasound and CT scanning are indicated to determine the extent of visceral or

Figure 640-2 Large hemangioma with central crusted ulcer.

neural involvement. The disorder is often fatal because of high-output cardiac failure, visceral hemorrhage, obstruction of the respiratory tract, or compression of central neural tissue. In some cases, systemic corticosteroid therapy alone or in combination with IFN-a, surgery, or irradiation has been lifesaving.
Kasabach-Merritt Syndrome.

This syndrome is a combination of a rapidly enlarging vascular anomaly, thrombocytopenia, microangiopathic hemolytic anemia, and an acute or chronic consumption coagulopathy. The vascular lesion is most likely either a tufted angioma or a kaposiform hemangioendothelioma with lymphatic-like vessels. The lesions may not spontaneously regress; both lesions are uncommon compared to hemangiomas. The *clinical manifestations* are usually evident during early infancy, but the onset occasionally is later. The vascular lesion is usually cutaneous and is only rarely located in viscera. The associated platelet defect may lead to precipitous hemorrhage accompanied by ecchymoses, petechiae, and a rapid increase in size of the vascular lesion. Severe anemia as a result of hemorrhage or microangiopathic hemolysis may ensue. The platelet count is depressed, but the bone marrow contains increased numbers of normal or immature megakaryocytes. The thrombocytopenia has been attributed to sequestration or increased destruction of platelets within the lesion hemangioma. Hypofibrinogenemia and decreased levels of consumable clotting factors are relatively common (see Chapter 474).

Treatment includes management of thrombocytopenia, anemia, and consumptive coagulopathy by administering platelets and by transfusion of red blood cells and fresh frozen plasma. Heparinization is controversial but has benefited some patients when combined with transfusions. Arteriovenous shunts in large lesions may produce high-output heart failure requiring digitalization (see Chapter 436). Treatment of these lesions includes systemic steroids, embolization, radiation therapy, vincristine, aminocaproic acid (inhibits fibrinolysis), cyclophosphamide, pentoxifylline, or recombinant IFN-a, which may inhibit proliferation of endothelial and smooth muscle cells. The mortality rate is 20–30%.

Blue Rubber Bleb Nevus.

This syndrome consists of numerous vascular malformations of the skin, mucous membranes, and gastrointestinal tract. Typical lesions are blue-purple and rubbery in consistency; they vary in size from a few millimeters to a few centimeters in diameter. They are sometimes painful or tender. The nodules occasionally are present at birth but usually appear in childhood. New lesions may continue to develop throughout life. Large disfiguring and irregular blue marks may also occur. The lesions, which can rarely be located in the liver, spleen, and central nervous system in addition to the skin and gastrointestinal tract, do not involute spontaneously. Recurrent gastrointestinal hemorrhage may lead to severe anemia. Palliation can be achieved by excision of involved bowel. Cutaneous angiomas have been successfully removed by laser therapy.

Pyogenic Granuloma (Lobular Capillary Hemangioma, Telangiectatic Granuloma).

A pyogenic granuloma is a small red, glistening, sessile, or pedunculated papule that often has a discernible epithelial collarette (Fig. 640–3). The surface may be weeping and crusted or completely epithelialized. Pyogenic granulomas initially grow rapidly, may ulcerate, and bleed easily when traumatized because they consist of exuberant granulation tissue. They are relatively common in children, particularly on the face, arms, and hands. Those located on a finger or hand may appear as a subcutaneous nodule. Lesions that develop on the oral mucosa during pregnancy are called *granuloma gravidarum*. Pyogenic granulomas generally arise at sites of injury, but a history of trauma often cannot be elicited. Clinically, they resemble and are often indistinguishable from small hemangiomas. Microscopically, an early lesion

resembles an early capillary

Figure 640-3 Pyogenic granuloma with a moist surface and epithelial collarette at the base.

hemangioma. Collarette formation at the base of the tumor and edema of the stroma may allow differentiation from a capillary hemangioma.

Pyogenic granulomas are benign but a nuisance because they bleed easily with trauma and may recur if incompletely removed. Numerous satellite papules have developed after incomplete removal of pyogenic granulomas from the back, particularly in the interscapular region. Small lesions may regress after cauterization with silver nitrate; larger lesions require excision and electrodesiccation of the base of the granuloma. They also have been treated successfully with the flashlamp-pumped-pulsed dye laser.

Maffucci Syndrome.

The association of numerous vascular and, occasionally, lymphatic malformations with nodular enchondromas in the metaphyseal or diaphyseal portion of long bones is known as Maffucci syndrome. Vascular lesions typically are soft, compressible, asymptomatic blue-to-purple subcutaneous masses that grow in proportion to a child's growth and stabilize by adult life. Mucous membranes or viscera also may be involved. Onset occurs during childhood. Bone lesions may produce limb deformities and pathologic fractures. Malignant transformation of enchondromas (chondrosarcoma, angiosarcoma) or primary malignancies (ovarian, fibrosarcoma, glioma, pancreatic) may be a complication (Chapters 492 and 493).

Klippel-Trenaunay-Weber Syndrome.

A cutaneous vascular malformation in combination with bony and soft tissue hypertrophy and venous varicosities constitutes the triad of defects of this nonheritable disorder. The anomaly is present at birth and usually involves a lower limb but may involve more than one and portions of the trunk or face (see Fig. 640–1). Enlargement of the soft tissues may be gradual and may involve the entire extremity, a portion of it, or selected digits. The vascular lesion most often is a nevus flammeus, generally localized to the hypertrophied area. Venous blebs and/or vesicular lymphatic lesions may be present on their surface. Thick-walled venous varicosities typically become apparent ipsilateral to the vascular malformation after the child begins to ambulate. The deep venous system may be absent, hypoplastic, or obstructed, resulting in lymphedema. Arteriovenous fistulas can develop, and

bruits may be audible in the affected part. This disorder can be confused with Maffucci syndrome or, if the surface vascular lesion is minimal, with Milroy disease. Pain, limb swelling, and cellulitis may occur. Thrombophlebitis, dislocations of joints, gangrene of the affected extremity, congestive heart failure, hematuria secondary to angiomatous involvement of the urinary tract, rectal bleeding from lesions of the gastrointestinal tract, pulmonary lesions, and malformations of the lymphatic vessels are infrequent complications. Arteriograms, venograms, and CT or MRI scans may delineate the extent of the anomaly, but surgical correction or palliation is often difficult. The indications for radiologic studies of viscera and bones are best determined by clinical evaluation. Supportive care includes compression bandages for varicosities; surgical treatment may help carefully selected patients. Leg-length differences should be treated with orthotic devices to prevent the development of spinal deformities. Corrective bone surgery may eventually be needed to treat significant leg-length discrepancy.

Phakomatosis Pigmentovascularis.

This rare disorder is characterized by the association of a nevus flammeus and melanocytic lesions. Typically, the nevus flammeus is extensive, and associated pigmentary lesions may include dermal melanocytosis (i.e., Mongolian spots), café-au-lait macules, or a nevus spilus (speckled nevus). Nonpigmented skin lesions that may occur in this setting include nevus anemicus and epidermal nevi. Systemic anomalies include ocular abnormalities, colonic polyposis, renal angiomas, granular cell tumors, moyamoya disease, and selective IgA deficiency.

Hereditary Hemorrhagic Telangiectasia (Osler-Weber-Rendu Disease).

This disorder is inherited as an autosomal dominant trait. One involved gene encodes endoglin, a membrane glycoprotein on endothelial cells that binds transforming growth factor-ß. Affected children may experience recurrent epistaxis before detection of the characteristic skin and mucous membrane lesions. The mucocutaneous lesions, which usually develop at puberty, are 1–4?mm, sharply demarcated red to purple macules, papules, or spider-like projections, each composed of a tightly woven mat of tortuous telangiectatic vessels. The nasal mucosa, lips, and tongue are usually involved; less commonly, cutaneous lesions occur on the face, ears, palms, and nail beds. Vascular ectasias may also arise in the conjunctivae, larynx, pharynx, gastrointestinal tract, bladder, vagina, bronchi, brain, and liver.

Massive hemorrhage is the most serious complication and may result in severe anemia. Bleeding may occur from the nose, mouth, gastrointestinal tract, genitourinary tract, and lungs; epistaxis often is the only complaint, however, occurring in 80% of patients. Approximately 15–20% of patients with arteriovenous malformations in the lungs present with stroke due to embolic abscesses. Persons with hereditary hemorrhagic telangiectasia have normal levels of clotting factors and an intact clotting mechanism. In the absence of serious complications, life span is normal. Local lesions may be ablated temporarily with chemical cautery or electrocoagulation. More drastic surgical measures may be required for lesions in critical sites such as the lung or gastrointestinal tract. Anemia should be treated with iron.

Spider Angiomas.

A vascular spider (nevus araneus) consists of a central feeder artery with many dilated radiating vessels and a surrounding erythematous flush, varying from a few millimeters to several centimeters in diameter. Pressure over the central vessel

causes blanching; pulsations visible in larger nevi are evidence for the arterial source of the lesion. Spider angiomas are associated with conditions in which there are increased levels of circulating estrogens, such as cirrhosis and pregnancy, but they also occur in up to 15% of normal preschool-aged children and 45% of school-aged children. Sites of predilection in children are the dorsum of the hand, forearm, face, and ears. Angiomas can be obliterated by application of liquid nitrogen, electrocoagulation, or pulsed dye laser; they may also regress spontaneously.

Generalized Essential Telangiectasia.

A rare and presumably nevoid anomaly of unknown cause, essential telangiectasia may have its onset in childhood or adulthood. Mild expression consists of patchy retiform telangiectases, particularly on the limbs, with occasional progression to involve large areas of the body surface. The condition must be distinguished from the secondary telangiectasias of connective tissue diseases, xeroderma pigmentosum, poikiloderma, and ataxia-telangiectasia. There is no treatment; however, patients can be reassured that their health will not be affected by the cutaneous disorder.

Unilateral Nevoid Telangiectasia.

This unusual entity is characterized by the appearance of telangiectasia in a unilateral distribution, primarily on the face, neck, chest, and arms. The acquired form occurs particularly in females at onset of menses or during pregnancy. The congenital form predominantly affects males who lack endocrine abnormalities. The appearance of these lesions usually coincides with elevated levels of circulating estrogens, whatever the cause. When initiated by pregnancy, the telangiectasia may fade or disappear postpartum.

Hereditary Benign Telangiectasia.

This rare disorder is inherited as an autosomal dominant trait and develops during childhood. The face, upper trunk, and arms are the areas of predilection. The condition is progressive but remains limited to the skin.

Cutis Marmorata Telangiectatica Congenita (Congenital Generalized Phlebectasia).

This benign vascular anomaly represents dilatation of superficial capillaries and veins and is apparent at birth. Involved areas of skin have a reticulated red or purple hue that resembles physiologic cutis marmorata but is more pronounced and relatively unvarying (Fig. 640–4). The lesions may be restricted to a single limb and a portion of the trunk or may be more widespread. Port-wine stain may also be associated. The lesions become more pronounced during changes in environmental temperature, physical activity, or crying. In some cases, the underlying subcutaneous tissue is underdeveloped, and ulceration may occur within the reticulated bands. Rarely, defective growth of bone and other congenital abnormalities may be present. No specific therapy is indicated; the expected

Figure 640-4 Marbled pattern of cutis marmorata telangiectatica congenita on the right leg. See also color plates.

course is one of gradual improvement, with partial or complete resolution by adolescence.

Ataxia-Telangiectasia (see Chapter 116.12).

This disorder *(Louis-Bar syndrome)* is transmitted as an autosomal recessive trait due to a mutation in the ATM gene. The characteristic telangiectasias develop at about 3 yr of age, first on the bulbar conjunctivae and later on the nasal bridge, malar areas, external ears, hard palate, upper anterior chest, and antecubital and popliteal fossae. Additional cutaneous stigmata include café-au-lait spots, premature graying of the hair, and sclerodermatous changes.

Angiokeratomas.

Several forms of angiokeratomas have been described, but some do not occur during childhood or adolescence. Angiokeratomas, characterized by ectasia of superficial dermal vessels and hyperkeratosis of the overlying epidermis, look like flat hemangiomas with a verrucous, irregular surface. *Angiokeratoma of Mibelli*, probably transmitted in an autosomal dominant pattern, is characterized by 1–8?mm red, purple, or black scaly, verrucous, occasionally crusted papules and nodules that appear on the dorsum of the fingers and toes and on the knees and the elbows. Less commonly, palms, soles, and ears may be affected. In many patients, onset has followed frostbite or chilblains. These nodules bleed freely after injury and may involute in response to trauma. *Angiokeratoma circumscriptum* is a rare solitary lesion that presents as a plaque of blue-red papules or nodules with a verrucous surface. These usually develop during infancy and early childhood, and they increase in size at adolescence. The lower limb is the site of predilection. They may be effectively eradicated by cryotherapy, fulguration, excision, or laser ablation.

Angiokeratoma Corporis Diffusum (Fabry Disease) (see Chapter 75).

This inborn error of glycolipid metabolism is an X-linked recessive disorder that is fully penetrant in males and is of variable penetrance in carrier females. Angiokeratomas have their onset before puberty and occur in profusion over the genitalia, hips, buttocks, and thighs and in the umbilical and inguinal regions. They consist of 0.1–3?mm red to blue-black papules that may have a hyperkeratotic surface. Telangiectasias are seen in the mucosa and conjunctiva. On light microscopy, these angiokeratomas appear as blood-filled, dilated, endothelium-lined vascular spaces. Granular lipid deposits are demonstrable in dermal macrophages, fibrocytes, and endothelial cells.

Additional *clinical manifestations* include recurrent episodes of fever and agonizing pain, cyanosis and flushing of the acral limb areas, paresthesias of the hands and feet, corneal opacities detectable by slit-lamp examination, and hypohidrosis. Renal and cardiac involvement are the usual causes of death. The biochemical defect is a

deficiency of the lysosomal enzyme a-galactosidase, with accumulation of ceramide trihexoside in tissues, particularly vascular endothelium, and excretion in urine. Similar cutaneous lesions have also been described in another lysosomal enzyme disorder, a-L-fucosidase deficiency, and in sialidosis, a storage disease with neuraminidase deficiency. See Chapter 75 for therapy.

Nevus Anemicus.

Although present at birth, nevus anemicus may not be detectable until early childhood. The nevus consists of solitary or numerous sharply delineated pale macules that are most often on the trunk but may also occur on the neck or limbs. These nevi may simulate plaques of vitiligo, leukoderma, or nevoid pigmentary defects, but they can be readily distinguished by their response to firm stroking. Stroking evokes an erythematous line and flare in normal surrounding skin, but the skin of a nevus anemicus does not redden. Although the cutaneous vasculature appears normal histologically, the blood vessels within the nevus do not respond to injection of vasodilators. It has been postulated that the persistent pallor may represent a sustained localized adrenergic vasoconstriction.

Lymphangiomas.

See Chapter 481 .

Chapter 641 - Cutaneous Nevi

Nevus skin lesions are characterized histopathologically by collections of well-differentiated cell types normally found in the skin. Vascular nevi are described in Chapter 640 . Melanocytic nevi are subdivided into two broad categories: those that appear after birth, or acquired nevi, and those that are present at birth, the congenital nevi.

Acquired Melanocytic Nevus.

Melanocytic nevi are a benign cluster of melanocytic nevus cells that arise as a result of proliferation of melanocytes at the epidermal-dermal junction. Nevus cells may have the same origin as melanocytes and are probably identical to them. An alternative, less popular theory is that nevus cells are of dual origin, with superficially located cells arising from melanocytes *(melanocytic nevus)* and cells in the deeper layers arising from Schwann cells *(neuroid nevus)*.

EPIDEMIOLOGY.

The number of acquired melanocytic nevi increases gradually during childhood, sharply at adolescence, and more slowly in early adulthood. It reaches a plateau in number during the 3rd or 4th decade and then slowly decreases thereafter. The mean number of melanocytic nevi in an adult is

---

25–35. The greater the number of nevi present, the greater is the risk for development of melanoma. Sun exposure during childhood, particularly intermittent, intense exposure of an individual with light skin, and a propensity to burn and freckle rather than tan are important determinants of the number of melanocytic nevi that develop. Increased numbers of nevi are also associated with immunosuppression and administration of chemotherapy.

CLINICAL MANIFESTATIONS.

Nevocellular nevi have a well-defined life history and are classified as junctional, compound, or dermal in accordance with the location of the nevus cells in the skin. In childhood, more than 90% of nevi are junctional; melanocyte proliferation occurs at the junction of the epidermis and dermis to form nests of cells. *Junctional nevi* appear anywhere on the body in various shades of brown; they are relatively small, discrete, flat, and variable in shape. The melanized nevus cells are cuboidal or epithelioid in configuration and occur in nests on the epidermal side of the basement membrane. Although some nevi, particularly those on the palms, soles, and genitalia, remain junctional throughout life, most become compound as melanocytes migrate into the papillary dermis to form nests at both the epidermal-dermal junction and within the dermis. If the junctional melanocytes stop proliferating, nests of melanocytes remain only within the dermis, forming an intradermal nevus. With maturation, *compound* and *intradermal nevi* may become raised, dome shaped, verrucous, or pedunculated. Slightly elevated lesions are usually compound. Distinctly elevated lesions are usually intradermal. With age, the dermal melanocytic nests regress and the nevi gradually disappear.

PROGNOSIS AND TREATMENT.

Acquired pigmented nevi are benign, but a very small percentage undergo malignant transformation. Suspicious changes such as rapid increase in size; development of satellite lesions; variegation of color, particularly with shades of red, brown, gray, black, and blue; pigmentary incontinence; notching or irregularity of the borders; changes in texture such as scaling, erosion, ulceration, and induration; and regional lymphadenopathy are indications for excision and histopathologic evaluation. Most of these changes are due to irritation, infection, or maturation; darkening and gradual increase in size and elevation normally occur during adolescence and should not be cause for concern. Consideration should be given to the presence of risk factors for development of melanoma and the parents' wishes about removal of the nevus. If doubt remains about the benign nature of a nevus, excision is a safe and simple outpatient procedure that may be justified to allay anxiety.

Atypical Melanocytic Nevus.

Atypical nevocellular nevi occur both in an autosomal dominant familial melanoma-prone setting (familial mole-melanoma syndrome, dysplastic nevus syndrome, BK mole syndrome) and as a sporadic event. Only 2% of all pediatric melanomas occur in individuals with this familial syndrome, and 10% of those with the syndrome have a melanoma develop before age 20 yr. Malignant melanoma has been reported in children with the dysplastic nevus syndrome as early as age 10 yr. Risk for development of melanoma is essentially 100% in individuals with dysplastic nevus syndrome and two family members who have had melanomas. The term *atypical mole syndrome* has been proposed to describe lesions in those individuals without an autosomal dominant familial history of melanoma but with more than 50 nevi, some of which are atypical. The lifetime risk of melanoma associated with dysplastic nevi in this context is estimated to be 5–10%.

Atypical nevi tend to be large (5–15?mm) and round to oval. They have irregular margins, variegated color, and elevation of a portion of the lesion. These nevi are most common on the posterior trunk, suggesting that intermittent, intense sun exposure has a role in their genesis. They may also occur, however, in sun-protected areas such as the breasts, buttocks, and scalp. Atypical nevi do not usually develop until puberty, although scalp lesions may be present earlier. Atypical nevi demonstrate disordered proliferation of atypical intraepidermal melanocytes, lymphocytic infiltration, fibroplasia, and angiogenesis. It may be helpful to obtain histopathologic documentation of dysplastic change by biopsy to identify these

individuals. It is prudent to excise borderline atypical nevi in immunocompromised children or in those treated with irradiation or chemotherapeutic agents. Although chemotherapy has been associated with the development of a greater number of melanocytic nevi, it has not been directly linked to increased risk for development of melanoma. The threshold for removal of clinically atypical nevi is also lower at sites that are difficult to observe, such as the scalp. Children with atypical nevi should have a complete skin examination every 6–12 mo. Parents must be counseled about the importance of sun protection and avoidance and be instructed to look for early signs of melanoma on a regular basis, approximately every 3–4 mo.

Congenital Melanocytic Nevus.

Congenital melanocytic nevi are present in approximately 1% of newborn infants. These nevi have been categorized by size: giant congenital nevi are more than 20?cm in diameter (adult size), small congenital nevi are less than 2?cm in diameter, and intermediate nevi are in between in size. Congenital nevi are characterized by the presence of nevus cells in the lower reticular dermis; between collagen bundles; surrounding cutaneous appendages, nerves, and vessels in the lower dermis; and occasionally extending to the subcuticular fat. Identification is often uncertain, however, because they may have the histologic features of ordinary junctional, compound, or intradermal nevi. Some nevi that were not present at birth display histopathologic features of congenital nevi. Furthermore, congenital nevi may be difficult to distinguish clinically from other types of pigmented lesions, adding to the difficulty that parents may have in identifying nevi that were present at birth. The clinical differential diagnosis includes mongolian spots, café-au-lait spots, smooth muscle hamartoma, and dermal melanocytosis (nevi of Ota and Ito).

Sites of predilection of *small congenital nevi* are the lower trunk, upper back, shoulders, chest, and proximal limbs. The lesions may be flat, elevated, verrucous, or nodular and may be various shades of brown, blue, or black. Given the difficulty in identifying small congenital nevi with certainty, data regarding their malignant potential are controversial. Based on historical criteria, it is estimated that approximately 15% of melanomas arise within small congenital nevi. With histopathologic criteria, a congenital nevus has been found in association with approximately 3–8% of melanomas. Removal of all small congenital nevi is not warranted, particularly in view of the fact that development of melanoma in a small congenital nevus is an exceedingly rare event before puberty. A number of factors must be weighed in the decision about whether or not to remove a nevus, including its location and ability to be monitored clinically, the potential for scarring, the presence of other risk factors for melanoma, and the presence of atypical clinical features.

Giant congenital pigmented nevi (<1/20,000 births) occur most commonly on the posterior trunk but may also appear on the head or the extremities. These nevi are of special significance because of their association with leptomeningeal melanocytosis and their predisposition for development of malignant melanoma. Leptomeningeal involvement occurs most often when the nevus is located on the head or midline on the trunk, particularly when associated with “satellite” melanocytic nevi. Nevus cells within the leptomeninges and brain parenchyma may cause increased intracranial pressure, hydrocephalus, seizures, retardation, and motor deficits and may result in melanoma. Malignancy can be identified by careful cytologic examination of the cerebrospinal fluid for melanin-containing

cells. Asymptomatic leptomeningeal melanosis on MRI scans is seen in approximately 30% of individuals with a giant congenital nevus. The overall incidence of malignant melanoma arising in a giant congenital nevus is estimated to be approximately 5–10%; approximately 3% of all melanomas arise within a giant congenital nevus. Half of all melanomas that arise within a giant congenital nevus do so by age 5 yr. The mortality rate is 45%. Management of giant congenital nevi remains controversial and should involve the parents, pediatrician, dermatologist, and plastic surgeon. If the nevus lies over the head or spine, an MRI scan may allow detection of neural melanosis; its presence makes gross removal of a nevus from the skin a futile effort. In the absence of neural melanosis, early excision and repair aided by tissue expanders or grafting may reduce the burden of nevus cells and thus the potential for development of melanoma, but at the cost of many potentially disfiguring surgeries. Even then, nevus cells deep within subcutaneous tissues may evade excision. Random biopsies of the nevus are not helpful, but biopsy of newly expanding nodules is indicated. Follow-up is recommended every 6 mo for 5 yr and every 12 mo thereafter. Serial photographs of the nevus may aid in detecting changes.

Melanoma.

Malignant melanoma accounts for 1–3% of all pediatric malignancies and is the most common cancer in young adults age 25–29 yr. The incidence of melanoma has increased 150% since 1973. Melanoma develops primarily in white individuals, on the head and trunk in males and on the extremities in females. Risk factors for development of melanoma include the presence of the familial atypical mole-melanoma syndrome or xeroderma pigmentosum; increased number of melanocytic nevi, consisting of acquired nevi, giant congenital nevus, or atypical nevi; fair complexion; excessive sun exposure, especially intense sunlight intermittently; a personal or family (i.e., first-degree relative) history of a previous melanoma; and immunosuppression. In previously well children, UV radiation is responsible for most melanomas. Fewer than 5% of childhood melanomas develop within giant congenital nevi or in those with the familial atypical mole-melanoma syndrome. Approximately 40–50% of the time, melanoma develops at a site where there was no apparent nevus. The mortality rate from melanoma is related primarily to tumor thickness and the level of invasion into the skin. The overall mortality rate reaches approximately 40%, regardless of whether it arises in a child or adult. Given the lack of effective therapy for melanoma, prevention and early detection are the most effective measures. Avoidance of intense midday sun exposure between 10 a.m. and 3 p.m.; use of protective clothing such as a hat, long sleeves, and pants; and use of sunscreen should be emphasized. Early detection includes frequent clinical and photographic examinations for patients at risk (dysplastic nevus syndrome) and prompt response to rapid changes in nevi (size, shape, color, inflammation, bleeding or crusting, and sensation).

Halo Nevus (Leukoderma Acquisitum Centrifugum).

Halo nevi occur primarily in children and young adults, most commonly on the back (Fig. 641–1). Development of the halo may coincide with puberty or pregnancy. Several pigmented nevi frequently develop a halo simultaneously. Subsequent disappearance of the central nevus over several months is the usual outcome, and the depigmented area may or may not become repigmented. Excision and histopathologic examination of the lesion is indicated only when the nature of the central lesion is in question. An acquired melanocytic nevus occasionally develops a peripheral zone of depigmentation over a period of days to weeks. There is a dense inflammatory infiltrate of lymphocytes and histiocytes in addition to the nevus cells. The pale halo reflects disappearance of the melanocytes. This phenomenon is associated with congenital nevi, blue nevi, Spitz nevi, dysplastic nevi, neurofibromas, and primary and secondary malignant melanoma

Figure 641-1 Well-developed halo nevus.

and occasionally with poliosis, Vogt-Koyanagi-Harada syndrome, and pernicious anemia. Patients with vitiligo have an increased incidence of halo nevi. Individuals with halo nevi have circulating antibodies against the cytoplasm of malignant melanoma cells, and their lymphocytes display enhanced killing of melanoma cells in culture.

Spitz Nevus (Spindle and Epithelioid Cell Nevus).

Spitz nevus presents most commonly during the first 2 decades of life as a pink to red, smooth, dome-shaped, firm, hairless papule on the face, shoulder, or upper limb. Most are less than 1?cm in diameter, but they can achieve a size of 3?cm. Rarely, they occur as numerous grouped lesions. Visually similar lesions include pyogenic granuloma, hemangioma, nevocellular nevus, juvenile xanthogranuloma, and basal cell carcinoma, but histologically these entities are distinguishable. Spitz nevus may be difficult to distinguish histopathologically from malignant melanoma because nuclear atypia is a common feature, particularly after local recurrence of the nevus. Local recurrence after excision may occur up to 5% of the time. If a nevus arouses clinical suspicion that it may be a melanoma, an excisional biopsy of the entire lesion is recommended. If the margins of excision of a Spitz nevus are positive, re-excision of the site is prudent to avoid difficulties in histopathologic interpretation of the lesion in the future.

Zosteriform Lentiginous Nevus (Agminated Lentigines).

This nevus is a unilateral, linear, bandlike collection of numerous 2–10?mm brown or black macules on the face, trunk, or limbs. The nevus may be present at birth or may develop during childhood. Seen histopathologically are increased numbers of melanocytes in elongated rete ridges of the epidermis.

Nevus Spilus (Speckled Lentiginous Nevus).

This nevus is a flat brown patch within which are darker, flat or raised brown melanocytic elements. These nevi vary considerably in size and can occur anywhere on the body. Nevus spilus is rare at birth and is commonly acquired during late infancy or early childhood. Dark elements within the nevus are usually present initially and tend to increase in number gradually over time. The darker macules represent nevus cells in a junctional or dermal location; the patch has increased numbers of melanocytes in a lentiginous epidermal pattern. The malignant potential of these nevi is uncertain; nevus spilus is found more commonly in individuals with melanoma than in matched control subjects. The nevi need not be excised, unless atypical features or recent clinical changes are noted.

Nevus of Ota.

Nevus of Ota is more common in females and in Asian and black patients. This nevus consists of a permanent patch composed of blue, black, and brown, partially confluent macules. The intensity of pigmentation may vary from day to day, and enlargement and darkening may occur with time. Some areas of the nevus occasionally are raised. The macular nevi resemble mongolian spots in color and occur unilaterally in the areas supplied by the 1st and 2nd divisions of the trigeminal nerve. Nevus of Ota differs from a mongolian spot, not only by its distribution but also by having a speckled rather than a uniform appearance. It also has a greater concentration of elongated, dendritic dermal melanocytes located in the upper rather than the lower portion of the dermis. Nevus of Ota is sometimes present at birth; in other cases, it may arise during the 1st or 2nd decade of life. Patchy involvement of the conjunctiva, hard palate, pharynx, nasal mucosa, buccal mucosa, or tympanic membrane occurs in some patients. Malignant change is exceedingly rare. Laser therapy may effectively decrease the pigmentation.

Nevus of Ito is localized to the supraclavicular, scapular, and deltoid regions. This nevus tends to be more diffuse in its distribution and less mottled than the nevus of Ota. The only available treatment is masking with cosmetics or laser therapy.

Blue Nevi.

The *common blue nevus* is a solitary, asymptomatic, smooth, dome-shaped, blue to blue-gray papule less than 10?mm in diameter on the dorsal aspect of the hands and feet. Rarely, common blue nevi form large plaques. Blue nevus is nearly always acquired, often during childhood and more commonly in females. Microscopically, it is characterized by groups of intensely pigmented spindle-shaped melanocytes in the dermis. This nevus is benign.

The *cellular blue nevus* is typically 1–3?cm in diameter and occurs most frequently on the buttocks and in the sacrococcygeal area. In addition to collections of deeply pigmented dermal dendritic melanocytes, cellular islands composed of large spindle-shaped cells are noted in the dermis and may extend into the subcutaneous fat. The cellular blue nevus has a low but definite incidence of malignant transformation; therefore, excision is the treatment of choice. A *combined nevus* is the association of a blue nevus with an overlying melanocytic nevus.

The blue-gray that is characteristic of these nevi is an optical effect caused by dermal melanin. Longer wavelengths of visible light penetrate to the deep dermis and

are absorbed there by melanin; shorter-wavelength blue light cannot penetrate deeply but instead is reflected back to the observer.

Achromic Nevus (Nevus Depigmentosus).

These nevi are usually present at birth; they are localized macular hypopigmented patches or streaks, often with bizarre, irregular borders. They can resemble hypomelanosis of Ito clinically, except that they are more localized and often unilateral. Small lesions may also resemble the white leaf macules of tuberous sclerosis. They appear to represent a focal defect in transfer of melanosomes to keratinocytes.

Epidermal Nevi.

These may be visible at birth or may develop within the first months or years of life. They affect both sexes equally and usually occur sporadically. Epidermal nevi are hamartomatous lesions characterized by hyperplasia of the epidermis and/or adnexal structures in a focal area of the skin. Proliferation of nevocellular nevus cells is not present in these lesions.

Epidermal nevi are classified into a number of variants, depending on the morphology and extent of the nevus and the epidermal structure that is predominant. An epidermal nevus may appear initially as a discolored, slightly scaly patch that, with maturation, becomes more linear, thickened, verrucous, and hyperpigmented. *Systematized* refers to a diffuse or extensive distribution of lesions, and *ichthyosis hystrix* indicates that the distribution is extensive and bilateral. Morphologic types include pigmented papillomas, often in a linear distribution; unilateral hyperkeratotic streaks involving a limb and perhaps a portion of the trunk; velvety hyperpigmented plaques; and whorled or marbled hyperkeratotic lesions in localized plaques (Fig. 641–2) or over extensive areas of the body along Blaschko lines. An inflammatory linear verrucous variant is markedly pruritic and tends to become erythematous, scaling, and crusted.

The histologic pattern evolves as the lesion matures, but epidermal hyperplasia of some degree is apparent in all stages of development. One or another dermal appendage may predominate in a particular lesion. These nevi must be distinguished from lichen striatus, lymphangioma circumscriptum, shagreen patch of tuberous sclerosis, congenital hairy nevi, linear porokeratosis, linear lichen planus, linear psoriasis, the verrucous stage of incontinentia pigmenti, and nevus sebaceus (Jadassohn). Keratolytic agents such as retinoic acid or salicylic acid may be moderately effective in reducing scaling and controlling pruritus, but definitive *treatment* requires full-thickness excision; recurrence is usual if more superficial removal is attempted. Alternatively, the nevus may be left intact. Rarely, basal cell carcinoma or squamous cell carcinoma has developed in a verrucous epidermal nevus that shows sudden growth, nodularity, or erosions.

Epidermal nevi are occasionally associated with other abnormalities of the skin and soft tissues, eyes, and nervous, cardiovascular, musculoskeletal, and urogenital systems. In these instances, referred to as *epidermal nevus syndrome,* a mosaic phenotype is expressed. This syndrome, however, is not a distinct clinical entity. The well established syndromes that involve a type of epidermal nevus and distinct birth defects include the sebaceous nevus, *Proteus*, and CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects) syndromes.

NEVUS SEBACEUS (JADASSOHN).

This is a relatively small, sharply demarcated, oval or linear, yellow-orange, elevated plaque that is usually devoid of hair and occurs on the head and neck of infants. It may occur occasionally on the trunk. Although the lesion is characterized histopathologically by an abundance of sebaceous glands, all elements of the skin are represented. It is frequently flat and inconspicuous in early childhood. With maturity, usually during adolescence, the lesions become verrucous and studded with large rubbery nodules. The changing clinical appearance reflects the histologic pattern, which is characterized by a variable degree of hyperkeratosis, hyperplasia of the epidermis, malformed hair follicles, and often a profusion of sebaceous glands and the presence of

Figure 641-2 Verrucous streaky epidermal nevus on the neck.

ectopic apocrine glands. It is believed that these nevi form from pluripotential primary epithelial germ cells, which can dedifferentiate into various epithelial tumors. Consequently, during adulthood, these nevi are frequently complicated by secondary malignancies and benign adnexal tumors, most commonly basal cell carcinoma or syringocystadenoma papilliferum. The risk of malignancy may be smaller than previously recognized. The risk of basal cell carcinoma may be close to 1%, with a significantly greater risk of benign neoplasia. Deletions in the PTCH gene, the putative gene defect in basal cell carcinoma, have been found in sebaceous nevi. Diagnosis can be established by biopsy; the treatment of choice is total excision before adolescence. Sebaceous nevi associated with central nervous system, skeletal, and ocular defects represent a variant of the epidermal nevus syndrome.

BECKER NEVUS (BECKER MELANOSIS).

This form of epidermal nevus develops predominantly in males, during childhood or adolescence, initially as a hyperpigmented patch. The lesion commonly develops hypertrichosis, limited to the area of hyperpigmentation, and evolves into a unilateral, slightly thickened, irregular, hyperpigmented plaque. The most common sites are the upper torso and upper arm. The nevus shows an increased number of basal melanocytes and variable epidermal hyperplasia. Becker melanosis is commonly associated with a smooth muscle hamartoma, which may appear as slight perifollicular papular elevations or slight induration. Stroking such a lesion may induce smooth muscle contraction and make the hairs stand up. Androgen sensitivity may have a role in the development of Becker melanosis. The nevus is benign, has no risk for malignant change, and is rarely associated with other anomalies.

Nevus Comedonicus.

This is an uncommon organoid nevus of epithelial origin that consists of linear plaques of plugged follicles that simulate comedones; they may be present at birth or may appear during childhood. The horny plugs represent keratinous debris within dilated, malformed pilosebaceous follicles. The lesions are most often unilateral and may develop at any site. Rarely, they are associated with other congenital malformations, including skeletal defects, cerebral anomalies, and cataracts. Although these lesions are often asymptomatic, some individuals experience recurrent inflammation, resulting in cyst formation, fistulas, and scarring. There is no effective treatment except full-thickness excision; palliation of larger lesions may be achieved by regular applications of a retinoic acid preparation.

Connective Tissue Nevus.

This is a hamartoma of collagen, elastin, and/or glycosaminoglycans of the dermal extracellular matrix. It may occur as a solitary defect or as a manifestation of an associated disorder. These nevi may occur at any site but are most common on the back, buttocks, arms, and thighs. They are skin-colored, ivory, or yellow plaques, 2–15?cm in diameter, composed of many tiny papules or grouped nodules that are frequently difficult to appreciate visually because of the subtle color changes. The plaques have a rubbery or cobblestone consistency on palpation. Biopsy findings are variable and include increased amounts and/or degeneration or fragmentation of dermal collagen, elastic tissue, or ground substance. Similar lesions occurring with tuberous sclerosis are called shagreen patches; however, shagreen patches consist only of excessive amounts of collagen. The association of many small papular connective tissue nevi with osteopoikilosis is called *dermatofibrosis lenticularis disseminata* (Buschke-Ollendorf syndrome).

Smooth Muscle Hamartoma.

This hamartoma is a developmental anomaly resulting from hyperplasia of the smooth muscle (arrector pili) associated with hair follicles. It is usually evident at birth or shortly thereafter as a flesh-colored or lightly pigmented plaque with overlying hypertrichosis on the trunk or limbs. Transient elevation or a rippling movement of the lesion, caused by contraction of the muscle bundles, can sometimes be elicited by stroking the surface. Smooth muscle hamartoma can be mistaken for congenital pigmented nevus, but the distinction is important because it has no risk for malignant melanoma and need not be removed.

Chapter 642 - Hyperpigmented Lesions

Disorders of Pigment.

Increased skin color may be generalized or localized and may result from various defects in melanocyte formation, differentiation, migration, or distribution or in the production or distribution of melanin. Some of these aberrations are a manifestation of systemic disease (hyperpigmentation of Addison disease); others represent generalized or focal developmental defects (piebaldism); still others may be nonspecific and the result of cutaneous inflammation (postinflammatory hyperpigmentation).

Ephelides (Freckles).

These are light or dark brown macules usually less than 3?mm in diameter, with a poorly defined margin that occur in sun-exposed areas, such as the face, upper back, arms, and hands. They are induced by exposure to sun, particularly during the summer, and may fade or disappear during the winter. They are more common in fair-haired individuals, appear first during the preschool years, and are determined by an autosomal dominant gene. Histologically, they are marked by increased melanin pigment in epidermal basal cells, which have more numerous and larger dendritic processes than the

---

melanocytes of the surrounding paler skin. The lack of melanocytic proliferation or elongation of epidermal rete ridges distinguishes them from lentigines. Freckles have been identified as a risk factor for melanoma independent of melanocytic nevi.

Lentigines.

Lentigines, often mistaken for freckles or junctional nevi, are small (<3?cm), round, dark-brown macules that can appear anywhere on the body. They are unrelated to sun exposure and remain permanently. Histologically, they have elongated, club-shaped, epidermal rete ridges with increased numbers of melanocytes and dense epidermal deposits of melanin. No nests of melanocytes are found. The lesions are benign and, when few, may be viewed as a normal occurrence.

Lentigines may increase in number and darken excessively in Addison disease and

during pregnancy. *Lentiginosis profusa* involves innumerable small, pigmented macules that are present at birth or appear during childhood. There are no associated abnormalities, and mucous membranes are spared. *LAMB syndrome* consists of *l*entigines of the face and vulva, *a*trial myxoma, *m*ucocutaneous myxomas, and *b*lue nevi. The *multiple lentigines (LEOPARD) syndrome* is an autosomal dominant entity consisting of a generalized, symmetric distribution of *l*entigines in association with *e*lectrocardiogram abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitals (cryptorchidism, hypogonadism, hypospadias), growth *r*etardation, and sensorineural *d*eafness. Other features include hypertrophic obstructive cardiomyopathy and pectus excavatum or carinatum.

The *Peutz-Jeghers syndrome* is characterized by melanotic macules on the lips and mucous membranes and by gastrointestinal (GI) polyposis. It is inherited as an autosomal dominant trait. The causative gene encodes a nuclear serine/threonine kinase, LKB1, which functions as a tumor suppressor. Onset is noted during infancy and early childhood when pigmented macules appear on the lips and buccal mucosa. The macules are usually a few millimeters in size but may be as large as 1–2?cm. Macules also appear occasionally on the palate, gums, tongue, and vaginal mucosa. Cutaneous lesions may develop on the nose, hands, and feet; around the mouth, eyes, and umbilicus; and as longitudinal bands or diffuse hyperpigmentation of the nails. Pigmented macules often fade from the lips and skin during puberty and adulthood but generally do not disappear from mucosal surfaces. Buccal mucosal macules are the most constant feature of the disorder; in some families, however, occasional members may be affected only with the pigmentary changes. Indistinguishable pigmentary changes beginning in adult life also occur sporadically in individuals without intestinal involvement.

Polyposis usually involves the jejunum and ileum but may also occur in the stomach, duodenum, colon, and rectum (Chapter 326). Episodic abdominal pain, diarrhea, melena, and intussusception are frequent complications. Patients have a significantly increased risk of GI tract and non-GI tract tumors at a young age. GI cancer has been reported in approximately 2–3% of patients; the lifetime relative risk of GI malignancy is 13. The relative risk of non-GI tract malignancies is 9, including ovarian, cervical, and testicular tumors. Peutz-Jeghers syndrome must be differentiated from other syndromes associated with multiple lentigines *(Laugier-Hunziker syndrome)*, from ordinary freckling, from *Gardner syndrome*, and from *Cronkhite-Canada syndrome*, a disorder characterized by GI polyposis; alopecia; onychodystrophy; and diffuse pigmentation of the palms, volar aspects of the fingers, and dorsal hands. Treatment of Peutz-Jeghers melanotic macules has been successful, in some cases, with carbon dioxide, ruby, or argon lasers.

Café-au-Lait Spots.

These are uniformly hyperpigmented, sharply demarcated macular lesions, the hues of which vary with the normal degree of pigmentation of the individual: They are tan or light brown in white individuals and may be dark brown in black children. Café-au-lait spots vary tremendously in size and may be large, covering a significant portion of the trunk or limb. Generally, the borders are smooth, but some have an exceedingly irregular border. The lesions are characterized by increased numbers of melanocytes and melanin in the epidermis but lack the clubbed rete ridges that typify lentigines. One to three café-au-lait spots are common in normal children; approximately 10% of normal children have café-au-lait macules. They may be present at birth or develop during childhood.

Large, often asymmetric café-au-lait spots with irregular borders are characteristic of patients with *McCune-Albright syndrome* (see Chapter 556.6). This disorder includes polyostotic fibrous dysplasia of bone, leading to pathologic fractures; precocious puberty; and numerous hyperfunctional endocrinopathies. The macular hyperpigmentation may be present at birth or develop late in childhood. Cutaneous pigmentation typically is most extensive on the side showing the most severe bone involvement. The full syndrome with precocious puberty occurs only in girls. A mutation in the gene for the a subunit of G_s , resulting in stimulation of cyclic adenosine monophosphate formation, occurs in these patients.

NEUROFIBROMATOSIS TYPE 1 (VON RECKLINGHAUSEN DISEASE).

The café-au-lait spot is the most familiar cutaneous hallmark of this autosomal dominant neurocutaneous syndrome (see Chapter 589.1). These lesions also occur with certain other disorders, including other types of neurofibromatosis (Box 642–1). Included in the criteria for this diagnosis is the presence of five or more café-au-lait spots more than 5?mm in diameter in prepubertal patients or six or more café-au-lait spots more than 15?mm in diameter in postpubertal children. Multiple café-au-lait macules commonly produce a freckled appearance of non–sun-exposed areas such as the axillae (Crowe sign), the inguinal and inframammary regions, and under the chin.

Incontinentia Pigmenti (Bloch-Sulzberger Disease).

This rare, heritable, multisystem ectodermal disorder features dermatologic, dental, and ocular abnormalities. The phenotype is produced by functional mosaicism caused by random X-inactivation of an X-linked dominant gene that is lethal in males. The paucity of affected males, the occurrence of female-to-female transmission, and an increased frequency of spontaneous abortions in carrier females supports this supposition. The gene, nuclear factor kappa B essential modulator (NEMO), is located at Xq28.

CLINICAL MANIFESTATIONS.

This disease has four phases, not all of which may occur in a given patient. The *first phase* is evident at birth or during the first few weeks of life and consists of erythematous linear streaks and plaques of vesicles that are most pronounced on the limbs and circumferentially on the trunk. The lesions may be confused with those of herpes simplex, bullous impetigo, or mastocytosis, but the linear configuration is unique. Histopathologically, epidermal edema and eosinophil-filled intraepidermal vesicles are present. Eosinophils also infiltrate the adjacent epidermis and dermis. Blood eosinophilia up to 65% also is common. The first stage generally resolves by 4 mo of age, but mild, short-lived recurrences of

blisters may develop during febrile illnesses of childhood. In the *second phase,* as blisters on the distal limbs resolve, they become dry and hyperkeratotic, forming verrucous plaques. The verrucous plaques rarely affect the trunk or face and generally involute within 6 mo. Epidermal hyperplasia, hyperkeratosis, and papillomatosis are characteristic. The *third* or *pigmentary stage* is the hallmark of incontinentia pigmenti. It generally develops over weeks to months and may overlap the earlier phases, be evident at birth, or, more commonly, begin to appear within the first few weeks of life. Hyperpigmentation more often is apparent on the trunk than the limbs and is distributed in macular whorls, reticulated patches, flecks, and linear streaks that follow Blaschko lines. The axillae and groin are invariably affected. The sites of involvement are not necessarily those of the preceding vesicular and warty lesions. The pigmented lesions, once present, persist throughout childhood (Fig. 642–1). They generally begin to fade by early adolescence, however, and often have disappeared by age 16 yr. Occasionally, the pigmentation remains permanently, particularly in the groin. The lesion, histopathologically, shows vacuolar degeneration of the epidermal basal cells and melanin in melanophages of the upper dermis as a result of incontinence of pigment. In the *fourth stage*, hypopigmented, hairless, anhidrotic patches or streaks occur as a late manifestation of incontinentia pigmenti; they may develop, however, before the hyperpigmentation of stage three has resolved. The lesions develop mainly on the flexor aspect of the lower legs and less often on the arms and trunk.

Although skin lesions may constitute the only manifestation, approximately 80% of affected children have other defects. Alopecia, which may be scarring and patchy or diffuse, is most common on the vertex and occurs in up to 40% of patients. Hair may be lusterless, wiry, and coarse. Dental anomalies, which are present in up to 80% of patients and are persistent throughout life, consist of late dentition, hypodontia, conical teeth, and impaction. Central nervous system manifestations, including motor and cognitive developmental retardation, seizures, microcephaly, spasticity, and paralysis, are found in up to one third of affected children. Ocular anomalies, such as

Figure 642-1 Whorled macular hyperpigmentation of incontinentia pigmenti.

neovascularization, microphthalmos, strabismus, optic nerve atrophy, cataracts, and retrolenticular masses, occur in more than 30% of children. Nonetheless, more than 90% of patients have normal vision. The ocular and central nervous system lesions may be secondary to an occlusive vasculopathy. Less common abnormalities include dystrophy of nails (ridging, pitting) and skeletal defects.

Diagnosis of incontinentia pigmenti is made on clinical grounds, although major and minor criteria have been established to aid in diagnosis. Wood lamp examination may be useful in older children and adolescents to highlight pigmentary abnormalities.

TREATMENT.

The choice of investigative studies and the plan of management depend on the occurrence of particular noncutaneous abnormalities because the skin lesions are benign. The high incidence of associated major anomalies warrants genetic counseling.

Postinflammatory Pigmentary Changes.

Either hyperpigmentation or hypopigmentation can occur as a result of cutaneous inflammation. Alteration in pigmentation usually follows a severe inflammatory reaction but may result from mild dermatitis. Dark-skinned children are more likely to show these changes than fair-skinned ones. Although altered pigmentation may persist for weeks to months, patients can be reassured that these lesions are usually temporary. These changes must be distinguished from nevoid lesions and diseases manifested by pigmentary alterations such as vitiligo.

Chapter 643 - Hypopigmented Lesions

Albinism.

Several types of congenital oculocutaneous albinism consist of partial or complete failure of melanin production in the skin, hair, and eyes despite the presence of normal number, structure, and distribution of melanocytes. The various forms of albinism, including nine autosomal recessive and one rare autosomal dominant variants, may be distinguished by clinical manifestations, morphology of the melanosomes, and the hair bulb incubation test, in which hair bulbs are plucked and incubated with tyrosine to determine whether tyrosinase is present. Tyrosinase is the copper-containing enzyme that catalyzes at least three steps in melanin biosynthesis (see Chapter 74.2). Tyrosinase-positive variants, which are characterized by darkening of the hair bulb on incubation with tyrosine, are most common.

Ocular albinism, which involves only the eyes, presents in X-linked and autosomal dominant forms, and one autosomal recessive form. Two of these types are associated with deafness.

Female carriers of the X-linked types may show irregular retinal pigmentation.

Tyrosinase-negative or type 1 oculocutaneous albinism is characterized by greatly reduced or absent tyrosinase activity. Type 1A albinism, the most severe form, is characterized by a lack of visible pigment in hair, skin, and eyes. This is manifested as photophobia, nystagmus, defective visual acuity, white hair, and white skin. The irises are blue-gray in oblique light and prominent pink in reflected light. Type 1B or yellow mutant albinism presents at birth with white hair, pink skin, and gray eyes. This type is particularly prevalent in Amish communities. Progressively, however, the hair becomes yellow-red, the skin tans lightly on exposure to the sun, and the irises may accumulate some brown pigment, with a resultant improvement in visual acuity. Photophobia and nystagmus are present but are mild. Numerous different allelic mutations in the tyrosinase gene account for types 1A and 1B albinism. In whites, no single mutant tyrosinase allele accounts for a significant fraction of the total, and this fact complicates molecular approaches to carrier detection and prenatal diagnosis.

The phenotype of *tyrosinase-positive or type 2 albinism* ranges from nearly normal to closely resembling type 1 albinism. Little or no melanin is present at birth, but pigment, particularly red-yellow pigment, may accumulate rapidly during childhood to

produce straw-colored or light brown skin in whites. Progressive improvement in visual acuity and nystagmus occurs with aging. Blacks may have yellow-brown skin, dark-brown freckles in sun-exposed areas, and brown coloration of the irises. The defect in type 2 albinism has been mapped to chromosome 15 (the P gene) and may involve a tyrosine-specific transport protein. Deletions in this region also result in the Prader-Willi and Angelman syndromes, which include hypopigmentation.

The *Hermansky-Pudlak syndrome, due to mutations in the HPS gene,* is tyrosinase-positive albinism, with variable pigmentation, in association with a platelet storage pool deficiency and a hemorrhagic diathesis. Additional features include accumulation of a ceroid-like pigment in cells of the reticuloendothelial system, pulmonary fibrosis, and granulomatous colitis.

The *Cross-McKusick-Breen syndrome* consists of tyrosinase-positive albinism with ocular abnormalities, retardation, spasticity, and athetosis. Some patients have darkly pigmented hairs distributed among hair without color in the eyebrows and eyelashes.

Because of the absence of normal protection by adequate amounts of epidermal melanin, persons with albinism are predisposed to develop actinic keratoses and cutaneous carcinoma secondary to skin damage by ultraviolet light. Protective clothing and a broad-spectrum sunscreen preparation (see Chapter 646) should be worn during exposure to sunlight.

Partial Albinism (Piebaldism).

This congenital autosomal dominant disorder is characterized by sharply demarcated amelanotic patches that occur most frequently on the forehead, anterior scalp (producing a white forelock), ventral trunk, elbows, and knees. Islands of normal pigmentation may be present within the amelanotic areas. The plaques are a result of a permanent localized absence of melanocytes and melanosomes or reduced numbers of abnormally large melanocytes. Piebaldism results from mutations in the *KIT* proto-oncogene, which encodes the cellular transmembrane tyrosinase kinase for mast/stem cell growth factor. The pattern of depigmentation is thought to stem from defective melanocyte proliferation or migration from the neural crest during development. Piebaldism must be differentiated from vitiligo, which may be progressive and is not usually congenital; nevus depigmentosus; and Waardenburg syndrome.

Waardenburg Syndrome.

Waardenburg syndrome is an autosomal dominantly inherited disorder characterized by pigmentary abnormalities and defects in other tissues derived from the neural crest. Mutations in one of three transcription factors, PAX3, MITF, and SOX 10, lead to several distinctive presentations. Common features include lateral displacement of the medial canthi with dystopia canthorum (99%), broad nasal root (80%), heterochromic irises (25%), congenital deafness (20%), a white forelock (17%), and cutaneous hypopigmentation. A few patients have skin changes identical to piebaldism. Premature graying may develop in the 3rd decade. Waardenburg syndrome is inherited as an autosomal dominant trait with variable penetrance. It is due to defective migration and differentiation of neural crest cells.

Chédiak-Higashi Syndrome.

See Chapter 120.3

Tuberous Sclerosis.

See Chapter 589.2 This disorder is a multisystemic disorder affecting primarily tissues derived from ectoderm but also involving organs of mesodermal and endodermal origin, particularly the eyes, kidneys, and heart. The classic clinical triad is skin lesions in association with epilepsy and mental retardation.

ETIOLOGY AND EPIDEMIOLOGY.

This is an autosomal dominant condition with variable expression. Mutations have been mapped to chromosome 9q34.3 (TSC1) and 16p13.3 (TSC2). The TSC2 product is tubern, which has sequence homology with a GTPase-activating protein and may have a role in regulating cellular growth by acting as a growth suppressor gene. TSC1 also is postulated to act as a growth suppressor. Approximately half of cases are due to new mutations. The most reliable early cutaneous sign is the white- or ash-leaf macule, which presents at birth or in early infancy, often years before other signs of the disease. Ash-leaf macules also appear in 2–3/1,000 normal newborns. They are sharply demarcated, pale, 0.5–3?cm lesions that often assume the shape of a mountain ash leaflet.

CLINICAL MANIFESTATIONS.

Single or multiple ash-leaf lesions are most often found on the trunk (Fig. 643–1*A*) but also occur on the face and limbs. Small, confetti-like hypopigmented macules are also present in some instances, reflecting inadequate melanization of the melanosomes in melanocytes. *Adenoma sebaceum* is the most commonly recognized cutaneous marker of tuberous sclerosis; the lesions appear on the face during middle to late childhood or adolescence in approximately 80% of patients. These red-brown or flesh-colored, smooth, glistening, telangiectatic 1–10?mm papules may extend from the nasolabial folds to the cheeks and chin (see Fig. 643–1 *B*). The presence of telangiectasias and the lack of comedones and pustules help to distinguish this eruption from acne vulgaris. Adenoma sebaceum is a misnomer because these growths are angiofibromas rather than tumors of the sebaceous gland tumors. Similar fibromatous nodules may be scattered on the forehead, trunk, and limbs. Large, skin-colored, irregularly thickened plaques with an orange peel or cobblestone texture *(shagreen patch)* may occur in the lumbosacral area. At puberty, firm, flesh-colored *periungual fibromas* (see Fig. 643–1 *C*) emerge on the nail folds of some children; gingival fibromas may also occur, unassociated with the administration of anticonvulsant medications. Café-au-lait spots occur with increased frequency but are not as numerous as in neurofibromatosis. Mental deficiency occurs in 60–70%; nearly all have epilepsy. Epilepsy is also present in approximately 70% of those patients without mental retardation. Epilepsy begins in infancy or early childhood and is often progressively more severe. Cardiac rhabdomyomas are present in approximately one half of infants and usually regress; mechanical obstruction is a potential complication. Rarely, the presenting sign of tuberous

sclerosis is hematuria, caused by a renal angiomyolipoma, which is characteristic of this condition. Seventy-five per cent of patients with tuberous sclerosis die before the age of 25 yr, most commonly as a complication of epilepsy, of intercurrent infection, or occasionally of cardiac failure or pulmonary fibrosis.

Figure 643-1 Tuberous sclerosis. *A*, Multiple white-leaf macules, small papular fibromas, and shagreen patch on lower back. *B*, Angiofibromas and angiofibromatous plaques on the temple. *C*, Periungual fibromas.

Hypomelanosis of Ito (Incontinentia Pigmenti Achromians).

This congenital skin disorder affects children of both sexes and is frequently associated with defects in several organ systems. There is no evidence for genetic transmission; chromosomal mosaicism and chromosomal translocations have been reported. Hypomelanosis of Ito currently is a descriptive rather than definitive diagnosis.

The skin lesions of hypomelanosis of Ito are generally present at birth but may be acquired within the first 2 yr of life. The lesions are similar to a negative image of that present in incontinentia pigmenti, consisting of bizarre, patterned, hypopigmented macules arranged over the body surface in sharply demarcated whorls, streaks, and patches that follow the lines of Blaschko (Fig. 643–2). The palms, soles, and mucous membranes are spared. The hypopigmentation remains unchanged throughout childhood but fades during adulthood. The degree of depigmentation varies from hypopigmented to achromic. Neither inflammatory nor vesicular lesions precede the development of the pigmentary changes as in incontinentia pigmenti. The hypopigmented areas demonstrate fewer and smaller melanocytes and a decreased number of melanin granules in the basal cell layer than normal. Inflammatory cells and pigment incontinence are lacking.

The most commonly associated abnormalities involve the nervous system, including mental retardation (70%), seizures (40%), microcephaly (25%), and muscular hypotonia (15%). The musculoskeletal system is the second most frequently involved system, affected by scoliosis and thoracic and limb deformities. Minor ophthalmologic defects (strabismus, nystagmus) are present in 25% of patients, and 10% have cardiac defects. The differential diagnosis includes systematized nevus depigmentosus, which is a stable leukoderma not associated with systemic manifestations. Differentiation from incontinentia pigmenti, particularly the hypopigmented fourth stage, is critical for genetic counseling because incontinentia pigmenti, unlike hypomelanosis of Ito, is inherited.

Vitiligo.

Approximately half of cases of this acquired pigmentary defect present before age 20 yr. The lesions are sharply circumscribed, depigmented macules that vary in size and shape.

EPIDEMIOLOGY AND ETIOLOGY.

Although no clear-cut pattern of genetic transmission is established, 30–40% of patients have a positive family history. Associated abnormalities include uveitis and premature graying of hair. ***Vogt-Koyanagi syndrome*** presents with vitiligo, uveitis, and premature graying of hair but also involves the central nervous system. Vitiligo is

---

Figure 643-2 Marbled hypopigmented streaks of hypomelanosis of Ito (incontinentia pigmenti achromians).

more prevalent in patients with thyroid disease (hypothyroidism or hyperthyroidism), adrenal insufficiency, pernicious anemia, and diabetes mellitus. The cause of vitiligo is unknown, but trauma appears to have a role in induction of the lesions. A popular theory on the pathogenesis of vitiligo proposes an autoimmune mechanism, based on the finding that organ-specific autoantibodies to thyroid, gastroparietal, and adrenal tissue are found more frequently in the serum of patients with vitiligo than in the general population. Alternatively, a neurogenic theory purports that a compound that is released at peripheral nerve endings in the skin may inhibit melanogenesis; a self-destruct theory suggests that melanocytes destroy themselves as a result of a defective protective mechanism that normally would remove toxic melanin precursors.

CLINICAL MANIFESTATIONS.

Areas of predilection are normally relatively hyperpigmented, such as the face, particularly around the eyes or mouth, the axillae, the inguinal region and genitals, and the areolas. Sites that are frequently subjected to trauma and friction are also likely to be affected, including the hands and feet, elbows, knees, and ankles (Fig. 643–3). When the scalp or brow is affected, the hair may lose pigment. The distribution of involvement is generally symmetric but occasionally is unilateral or dermatomal.

The course of vitiligo varies; some lesions may remit spontaneously while others are developing, but relentlessly progressive depigmentation may occur. Spontaneous repigmentation occurs in 10–20% of patients, most commonly in lesions that are in a sun-exposed distribution. Histopathologically, melanocytes are absent from involved sites and repopulate the epidermis from the hair follicle epithelium when repigmentation occurs. Although the diagnosis is usually made clinically, the disappearance of melanocytes can be confirmed by DOPA stains or electron microscopy of specimens obtained from depigmented skin.

Figure 643-3 Multiple, sharply demarcated, symmetric, depigmented areas of vitiligo.

TREATMENT.

Treatment of vitiligo is challenging. In adults, treatment usually involves administration of oral or topical psoralen compounds in conjunction with exposure to sunlight or an ultraviolet light source. Repigmentation may be partial or complete, but many months of therapy may be required. In the pediatric population, the risk/benefit ratio of phototherapy for vitiligo is less clear. High-potency topical steroids are sometimes effective in repigmenting small areas of vitiligo or early lesions in areas not amenable to phototherapy (lips). Small lesions may be camouflaged by application of a specially prepared makeup (Covermark, Dermablend). Because of the absence of melanin, vitiliginous skin burns readily on sun exposure and should be protected at all times with an appropriate sunscreen. Therapies that have anecdotal support include vitamin supplementation, pseudocatalase cream in association with ultraviolet light, and topical immunomodulators such as tacrolimus, but controlled trials are lacking.

Chapter 644 - Vesiculobullous Disorders

Many diseases are characterized by vesiculobullous lesions; they vary considerably in cause, age of onset, and pattern. Some of them (varicella) are discussed in other chapters; some are described in other chapters of this part because the vesiculobullous lesions represent only a transient stage of the disease (incontinentia pigmenti) or are seen only on occasion (mastocytosis). The morphology of the blister often provides a visual clue to the location of the lesion within the skin. Blisters localized to the epidermal layers are thin walled, relatively flaccid, and easily ruptured. Subepidermal blisters are tense, thick walled, and more durable. Biopsies of blisters can be diagnostic because the level of cleavage within the skin and associated findings such as the nature of the inflammatory infiltrate are characteristic for a particular disorder. Other diagnostic procedures such as

immunofluorescence and electron microscopy can often help distinguish vesiculobullous disorders that have nearly identical histopathologic findings (Table 644–1).

Erythema Multiforme.

Erythema multiforme (EM) has numerous morphologic manifestations on the skin, varying from erythematous macules, papules, vesicles, bullae, or urticaria-appearing plaques to patches of confluent erythema. The eruption appears most commonly in patients between the ages of 10 and 30 yr and usually is asymptomatic, although a burning sensation or pruritus may be present. The *diagnosis* of EM is established by finding the classic lesion: doughnut-shaped, target-like (iris, or bull's eye) papules with an erythematous outer border, an inner pale ring, and a dusky purple to necrotic center.

EM is characterized by an abrupt, symmetric cutaneous eruption, most commonly on the extensor upper extremities; lesions are relatively sparse on the face, trunk, and legs. The eruption often appears initially as red macules or urticarial plaques that expand centrifugally to form lesions up to 2?cm in diameter with a dusky to necrotic center. Lesions of a particular episode typically appear within 72?hr and remain fixed in place. Oral lesions may occur, but other mucosal surfaces are spared. Approximately 25% of cases of EM appear to be confined to the oral mucosa, with a predilection for the vermilion border of the lips and the buccal mucosa, generally sparing the gingivae. Prodromal symptoms generally are absent. Lesions typically resolve without sequelae in about 2 wk; progression to Stevens-Johnson syndrome does not occur.

Although EM may present initially with urticarial lesions, unlike urticaria, a given lesion of EM does not fade within 24?hr. Serum sickness–like reaction (SSLR) to cefaclor also may present with EM-like lesions. Although the lesions may develop a dusky to purple center, in most cases the eruption of cefaclor-induced

SSLR is pruritic, transient, and migratory and is probably urticarial rather than true EM.

The *differential diagnosis* of EM also includes bullous pemphigoid, pemphigus, linear IgA dermatosis, graft vs host disease, bullous drug eruption, urticaria, viral infections such as herpes simplex, Reiter disease, Kawasaki disease, Behçet disease, allergic vasculitis, erythema annulare centrifugum, and periarteritis nodosa. EM that primarily involves the oral mucosa may be confused with a handful of other conditions, including bullous pemphigoid, pemphigus vulgaris, vesiculobullous or erosive lichen planus, Behçet syndrome, recurrent aphthous stomatitis, and primary herpetic gingivostomatitis.

Among the numerous factors implicated in the *etiology* of EM, infection with herpes simplex virus (HSV) is the most common. HSV labialis and, less commonly, HSV genitalis have been implicated in 60% of episodes of EM and are believed to trigger nearly all episodes of recurrent EM, frequently in association with sun exposure, despite the presence of robust HSV-specific immunity. HSV antigens and DNA are present in skin lesions of EM but are absent in nonlesional skin. Presence of the human leukocyte antigens B62, B35, and DR53 is associated with an increased risk of HSV-induced EM, particularly the recurrent form. Most patients experience a single self-limited episode of EM. Lesions of HSV-induced recurrent EM typically develop 10–14 days after onset of recurrent HSV eruptions, have a similar appearance from episode to episode, but may vary in frequency and duration in a given patient. Not all episodes of recurrent HSV evolve into EM in susceptible patients.

The *pathogenesis* of EM is unclear, but it may be a host-specific cell-mediated immune response to an antigenic stimulus, resulting in damage to keratinocytes. Cytokines released by activated mononuclear cells and keratinocytes may contribute to epidermal cell death and constitutional symptoms.

Microscopic findings of EM, as with the gross appearance of the cutaneous eruption, are variable but are significant *diagnostically*. Early lesions typically show slight intercellular edema, rare dyskeratotic keratinocytes, and basal vacuolation in the epidermis and a perivascular lymphohistiocytic infiltrate with edema in the upper dermis. More mature lesions show an accentuation of these characteristics and the development of lymphocytic exocytosis and an intense, perivascular and interstitial mononuclear infiltrate, lacking in significant numbers of eosinophils or neutrophils, in the upper third of the dermis. The entire epidermis becomes necrotic in severe cases.

Treatment of EM is supportive. Topical emollients and systemic antihistamines and nonsteroidal anti-inflammatory agents do not alter the course of the disease but may provide symptomatic relief. No controlled, prospective studies support the use of corticosteroids in the management of EM. Rather, glucocorticoid therapy may be permissive of HSV replication and make EM episodes more frequent or continuous. Prophylactic oral acyclovir given for 6 mo may be effective in controlling recurrent episodes of HSV-associated EM. On discontinuation of acyclovir, both HSV and EM may recur, although episodes may be less frequent and more mild.

Stevens-Johnson Syndrome.

Cutaneous lesions in Stevens-Johnson syndrome generally consist initially of erythematous macules that rapidly and variably develop central necrosis to form vesicles, bullae, and areas of denudation on the face, trunk, and extremities. The skin lesions typically are more widespread than in EM and are accompanied by involvement of two or more mucosal surfaces, namely the eyes, oral cavity, upper airway or esophagus, gastrointestinal tract, or anogenital mucosa. A burning sensation, edema, and erythema of the lips and buccal mucosa are often the presenting signs, followed by development of bullae, ulceration, and hemorrhagic crusting. Lesions may be preceded by a flulike upper respiratory illness. Pain from mucosal ulceration is often severe, but skin tenderness is minimal to absent, in contrast to toxic epidermal necrolysis. Corneal ulceration, anterior uveitis, panophthalmitis, bronchitis, pneumonitis, myocarditis, hepatitis, enterocolitis, polyarthritis, hematuria, and acute tubular necrosis leading to renal failure may occur. Disseminated cutaneous bullae and erosions may result in significant blood loss, increased insensible fluid loss, and a high risk of bacterial superinfection and sepsis. New lesions occur in crops, and complete healing may take 4–6 wk; ocular scarring and visual impairment and strictures of the esophagus, bronchi, vagina, urethra, or anus may remain. Nonspecific laboratory abnormalities in Stevens-Johnson syndrome include leukocytosis, elevated erythrocyte sedimentation rate and liver transaminase levels, and decreased serum albumin values. *Toxic*

epidermal necrolysis is the most severe disorder in the clinical spectrum of the disease, involving considerable constitutional toxicity and extensive necrolysis of the mucous membranes and more than 30% of the body surface area.

Mycoplasma pneumoniae is the most convincingly demonstrated infectious cause of Stevens-Johnson syndrome; the organism also has been detected in lesional skin. Drugs, particularly sulfonamides, nonsteroidal anti-inflammatory agents (butazones, pyrazolones, ibuprofen, piroxicam, and salicylates), and anticonvulsants (phenytoin), are the agents most commonly precipitating Stevens-Johnson syndrome and toxic epidermal necrolysis (Box 644–1).

TREATMENT.

Management of Stevens-Johnson syndrome is supportive and symptomatic. Potentially offending drugs must be discontinued as soon as possible. Ophthalmologic consultation is mandatory because ocular sequelae such as corneal scarring can lead to vision loss. Oral lesions should be managed with mouthwashes and glycerin swabs. Vaginal lesions should be observed closely and treated to prevent vaginal stricture or

fusion. Topical anesthetics (diphenhydramine, dyclonine, and viscous lidocaine) may provide relief from pain, particularly when applied before eating. Denuded skin lesions can be cleansed with saline or Burow solution compresses. Antibiotic therapy is appropriate for secondary bacterial infection. Treatment may require admission to an intensive care unit; intravenous fluids; nutritional support; sheepskin or air-fluid bedding; daily saline or Burow solution compresses; paraffin gauze or hydrogel dressing of denuded areas; saline compresses on the eyelids, lips, or nose; analgesics; and urinary catheterization (when needed). A daily examination for infection and ocular lesions, which constitute the major cause of long-term morbidity, is essential. Systemic antibiotics are indicated for urinary or cutaneous infections and for suspected bacteremia because infection is the leading cause of death. Prophylactic systemic antibiotics, however, are not necessary. Although corticosteroids are sometimes advocated in early, severe cases of Stevens-Johnson syndrome, no prospective double-blind studies evaluating their efficacy have been reported. Most authorities discourage their use because of reports of increased morbidity and mortality (sepsis) with their administration. Intravenous immunoglobulin has been used anecdotally.

Toxic Epidermal Necrolysis (Lyell Syndrome)

EPIDEMIOLOGY AND ETIOLOGY.

The pathogenesis of toxic epidermal necrolysis is not proved but may involve a hypersensitivity phenomenon that results in damage primarily to the basal cell layer of the epidermis. Epidermal damage appears to result from Fas-mediated keratinocyte apoptosis. This condition is triggered by many of the same factors that are thought to be responsible for Stevens-Johnson syndrome, principally drugs such as the sulfonamides, amoxicillin, phenobarbital, hydantoin, butazones, and allopurinol. Toxic epidermal necrolysis is defined by (1) widespread blister formation and morbilliform or confluent erythema, associated with skin tenderness; (2) absence of target lesions; (3) sudden onset and generalization within 24–48?hr; (4) histologic findings of full-thickness epidermal necrosis and a minimal to absent dermal infiltrate. These criteria categorize toxic epidermal necrolysis as a

separate entity from EM; some authorities, however, contend that toxic epidermal necrolysis represents the most severe form of the spectrum of EM. This condition is exceedingly rare in infants younger than 6 mo; only three such cases have been documented.

CLINICAL MANIFESTATIONS.

The prodrome consists of fever, malaise, localized skin tenderness, and diffuse erythema. Inflammation of the eyelids, conjunctivae, mouth, and genitals may precede skin lesions. Flaccid bullae may develop, although this is not a prominent feature. Characteristically, full-thickness epidermis is lost in large sheets. ***Nikolsky sign*** (denudation of the skin with gentle tangential pressure) is present but only in the areas of erythema. Conjunctivitis and oral lesions are usually not as severe as in Stevens-Johnson syndrome. Healing takes place over 14 or more days. Scarring, particularly of the eyes, may result in corneal opacity. The course may be relentlessly progressive, complicated by severe dehydration, electrolyte imbalance, shock, and secondary localized infection and septicemia. Loss of nails and hair may also occur. Long-term morbidity includes alterations in skin pigmentation, eye problems (lack of tears, conjunctival scarring, loss of lashes), and strictures of mucosal surfaces. The differential diagnosis includes staphylococcal scalded skin syndrome, in which the blister cleavage plane is intraepidermal; graft versus host disease; chemical burns; drug eruptions; and pemphigus.

Anticonvulsant hypersensitivity syndrome is a multisystem reaction that appears approximately 4 wk to 3 mo after starting phenytoin, carbamazepine, phenobarbitone, or primidone. The mucocutaneous eruption may be identical to that of EM, Stevens-Johnson syndrome, or toxic epidermal necrolysis, but the reaction typically also includes lymphadenopathy, as well as fever, hepatitis, eosinophilia, and leukocytosis.

TREATMENT.

Appreciation of the specific etiologic factor is crucial; particularly when the disorder is drug induced, its administration must be discontinued as soon as possible. Management is similar to that for severe burns and may be best accomplished in a burn unit. It may include strict reverse isolation, meticulous fluid and electrolyte therapy, use of an air-fluid bed, and daily cultures. Systemic antibiotic therapy is indicated when secondary infection is evident or suspected. Skin care consists of cleansing with isotonic saline or Burow solution and applications of mupirocin ointment. Biologic or hydrogel dressings alleviate pain and reduce fluid loss. Narcotics are often required for pain relief. Mouth and eye care may be necessary, such as for EM major. Early high-dose systemic corticosteroids are not of proven benefit; pulse methylprednisolone alone or in concert with intravenous immunoglobulin have produced positive results in small uncontrolled series.

Epidermolysis Bullosa.

Diseases categorized under this general term are a heterogeneous group of congenital, hereditary blistering disorders. They differ in severity and prognosis, clinical and histologic features, and inheritance patterns (Table 644–2) but are all characterized by induction of blisters by trauma and exacerbation of blistering in warm weather. The disorders can be categorized under three major headings: epidermolysis bullosa simplex, junctional epidermolysis bullosa, and dystrophic epidermolysis bullosa.

EPIDERMOLYSIS BULLOSA SIMPLEX.

This is a nonscarring, autosomal dominant disorder. The defect in all types of epidermolysis bullosa simplex is in the central a-helical coil of keratin 5 or 14, which makes up intermediate filaments of the basal keratinocytes. Keratin 5 and 14 genes are located on chromosomes 17q and 12q, respectively. The intraepidermal bullae result from cytolysis of the basal cells.

Blisters are usually present at birth or during the neonatal period. Sites of predilection are the hands, feet, elbows, knees, legs, and scalp. Intraoral lesions are minimal, nails rarely become dystrophic and usually regrow even when they are shed, and dentition is normal. Bullae heal with minimal to no scar or milia formation. Secondary infection is the primary complication. The propensity to blister decreases with age, and the long-term prognosis is good. Blisters should be drained by puncturing, but the blister top should be left intact to protect the underlying skin. Erosions may be covered with mupirocin if there is evidence of infection and with a semipermeable dressing. Genetic counseling should be offered to families of affected children.

Localized *epidermolysis bullosa simplex of hands and feet* (Weber-Cockayne type) often presents when a child begins to walk; onset may be delayed, however, until puberty or early adulthood when heavy shoes are worn or the feet are subjected to increased trauma. Bullae are usually restricted to the hands and feet; rarely, they occur elsewhere such as the dorsal aspect of the arms and the shins. The disorder ranges from mildly incapacitating to crippling at times of severe exacerbations. *Generalized epidermolysis bullosa simplex* (Koebner type) is characterized at birth or during early infancy by blisters on the occiput, back, and legs and in childhood by blisters on the hands, feet, and other friction points. The *herpetiformis (Dowling-Meara) variant of epidermolysis bullosa simplex* is characterized by grouped blisters. During infancy, blistering may be severe and extensive, may involve mucous membranes, and may result in shedding of nails, formation of milia, and mild pigmentary changes, without scarring. After the first few months of life, warm temperatures do not appear to exacerbate blistering. Hyperkeratosis and hyperhidrosis of the palms and soles may develop, but generally, the condition improves with age.

TABLE 644-2 -- **Characteristics of Epidermolysis Bullosa**

Type	Predominant Inheritance	Level of Blister Formation	Features
Simplex (epidermolytic)	Autosomal dominant	Superficial; basal cell layer; above hemidesmosomes	Usually congenital onset; hands and feet involved; minimal mucosal lesions; no scarring; defects in keratins 5 or 14 of basal keratinocytes
Junctional (letalis)	Autosomal recessive	Lamina lucida, between bullous pemphigoid antigen and laminin; absent or rare hemidesmosomes	Congenital; localized or progressive; heals with Scarring; pyloric atresia; mucosal lesions; dysplastic teeth; loss of nails; defects in basement membrane–associated proteins, e.g., laminin 5, bullous pemphigoid antigen 2, a6ß4 integrin
Recessive dystrophic (dermolytic)	Autosomal recessive	Deep in dermis below the lamina densa; excessive production of abnormal dermal collagenase; absent anchoring fibrils	Congenital; mitten scarring of the hands and feet; marked deformities; mucosal lesions produce esophageal stricture or gastrointestinal perforation; varied clinical course; risk for aggressive squamous cell cancer of the skin, tongue, esophagus; defects in type VII collagen
Dominant dystrophic (dermolytic)	Autosomal dominant	Deep in dermis below the lamina densa, below type IV collagen layer; sparse anchoring fibrils	Congenital; hyperkeratotic lesions; variable severity; risk for squamous cell cancer; defects in type VII collagen

JUNCTIONAL EPIDERMOLYSIS BULLOSA.

Epidermolysis bullosa letalis (Herlitz type) is an autosomal recessive condition that is life threatening; serious morbidity and disfigurement can be predicted from the complications. An afflicted infant is usually blistered at birth or develops lesions during the neonatal period, particularly on the perioral area, scalp, legs, diaper area, and thorax. In contrast to other variants of epidermolysis bullosa, the hands and feet tend to be relatively spared, with the exception of the distal digits and the nail plates; these are dystrophic or permanently lost. Mucous membrane involvement may be severe, and ulceration of the respiratory, gastrointestinal, and genitourinary epithelium has been documented in many affected children, although less frequently than in severe, recessive dystrophic epidermolysis bullosa. Healing is delayed, and vegetating granulomas, particularly in the generalized (Herlitz) variant, may persist for a long time. Large, moist, erosive plaques may provide a portal of entry for bacteria, and septicemia is a frequent cause of death. Mild atrophy may be seen in

areas of recurrent blistering. Defective dentition with early loss of teeth as a result of rampant caries is characteristic. Growth retardation and recalcitrant anemia are almost invariable. In addition to infection, cachexia and circulatory failure are common causes of death. Most patients die within the first 3 yr of life.

A subepidermal blister is found on light microscopic examination, and electron microscopy demonstrates a cleavage plane in the lamina lucida, between the plasma membranes of the basal cells and the basal lamina. Absent or greatly reduced anchoring filaments are seen on electron micrographs, along with diminished or absent laminin 5. Junctional epidermolysis bullosa is due to mutations in proteins in the basement membrane zone involved in keratinocyte-lamina densa adherence, particularly laminin 5, a glycoprotein associated with anchoring filaments beneath the hemidesmosomes. Defects have also been described in other hemidesmosomal components, such as bullous pemphigoid antigen 2 and a6ß4 integrin, a subset of patients that may have associated pyloric stenosis. Absence of laminin in amniocytes has been shown to be a prenatal marker for the Herlitz type of junctional epidermolysis bullosa.

Generalized atrophic benign epidermolysis bullosa, a milder autosomal recessive variant, presents with blistering at birth, is also nonscarring, and is characterized by identical histologic changes as the Herlitz type. It may be impossible to distinguish from the Herlitz variety for up to 2–3 yr. Pattern baldness with significant scalp atrophy is a prominent feature. The course is compatible with normal growth and life span. Mutations in collagen XVII (bullous pemphigoid antigen 180) cause this form of epidermolysis bullosa.

Treatment for junctional epidermolysis bullosa is supportive. The diet should provide adequate calories and supplemental iron. Infections should be treated promptly. Transfusions of packed red blood cells may be required if the patient does not respond to iron and erythropoietin therapy. Tissue engineered skin grafts (artificial skin derived from human keratinocytes and fibroblasts) may be beneficial.

DYSTROPHIC EPIDERMOLYSIS BULLOSA.

Dominant dystrophic epidermolysis bullosa occurs sporadically in some cases, although an autosomal dominant mode of transmission has been documented in many families. All forms of dystrophic epidermolysis bullosa result from mutations in collagen VII, a major component of anchoring fibrils that tether the basement membrane and overlying epidermis to its dermal foundation. The type and location of the mutation dictates the severity of the phenotype. Blisters may be present at birth and are often limited to the hands, feet, and sacrum. The lesions heal promptly, with the formation of soft, wrinkled scars, milia, and alterations in pigmentation. The general health is unimpaired; in many cases, the blistering process is mild, causing little restriction of activity and unimpaired growth and development. Mucous membrane involvement tends to be minimal, but nail loss is common.

The *Cockayne-Touraine variant* of dominant dystrophic epidermolysis bullosa presents during infancy or early childhood with blisters predominantly on the extremities, although widespread blistering may occur. The *albopapuloid Pasini form* presents during adolescence with blistering that may be widespread but occurs predominantly on the hands, feet, elbows, and knees and with flesh-colored papules called albopapuloid lesions on the trunk. Transient bullous dermolysis of the newborn affects a rare subset of patients with self-limited dystrophic disease; inheritance in most cases is autosomal dominant. Blistering at birth tends to be generalized but ceases within the first 1–2 yr. Resolution of clinical blistering and the immunohistochemically altered distribution of type VII collagen occur coincidentally. The blister is subepidermal in all variants, with separation beneath the basement membrane. On electron microscopy, anchoring fibrils, a major component of which is type VII collagen, are abnormal and decreased in number over the entire skin in the Pasini type but only in areas of blister predilection in the Cockayne-Touraine variant. The type VII collagen gene, located on the short arm of chromosome 3, is the major candidate gene for dystrophic epidermolysis bullosa.

Recessive dystrophic epidermolysis bullosa is probably the most incapacitating form of epidermolysis bullosa, although the clinical spectrum is wide. Some patients have blisters, scarring, and milia formation primarily on the hands, feet, elbows, and knees. Others at birth have extensive erosions and blister formation that seriously impede their care and feeding. Mucous membrane lesions are common and may cause severe nutritional deprivation, even in older children, whose growth may be retarded. During childhood, esophageal erosions and strictures, scarring of the buccal mucosa, flexion contractures of joints secondary to scarring of the integument, development of cutaneous carcinomas, and the development of digital fusion (Fig. 644–1) may significantly limit the quality of life. The subepidermal bullae are located beneath the basement membrane, where anchoring fibrils are absent.

Figure 644-1 Mitten-hand deformity of recessive dystrophic epidermolysis bullosa.

2186

Although the skin becomes less sensitive to trauma with aging, the progressive and permanent deformities complicate management, and the overall prognosis is poor. Foods that traumatize the buccal or esophageal mucosa should be avoided. If esophageal scarring develops, a semiliquid diet and esophageal dilatations may be required. Stricture excision or colonic interposition may be needed to relieve esophageal obstruction. In infants, severe oropharyngeal involvement may necessitate the use of special feeding devices such as a button gastrostomy tube. Continuous iron therapy for anemia; intermittent antibiotic therapy for secondary infections, which are a common cause of death; and periodic surgery for release of digits may reduce morbidity. Tissue engineered skin grafts containing keratinocytes and fibroblasts are of some benefit.

Pemphigus.

Pemphigus occurs during childhood as pemphigus vulgaris or pemphigus foliaceus.

PEMPHIGUS VULGARIS.

This usually first appears as painful oral ulcers, which may be the only evidence of the disease for weeks or months. Subsequently, large, flaccid bullae emerge on nonerythematous skin, most commonly on the face, trunk, pressure points, groin, and axillae. Nikolsky sign is present. The lesions rupture and enlarge peripherally,

producing painful raw, denuded areas that have little tendency to heal. When healing occurs, it is without scarring, but hyperpigmentation is common. Malodorous, verrucous, and granulomatous lesions may develop at sites of ruptured bullae, particularly in the skinfolds; as this becomes more pronounced, the condition may be more properly referred to as pemphigus vegetans.

Biopsy is best performed of a fresh small blister, which reveals a suprabasal (intraepidermal) blister containing loose, acantholytic epidermal cells that have lost their intercellular bridges and thus their contact with one another. IgG antibody to epidermal intercellular substance produces a characteristic pattern on direct immunofluorescence preparations of both involved and uninvolved skin of essentially all patients (see Table 635–1). Serum IgG antibody titers to the epidermal intercellular substance correlate with the clinical course of many patients; thus, serial determinations may have predictive value. Pemphigus antibodies are pathogenic. The antigen recognized by pemphigus vulgaris antibodies is a 130-kd glycoprotein known as desmoglein III that is complexed with plakoglobin, a plaque protein of desmosomes. The desmogleins are a subfamily of the cadherin cell adhesion molecules.

Neonatal pemphigus vulgaris develops in utero as a result of placental transfer of maternal antibodies from women who have active pemphigus vulgaris, although it may occur when the mother is in remission. High antepartum maternal titers of pemphigus vulgaris antibodies and increased maternal disease activity correlate with a poor fetal outcome, including demise.

The *differential diagnosis* includes EM, bullous pemphigoid, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Because the course may rapidly lead to debility, malnutrition, and death, prompt diagnosis is essential. The disease is best treated initially with high-dose systemic corticosteroid therapy. Azathioprine, cyclophosphamide, methotrexate, and gold therapy all have been useful in maintenance regimens.

PEMPHIGUS FOLIACEUS.

This extremely rare disorder is characterized by intraepidermal blistering; the site of cleavage, however, is high in the epidermis rather than suprabasal as in pemphigus vulgaris. The superficial blisters rupture quickly, leaving erosions surrounded by erythema that heal with crusting and scaling. Nikolsky sign is present. Focal lesions are usually localized to the scalp, face, neck, and upper trunk. Mucous membrane lesions are minimal or absent. Pruritus, pain, and a burning sensation are frequent complaints. When generalized, the eruption may resemble exfoliative dermatitis or any of the chronic blistering disorders, but localized erythematous plaques simulate seborrheic dermatitis, psoriasis, impetigo, eczema, or lupus erythematosus. The clinical course varies but is generally more benign than that of pemphigus vulgaris. *Fogo selvagem*, which is ecdemic in certain areas of Brazil, is identical clinically, histopathologically, and immunologically to pemphigus foliaceus.

An intraepidermal acantholytic bulla high in the epidermis is diagnostic; it is imperative, however, to select an early lesion for biopsy. Tissue-bound and circulating intercellular epidermal antibodies bind to a 50-kd portion of the 160-kd desmosomal glycoprotein, desmoglein I (see Table 635–1). Long-term remission is usual after suppression of the disease by systemic corticosteroid therapy. Dapsone or a topical corticosteroid preparation is occasionally sufficient.

Bullous Pemphigoid.

Bullous pemphigoid rarely occurs in children but must be considered in the differential diagnosis of any chronic blistering disorder.

CLINICAL MANIFESTATIONS.

The blisters typically arise in crops on a normal, erythematous, eczematous, or urticarial base. Bullae appear predominantly on the flexural aspects of the extremities, in the axillae, and on the groin and central abdomen. Infants have involvement of the palms, soles, and face more frequently than older children. Individual lesions vary greatly in size, are tense, and are filled with serous fluid that may become hemorrhagic or turbid. Oral lesions occur less frequently (50%) and are less severe than in pemphigus vulgaris but are found more commonly in children than in adults with bullous pemphigoid. Pruritus, a burning sensation, and subcutaneous edema may accompany the eruption, but constitutional symptoms are not prominent.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSES.

Biopsy material should be taken from an early bulla arising on an erythematous base. A subepidermal bulla and a dermal inflammatory infiltrate, predominantly of eosinophils, can be identified histopathologically. In sections of a blister or perilesional skin, a band of immunoglobulin (usually IgG) and C3 can be demonstrated in the basement membrane zone by direct immunofluorescence (see Table 635–1). Indirect immunofluorescence studies of serum have positive results in approximately 70% of cases for IgG antibodies to the basement membrane zone; the titers, however, do not correlate well with the clinical course. The differential diagnosis includes bullous erythema multiforme, pemphigus, linear IgA dermatosis, bullous drug eruption, dermatitis herpetiformis, herpes simplex infection, and bullous impetigo, which can be differentiated by histologic examination, immunofluorescence studies, and cultures. The large, tense bullae of bullous pemphigoid can generally be distinguished from the smaller, flaccid bullae of pemphigus vulgaris. The major targets for bullous pemphigoid autoantibodies are proteins of 230 and 180?kd. The 230-kd protein is part of the hemidesmosome, whereas the 180-kd antigen localizes to both the hemidesmosome and the upper lamina lucida and is a transmembrane collagenous protein.

TREATMENT.

Bullous pemphigoid can be successfully suppressed with topical or systemic corticosteroid therapy alone or in combination with azathioprine, sulfapyridine, or dapsone. Topical clobetasol improves outcome with fewer side effects. Ultimately, the condition usually remits permanently.

Dermatitis Herpetiformis.

This is seen most commonly in children 2–7 yr of age. It is characterized by

symmetric, grouped, small, tense, erythematous, stinging, intensely pruritic papules and vesicles. The eruption is pleomorphic, including erythematous, urticarial, papular, vesicular, and bullous lesions. Sites of predilection are the knees, elbows, shoulders, buttocks, and scalp; mucous membranes are usually spared. Hemorrhagic lesions may develop on the palms and soles. When pruritus is severe, excoriations may be the only visible sign.

ETIOLOGY.

Dermatitis herpetiformis, like celiac disease, has a strong genetic association with HLA DQ on chromosome 6.

IgA antibodies directed at the endomysial antigen transglutaminase (tissue transglutaminase, epidermal transglutaminase) appear to cause both gastrointestinal and cutaneous symptoms. This is unknown; however, an association with gluten-sensitive enteropathy is found in 75–90% of patients. Aggressive gluten challenge generally unmasks the condition in the remainder of patients with dermatitis herpetiformis (see Chapter 320.8). Subepidermal blisters composed predominantly of neutrophils are found in dermal papillae on skin biopsy, and IgA and C3 can be detected in the dermal papillary tips of normal and perilesional skin in the sublamina densa region of the dermoepidermal junction by immunofluorescence studies. The frequent finding of immune complexes and autoimmune antibodies in serum and the association with histocompatibility antigen HLA-B8 in approximately 85% of patients suggest an immune mechanism. An antibody to smooth muscle endomysium is found in 70% of patients with dermatitis herpetiformis-associated gluten-sensitive enteropathy. Antibody titers correlate with the severity of intestinal disease; they decline rapidly on institution of a gluten-free diet. Enteric infection with adenovirus type 12 or 40 may increase the risk of developing gluten-sensitive enteropathy and dermatitis herpetiformis in genetically susceptible individuals.

TREATMENT.

Dermatitis herpetiformis may mimic other chronic blistering diseases and may also resemble scabies, papular urticaria, insect bites, contact dermatitis, and papular eczema. The most effective treatment is oral administration of sulfapyridine or dapsone. These drugs provide immediate relief from the intense pruritus but must be used with caution because of possible serious side effects. Local antipruritic measures may also be useful. Jejunal biopsy is indicated to diagnose gluten-sensitive enteropathy because cutaneous manifestations may precede malabsorption. Enteropathy responds to a gluten-free diet more rapidly than skin lesions.

Linear IgA Dermatosis (Chronic Bullous Dermatosis of Childhood).

This rare dermatosis is most common in the 1st decade of life, with a peak incidence during the preschool years. The eruption consists of many large, tense bullae filled with clear or hemorrhagic fluid that develop on a normal or erythematous, urticarial base. Areas of predilection are the genitals and buttocks, the perioral region, and the scalp. Sausage-shaped bullae may be arranged in an annular or rosette-like fashion around a central crust (Fig. 644–2). Erythematous plaques with gyrate margins bordered by intact bullae may develop over larger areas. Pruritus may be absent or very intense, and systemic signs or symptoms are absent. Gluten-sensitive enteropathy is not present, but there is a strong association with HLA-B8.

ETIOLOGY.

The cause of the eruption is unknown. The subepidermal bulla are infiltrated with a mixture of inflammatory cells. Neutrophilic abscesses may be noted in the dermal papillary tips, indistinguishable from those of dermatitis herpetiformis. The infiltrate may also be largely eosinophilic, resembling bullous pemphigoid. Therefore, direct immunofluorescence studies are required for a definitive diagnosis; lesional or perilesional skin demonstrates linear deposition of IgA and sometimes C3 at the dermoepidermal junction (see Table 635–1). Results of indirect immunofluorescence studies are sometimes positive for circulating antibodies. Immunoelectron microscopy has localized the immunoreactants to the sublamina densa, although a combined sublamina densa and lamina lucida pattern has also been seen. The linear IgA bullous dermatosis antigen has a molecular mass of 120?kd. The eruption can be distinguished by histopathologic and immunofluorescence studies from pemphigus, bullous pemphigoid, dermatitis herpetiformis, and EM. Gram stain and culture preclude the diagnosis of bullous impetigo, with which dermatitis herpetiformis is often confused on initial presentation. The lack of bullous formation in response to trauma differentiates epidermolysis bullosa.

Figure 644-2 Rosette-like blisters around a central crust typical of linear IgA dermatosis (chronic bullous dermatosis of childhood).

TREATMENT.

Many patients respond favorably to oral sulfapyridine or dapsone. During therapy with sulfapyridine, attention should be paid to maintaining urinary output and alkalization to avoid crystal formation within the renal parenchyma. Hematologic and biochemical studies must be obtained at regular intervals during treatment with either drug to avoid serious side effects. Children who do not respond to either of these drugs may benefit from oral therapy with a corticosteroid or a combination of these drugs. The usual course is 2–4 yr, although some children have persistent or recurrent disease; there are no long-term sequelae.

Chapter 645 - Eczematous Disorders

Eczematous skin disorders are characterized by exudation, lichenification, and pruritus. Acute eczematous lesions demonstrate erythema, weeping, oozing, and the formation of microvesicles within the epidermis. Chronic lesions are generally thickened, dry, and scaly, with coarse skin markings (lichenification) and altered pigmentation. Many types of eczema occur in children; the most common is atopic dermatitis (see Chapter 135), although seborrheic dermatitis, allergic and irritant contact dermatitis, nummular eczema, and dyshidrosis also are relatively common in childhood. Various dermatoses that have pruritus as a common feature may become eczematized owing to scratching. Atopic skin is sensitive to many factors that increase pruritus, such as soap, wool, cool air, and food allergens.

Once the diagnosis of eczema has been established, it is important to classify the eruption more specifically for proper management. Pertinent historical data often provide the clue. In some instances, the subsequent course and character of the eruption permit classification. Histologic changes are relatively nonspecific, but all types of eczematous dermatitis are characterized by intraepidermal edema known as spongiosis.

Contact Dermatitis.

This form of eczema can be subdivided into irritant dermatitis, resulting from nonspecific injury to the skin, and allergic contact dermatitis, in which the mechanism is a delayed hypersensitivity reaction. Irritant dermatitis is more frequent in children, particularly during the early years of life.

Irritant contact dermatitis can result from prolonged or repetitive contact with various substances that include saliva, citrus juices, bubble bath, detergents, abrasive materials, strong soaps, and proprietary medications. Saliva is probably one of the most common offenders; it may cause dermatitis on the face and in the neck folds of a drooling infant or a retarded child. Older children who habitually lick their lips, frequently without awareness, because of dryness may develop a striking, sharply demarcated perioral rash (Fig. 645–1*A*). Among the exogenous irritants, citrus juices, proprietary medications, and bubble bath preparations are relatively common; bubble bath dermatitis can be a cause of severe pruritus. Excessive accumulation of sweat and moisture as a result of wearing occlusive shoes may also cause irritant dermatitis.

Clinically, irritant contact dermatitis may be indistinguishable from atopic dermatitis or allergic contact dermatitis. A detailed history and consideration of the sites of involvement, the age of the child, and contactants usually provide clues to the etiologic agent. The propensity to develop irritant dermatitis varies considerably among children; some may respond to minimal injury, making it difficult to identify the offending agent by history. In general, irritant contact dermatitis clears after removal of the stimulus and after temporary treatment with a topical corticosteroid preparation. Education of patients and parents about the causes of contact dermatitis is crucial to successful therapy.

Diaper dermatitis can be regarded as the prototype of irritant contact dermatitis. As a reaction to overhydration of the skin, friction, maceration, and prolonged contact with urine and feces, retained diaper soaps, and topical preparations, the skin of the diaper area may become erythematous and scaly, often

Figure 645-1 *A*, Perioral irritant contact dermatitis from lip licking. *B*, Allergic contact dermatitis to Merthiolate spray. Note the sharp angular border of vesicular eruption.

with papulovesicular or bullous lesions, fissures, and erosions. The eruption can be patchy or confluent, but the genitocrural folds are often spared. Chronic hypertrophic, flat-topped papules and infiltrative nodules may simulate syphilitic lesions. Secondary infection with bacteria and yeasts is common; discomfort may be marked because of intense inflammation. Such conditions as allergic contact dermatitis, seborrheic dermatitis, candidosis, atopic dermatitis, and rare disorders such as histiocytosis X (Langerhan cell histiocytosis) and acrodermatitis enteropathica should be considered when the eruption is persistent or recalcitrant to simple therapeutic measures.

Diaper dermatitis often responds to simple measures; however, some infants seem predisposed to diaper dermatitis, and management may be difficult. The damaging effects of overhydration of the skin and prolonged contact with feces and ammoniac urine can be obviated by frequent changing of diapers and meticulous washing of the genitals. Disposable diapers containing a superabsorbent material may help to maintain a relatively dry environment. Frequent topical applications of a bland protective barrier agent (petrolatum or zinc oxide paste) after thorough gentle cleansing may suffice to prevent dermatitis. When the aforementioned measures are not sufficient to promote healing, a light application of 0.5–1% topical hydrocortisone ointment after each diaper change for a limited time is often effective. Secondary complications can result from prolonged use of corticosteroids, especially fluorinated compounds. Before initiating such therapy, the possibility of candidal infection should be considered. Candidal infection can be identified by red-pink tender skin that has numerous 1–2?mm pustules and papules at the periphery of the dermatitis. Treatment with a topical anticandidal agent may be helpful.

Juvenile plantar dermatosis is a common form of irritant contact dermatitis occurring mainly in prepubertal children. The dermatitis characteristically involves the weight-bearing surfaces, is painful rather than pruritic, and causes a glazed appearance of the plantar skin. Fissuring may become extensive, producing considerable discomfort. The dermatitis results from alternating excessive hydration and rapid moisture loss, which causes chapping of the skin and cracking of the

stratum corneum. Affected children often have hyperhidrosis, wear occlusive synthetic footwear, and subject their feet to rapid drying without moisturization. Immediate application of a thick emollient when socks and shoes are removed or immediately after swimming usually prevents this condition.

Allergic contact dermatitis is a T-cell–mediated hypersensitivity reaction that is provoked by application of an antigen to the skin surface. The antigen penetrates the skin, where it is conjugated with a cutaneous protein, and the hapten-protein complex is transported to the regional lymph nodes by antigen-presenting Langerhans cells. A primary immunologic response occurs locally in the nodes and becomes generalized, presumably because of dissemination of sensitized T cells. Sensitization requires several days and, when followed by a fresh antigenic challenge, is manifested as allergic contact dermatitis. Generalized distribution may also occur if enough antigen finds its way into the circulation. Once sensitization has occurred, each new antigenic challenge may provoke an inflammatory reaction within 8–12?hr; sensitization to a particular antigen usually persists for many years.

Acute allergic contact dermatitis is an erythematous, intensely pruritic, eczematous dermatitis, which, if severe, may be edematous and vesiculobullous. The chronic condition has the features of long-standing eczema: lichenification, scaling, fissuring, and pigmentary change. The distribution of the eruption often provides a clue to the diagnosis. Volatile sensitizers usually affect exposed areas, such as the face and arms. Jewelry, topical agents, shoes, clothing, and plants cause dermatitis at points of contact.

Rhus dermatitis (poison ivy, poison sumac, poison oak) is often vesiculobullous and may be distinguished by linear streaks of vesicles where the plant leaves have brushed against the skin. Contrary to popular opinion, fluid from ruptured cutaneous vesicles does not spread the eruption; however, antigen retained on the skin, under the fingernails, and on clothing initiates new plaques of dermatitis if not removed by washing with soap and water. Antigen may also be carried by animals on their fur. The saplike allergen (oleoresin) is present on live and dead leaves, and sensitization to one plant produces cross reactions with the others.

Nickel dermatitis usually develops from contact with jewelry or metal closures on clothing and is seen most frequently on the earlobes, such as when nickel-containing posts rather than nonmetallic materials or stainless steel are used to keep a pierced tract open. Some children are exquisitely sensitive to nickel, with even the trace amounts found in gold jewelry provoking eruptions.

Shoe dermatitis typically affects the dorsum of the feet and toes, sparing the interdigital spaces; it is usually symmetric. Other forms of allergic contact dermatitis, in contrast to irritant dermatitis, rarely involve the palms and soles. Common allergens are the antioxidants and accelerators in shoe rubber and the chromium salts in tanned leather or shoe dyes. These substances are often leached out by excessive sweating.

Wearing apparel contains a number of sensitizers, including dyes, mordants, fabric finishes, fibers, resins, and cleaning solutions. Dye may be poorly fixed to clothing and leached out with sweating, as are the partially cured formaldehyde resins. The elastic in garments is also a frequent cause of clothing dermatitis.

Topical medications and cosmetics may be unsuspected as allergens, particularly if the medication is being used for a pre-existing dermatitis. The most common offenders are neomycin, thimerosal (Merthiolate) (see Fig. 645–1*B*), topical antihistamines (Caladryl), anesthetics (dibucaine [Nupercainal] and cyclomethycaine [Surfacaine]), preservatives (parabens), and ethylenediamine, a stabilizer present in many medications. All types of cosmetics can cause facial dermatitis; involvement of the eyelids is characteristic for nail polish sensitivity.

Contact dermatitis can be confused with other types of eczema, dermatophytoses, and vesiculobullous diseases. Patch testing may clarify the etiology. The essential principle in *treatment* is elimination of contact with the allergen. Acute dermatitis responds to cool compresses and topical application of a corticosteroid ointment. An antihistamine may be useful when taken orally. Massive acute bullous reactions or reactions that cause swelling around the eyes or genitals such as those of poison ivy may require treatment with a 2-wk tapering course of oral corticosteroids. If secondary infection has occurred, appropriate systemic antibiotic therapy should be given. Desensitization therapy is rarely indicated.

Nummular Eczema.

This disorder is unrelated to other types of eczema and is characterized by more or less coin-shaped eczematous plaques. Common sites are the extensor surfaces of the extremities (Fig. 645–2), buttocks, and shoulders. The plaques are relatively discrete, boggy, vesicular, severely pruritic, and exudative; when chronic, they often become thickened and lichenified. The cause is unknown. Most frequently, these lesions are mistaken for tinea corporis, but plaques of nummular eczema are distinguished by the lack of a raised, sharply circumscribed border, the lack of fungal organisms on a potassium hydroxide (KOH) preparation, and frequent weeping or bleeding when scraped. Secondary infection is common. Control of pruritus is usually achieved with a fluorinated corticosteroid preparation. Steroid-impregnated tapes may simultaneously treat and provide barrier protection to these circumscribed eczematous plaques. Sedation with an antihistamine may be

Figure 645-2 Multiple hyperpigmented scaly plaques of nummular eczema.

helpful, particularly at night. Antibiotics are indicated for secondary infection.

Pityriasis Alba.

This occurs mainly in children; the lesions are hypopigmented, round or oval, macular or slightly elevated patches with fine adherent scale (Fig. 645–3). They may be mildly erythematous and relatively well defined but lack a sharply marginated border. Lesions occur on the face, neck, upper trunk, and proximal portions of the arms. Itching is minimal or absent. The cause is unknown, but the eruption appears to be exacerbated by dryness and is often regarded as a mild form of eczema.

Pityriasis alba is frequently misdiagnosed as tinea versicolor or corporis, each of which can be readily precluded by performing a KOH examination of surface scale. The lesions wax and wane but eventually disappear. Application of a lubricant may ameliorate the condition; if pruritus is troublesome, a topical 1% hydrocortisone preparation applied three to four times daily may be more effective. Normal pigmentation returns in weeks to months.

Lichen Simplex Chronicus.

This lesion is characterized by a chronic pruritic, eczematous, circumscribed, solitary plaque that is usually lichenified and hyperpigmented. The most common sites are the posterior aspect of the neck, the dorsum of the feet, the wrists, and ankles. Trauma from rubbing and scratching accounts for persistence of the plaque, although the initiating event may be a transient lesion, such as an insect bite. Pruritus must be controlled to permit healing. A topical fluorinated corticosteroid preparation is often helpful, but constant irritation of the skin must be avoided. A covering to prevent scratching may be necessary.

Dyshidrotic Eczema (Dyshidrosis, Pompholyx).

This is a recurrent, sometimes seasonal, blistering disorder of the hands and feet; it occurs in all age groups but is uncommon in infancy. The pathogenesis is unknown; no genetic factor has been identified, although an increased incidence of atopy has been recorded in patients and their relatives. The disease is characterized by recurrent crops of intensely pruritic small vesicles on the hands and feet. Sites of predilection are the palms, soles, and lateral

Figure 645-3 Patchy hypopigmented lesions with diffuse borders characteristic of pityriasis alba. See also color section.

aspects of the fingers and toes. Primary lesions are noninflammatory and filled with clear fluid, which, unlike sweat, has a physiologic pH and contains protein. Larger vesicobullae may occur, and maceration and secondary infection are frequent because of scratching (Fig. 645–4). The chronic phase is characterized by thickened, fissured plaques that may cause considerable discomfort. Hyperhidrosis is common in many patients, but the association may be fortuitous. The diagnosis is made clinically. The disorder may be confused with allergic contact dermatitis, which usually affects the dorsal rather than the volar surfaces, and with dermatophytosis, which can be distinguished by a KOH preparation of the roof of a vesicle and by appropriate cultures.

Dyshidrotic eczema responds to wet dressings, followed by a topical corticosteroid preparation during the acute phase. Control of the chronic stage is difficult; lubricants containing mild keratolytic agents in conjunction with a potent topical fluorinated corticosteroid preparation may be indicated. Secondary bacterial infection should be treated systemically with an appropriate

Figure 645-4 Vesicular palmar lesions of dyshidrotic eczema that have become secondarily infected.

antibiotic. Patients should be told to expect recurrence and should protect their hands and feet from the damaging effects of excessive sweating, chemicals, harsh soaps, and adverse weather.

Seborrheic Dermatitis.

This chronic inflammatory disease is most common in the pediatric age group, during infancy and adolescence, paralleling the distribution, size, and activity of the sebaceous glands. The cause is unknown, as is the role of the sebaceous glands in this disease. A generalized eruption with features of seborrheic dermatitis is extremely common in HIV-infected children and adolescents.

CLINICAL MANIFESTATIONS.

The disorder may begin within the 1st mo of life and may be most troublesome during the 1st yr. Diffuse or focal scaling and crusting of the scalp, sometimes called *cradle cap*, may be the initial and at times the only manifestation. A greasy, scaly, erythematous papular dermatitis, which is usually nonpruritic, may involve the face, neck, retroauricular areas, axillae, and diaper area. The dermatitis may be patchy and focal or may spread to involve almost the entire body (Fig. 645–5). Postinflammatory pigmentary changes are common, particularly in black infants. When the scaling becomes pronounced, the condition may resemble psoriasis and, at times, can be distinguished only with difficulty. The possibility of coexistent atopic dermatitis must be considered when there is an acute weeping dermatitis with pruritus. An intractable seborrhea-like dermatitis with chronic diarrhea and failure to thrive *(Leiner disease)* may reflect dysfunction of the immune system. A chronic seborrhea-like pattern, which responds poorly to treatment, may also result from cutaneous histiocytic infiltrates in infants with Langerhans cell histiocytosis X. Seborrheic dermatitis is a common cutaneous manifestation of AIDS among young adults and is characterized by thick, greasy scales on the scalp and large hyperkeratotic erythematous plaques on the face, chest, and genitals.

During adolescence, seborrheic dermatitis is more localized and may be confined to the scalp and intertriginous areas. Also noted may be marginal blepharitis and involvement of the external auditory canal. Scalp changes may vary from diffuse, brawny scaling to focal areas of thick, oily, yellow crusts with underlying erythema. Loss of hair is not uncommon, and pruritus may be absent to marked. When the dermatitis is severe, erythema and scaling may occur at the frontal hairline, at the medial aspects of the eyebrows, and in the nasolabial and retroauricular folds. Red, scaly plaques may appear in the axillae, inguinal region, gluteal cleft, and umbilicus. On the extremities, seborrheic plaques may be more eczematous and less erythematous and demarcated.

ETIOLOGY.

Seborrheic dermatitis is a condition that is reactivated in some patients by stressful

situations, poor hygiene, and

Figure 645-5 Widespread seborrheic dermatitis in an infant.

excessive perspiration. ***Malassezia furfur*** has also been implicated as a causative agent, although its role in the etiology of infantile seborrheic dermatitis is unclear. The *differential diagnosis* includes psoriasis, atopic dermatitis, dermatophytosis, and candidosis. Secondary bacterial infections and superimposed candidosis are not uncommon.

TREATMENT.

Scalp lesions should be controlled with an antiseborrheic shampoo (selenium sulfide, sulfur, salicylic acid, zinc pyrithion, tar), used daily if necessary. Inflamed lesions usually respond promptly to topical corticosteroid therapy given two to four times daily. Topical immunomodulatory agents (e.g. tacrolimus, pimecrolimus) approved for the treatment of atopic dermatitis in children 2 years of age and older (see Chapter 135) may have a role in the treatment of other eczematous disorders such as seborrheic dermatitis. Concerns for systemic absorption and potential immunosuppression are higher in the younger patient population typically afflicted with seborrheic dermatitis. Topical or oral antifungal agents (terbinafine) effective against *Malassezia* have also been advocated as therapy. Wet compresses should be applied to the moist or fissured lesions before application of the steroid ointment. Many patients require continued use of an antiseborrheic shampoo for control. Response to therapy is usually rapid unless there are complicating factors or the diagnosis is in error.

Chapter 646 - Photosensitivity

Photosensitivity denotes a qualitatively or quantitatively abnormal cutaneous reaction to sunlight or artificial light.

Acute Sunburn Reaction.

The most common photosensitive reaction seen in children is acute sunburn. Sunburn is caused mainly by ultraviolet (UV) B radiation (290–320?nm wavelength). Sunlight contains many times more UVA (320–400?nm) than UVB radiation, but UVA must be encountered in much larger quantities than UVB radiation to produce sunburn.

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS.

Transmitted radiation below 300?nm is largely absorbed in the epidermis, whereas that above 300?nm is mostly transmitted to the dermis after variable epidermal melanin absorption. Children vary in susceptibility to UV radiation, depending on their skin type (amount of pigment) (Table 646–1). Immediate pigment darkening is due to UVA radiation-induced photo-oxidative darkening of existing melanin and its transfer from melanocytes to keratinocytes. This effect generally lasts for a few hours, and, like a UVA-induced tanning salon tan, is not photoprotective. UVB-induced effects appear 6–12?hr after initial exposure and reach a peak in 24?hr. Effects include redness, tenderness, edema, and blistering. The vasodilatation seen in UVB-induced erythema is mediated by prostaglandins E_2 and F_2 . Delayed melanogenesis as a result of UVB radiation begins in 2–3 days and lasts several days to a few weeks. Manufacture of new melanin in melanocytes, transfer of melanin from melanocytes to keratinocytes, increase in size

TABLE 646-1 -- **Sun-Reactive Skin Types**

Type	Demographics	Sunburn, Tanning History
I	Red hair, freckles, Celtic origin	Always burns easily, no tanning
II	Fair skin, fair-haired, blue-eyed, white	Usually burns, minimal tanning
III	Darker skinned white	Sometimes burns, gradual light brown tan
IV	Mediterranean background	Minimal to no burning, always tans
V	Middle eastern white, Mexican	Rarely burns, tans profusely dark brown
VI	Blacks	Never burns, pigmented black

and arborization of melanocytes, and activation of quiescent melanocytes produces delayed melanogenesis. This effect reduces skin sensitivity to development of erythema by approximately twofold to threefold. Additional effects and possible complications of sun exposure include increased thickness of the stratum corneum, recurrence or exacerbation of herpes simplex labialis, lupus erythematosus, and many other conditions (Box 646–1).

TREATMENT.

Acute severe sunburn should be managed with cool compresses; topical corticosteroids may diminish inflammation and pain, and oral prostaglandin inhibitors such as ibuprofen and indomethacin may decrease erythema and pain. Proprietary preparations containing topical anesthetics are relatively ineffective and potentially hazardous because of their propensity to cause contact dermatitis. A bland emollient is effective in the desquamative phase.

PROGNOSIS AND PREVENTION OF SEQUELAE.

The long-term sequelae of chronic and intense sun exposure are not often seen in children, but most individuals receive more than 50% of their lifetime UV dose by age 20 yr. Therefore, pediatricians have a pivotal role in educating patients and their parents about the harmful effects, potential malignancy risks, and irreversible skin damage that result from unduly prolonged exposure to the sun and tanning lights. Premature aging, senile elastosis, actinic keratoses, squamous and basal cell carcinomas, and melanomas all occur with greater frequency in sun-damaged skin. In particular, blistering sunburns in childhood and adolescence significantly increase the risk for development of *malignant melanoma*. Protection is enhanced by a wide variety of sunscreen agents. Physical opaque sunscreens (zinc oxide, titanium dioxide) block UV light, whereas chemical sunscreens (*p*-aminobenzoic acid [PABA], PABA esters, salicylates, benzophenones, dibenzoylmethanes, cinnamates) absorb

damaging radiation. The benzophenones and dibenzoylmethanes provide protection in both the UVA and UVB ranges. Children with skin types I to III (see Table 646–1) require sunscreens with a sun protection factor (SPF) of at least 15. SPF is defined as the minimal dose of sunlight required to produce cutaneous erythema after applying a sunscreen, divided by the dose required with no use of sunscreen. Protective clothing (hats) and avoidance of sun exposure between 10:00 a.m. and 2:00 p.m. are additional prudent practices.

Photosensitive Reactions.

Photosensitizers in combination with a particular wavelength of light cause dermatitis that can be classified as a phototoxic or a photoallergic reaction. Contact of the skin with the photosensitizer may occur externally, internally by enteral or parenteral administration, or by host synthesis of photosensitizers in response to an administered drug.

Photoallergic reactions occur in only a small percentage of persons exposed to photosensitizers and light and require a time interval for sensitization to take place. Thereafter, dermatitis appears within approximately 24?hr of re-exposure to the photosensitizer and light. Photoallergic dermatitis is a T-cell-mediated delayed hypersensitivity reaction in which the drug, acting as a hapten, may combine with a skin protein to form the antigenic substance. Photoallergic reactions vary in morphology

Box 646-1. Cutaneous Reactions to Sunlight

SUNBURN

PHOTOALLERGIC DRUG ERUPTIONS

Systemic drugs include tetracyclines, psoralens, chlorthiazides, sulfonamides, barbiturates, griseofulvin, thiazides, quinidine, phenothiazines

Topical agents include coal tar derivatives, psoralens, halogenated salicylanilides (soaps), perfume oils (e.g., oil of bergamot), sunscreens (e.g., PABA, cinnamates, benzophenones)

PHOTOTOXIC DRUG ERUPTIONS

High doses of agents causing photoallergic eruptions; nalidixic acid, 5-fluorouracil, psoralens, furosemide,

and may occur on partially covered and on light-exposed skin. Some of the important classes of drugs and chemicals responsible for photosensitivity reactions are listed in Box 646–1 .

Phototoxic reactions occur in all individuals who accumulate adequate amounts of a photosensitizing drug or chemical within the skin. Prior sensitization is not required. Dermatitis develops within hours after exposure to radiation in the range of 285–450?nm. The eruption is confined to light-exposed areas and often resembles an exaggerated sunburn, but it may be urticarial or bullous. It results in postinflammatory hyperpigmentation. All the drugs that cause photoallergic reactions may also cause a phototoxic dermatitis if given in sufficiently high doses. Several additional drugs and contactants cause phototoxic reactions, notably the plant-derived furocoumarins (see Box 646–1). Differentiation from contact dermatitis as a result of poison ivy or oak may be difficult, but itching is prominent in contact dermatitis. In phytophotodermatitis, burning is prominent and is

confined to sun-exposed areas, sparing the upper eyelids, beneath the nose and chin, and the retroauricular areas.

Although photodermatitis caused by drugs or chemicals may be diagnosed by photopatch testing, facilities for this diagnostic procedure are not widely available. A high index of suspicion combined with an appreciation of the distribution pattern of the eruption and a history of application or ingestion of a known photosensitizing agent is all that is required to make a diagnosis. Discontinuation of the offending medication or avoidance of sun exposure, oral administration of an antihistamine, and application of a topical corticosteroid to alleviate pruritus are appropriate therapeutic measures. Severe reactions may necessitate systemic corticosteroid therapy for a brief time.

Porphyrias (see Chapter 80).

Porphyrias are acquired or inborn disorders due to abnormalities of specific enzyme mutations in the heme biosynthetic pathway; they are diverse in their clinical manifestations. Two in particular occur in children and have photosensitivity as a consistent feature. Signs and symptoms may be negligible during the winter, when sun exposure is minimal.

Congenital erythropoietic porphyria (Günther disease) is a rare autosomal recessive disorder caused by a deficiency of uroporphyrinogen III cosynthase, which presents within the first few months of life with exquisite sensitivity to light and which may induce repeated severe bullous eruptions that result in mutilating scars. Hyperpigmentation, hyperkeratosis, vesiculation, and fragility of skin develop in light-exposed areas. Hirsutism in areas of mild involvement, scarring alopecia in severely affected areas, pink to red urine, brown teeth, hemolytic anemia, splenomegaly, and increased amounts of uroporphyrin I in urine, plasma, and erythrocytes and of coproporphyrin I in feces are additional characteristic manifestations. Urine from affected patients fluoresces reddish pink under a Wood light.

Erythropoietic protoporphyria, an autosomal dominant trait, is due to decreased activity of ferrochelatase, which converts protoporphyrin to heme. Photosensitivity becomes apparent in early childhood and is manifested by pain, tingling, and a burning sensation within approximately 30?min of sun exposure, followed by erythema, edema, urticaria, and, rarely, vesicles on light-exposed areas. Nail changes consist of opacification of the nail plate, onycholysis, pain, and tenderness. Mild systemic symptoms of malaise, chills, and fever may accompany the acute skin reaction. Recurrent sun exposure produces a chronic eczematous dermatitis with thickened, lichenified skin, especially over the finger joints, and persistent violaceous erythema, ulcers, and pitted or linear, crusted atrophic scars on the face and rims of the ears. Pigmentation, hypertrichosis, skin fragility, and mutilation are uncommon. Liver disease is generally mild. Symptoms often improve spontaneously after age 10–11 yr.

The wavelengths of light mainly responsible for eliciting cutaneous reactions in porphyria are in the region of 400?nm. Window glass, which transmits wavelengths greater than 320?nm, is not protective, and artificial lights of a certain wavelength may be pathogenic. Patients must avoid direct sunlight, wear protective clothing, and use a sunscreen agent that effectively blocks wavelengths in the region of 400?nm. Administration of ß-carotene (Solatene) quenches the fluorescence of the porphyrin molecule by yellowing the skin; its effectiveness in reducing photosensitivity in patients with protoporphyria has onset within 1–3 mo and is variable.

Colloid Milium.

This is a rare, asymptomatic disorder that occurs on the face (nose, upper lip, upper cheeks) and may extend to the dorsum of the hands and the neck as a profuse eruption of ivory to yellow, firm, tiny, grouped papules. Lesions appear before puberty on otherwise normal skin, unlike the adult variant that develops on sun-damaged skin. Onset may follow an acute sunburn or chronic sun exposure. Most cases reach maximal severity within approximately 3 yr and remain unchanged thereafter, although the condition may remit spontaneously after puberty. Histopathologic changes include well-circumscribed accumulations of fissured eosinophilic material, primarily in the upper dermis in contact with the epidermis. Basal cells, which are transformed into these colloid bodies, appear to be abnormally susceptible to degeneration after actinic exposure.

Hydroa Vacciniforme.

This vesicobullous disorder is more common in boys than in girls, begins in early childhood, but may remit at puberty. The peak incidence is in the spring and summer. Erythematous, pruritic macules develop symmetrically within hours of sun exposure over the ears, nose, lips, cheeks, and dorsal surfaces of the hands and forearms. Lesions progress to stinging tender papules and hemorrhagic vesicles and bullae. Severe lesions of hydroa vacciniforme resemble the vesicles of chickenpox; they become umbilicated, ulcerated, and crusted and heal with pitted scars and telangiectasias. Fever and malaise are noted occasionally during the acute phase. Histopathologically, lesions show intraepidermal multilocular vesicles, leading to focal epidermal and dermal necrosis. Noted early is a dermal perivascular mononuclear cell infiltrate that later surrounds areas of necrosis. This eruption should be distinguished from erythropoietic protoporphyria, which rarely shows vesicles. Pathogenesis of hydroa vacciniforme is unknown, but typical lesions have been reproduced with repeated doses of UVA light. A topical corticosteroid may be useful for the inflammatory phase of the eruption. Prophylactic broad-spectrum sunscreens may also be helpful, as may low-dose courses of UVB or psoralen with UVA (PUVA) therapy. ß-Carotene and antimalarial agents are sometimes beneficial.

Actinic Prurigo.

This is a chronic familial photodermatitis that is inherited as an autosomal dominant trait among the Native Americans of North and South America. The first episode generally occurs in early childhood several hours to 2 days after intense sun exposure. Most patients are female and are sensitive to UVA radiation. Lesions are intensely pruritic, erythematous papules on the face, lower lip, distal extremities, and, in severe cases, buttocks. Facial lesions may heal with minute pitted or linear scarring. Lesions often become chronic, without periods of total clearing, merging into eczematous plaques that lichenify and may become secondarily infected. Associated features that distinguish this disorder from other photoeruptions and atopic dermatitis include cheilitis, conjunctivitis, and traumatic alopecia of the outer half of the eyebrows. Actinic prurigo is a chronic condition that generally persists into adult life, although it may improve spontaneously in the late teenage years. Broad-spectrum sunscreens such as butyl methoxydibenzoylmethane may be helpful in preventing the eruption, but antimalarials and ß-carotene afford little to no protection. Topical corticosteroids palliate the pruritus and inflammation; thalidomide also may be effective.

Solar Urticaria.

This is a rare disorder induced by UV or visible irradiation. Primary solar urticaria is probably mediated by allergic type 1 hypersensitivity to a cutaneous or circulating irradiation-induced allergen, leading to mast cell degranulation and histamine release. This reaction occurs within 5–10?min of sun exposure, fades within 1–2?hr, and is characterized by widespread severe wheal formation, which may lead to faintness, headache, nausea, syncope, or bronchospasm. H_1 -blocking antihistamines may be useful to prevent or abate the eruption. Secondary solar urticaria is due to photosensitization to exogenous chemicals or systemic drugs and may rarely be a presenting sign of erythropoietic protoporphyria. Treatment consists of avoidance of the photosensitizing wavelength of light and/or the drug.

Polymorphous Light Eruption.

Polymorphous light eruption develops most commonly in females younger than 30 yr. The first

---

eruption typically appears after prolonged sun exposure during the spring or summer. Onset of the eruption is delayed by hours to days after sun exposure and lasts for hours to sometimes weeks. Areas of involvement tend to be symmetric and

are characteristic for a given patient, including some but not all of the exposed or lightly covered skin on the face, neck, upper chest, and distal extremities. Lesions have various morphologies but most commonly are pruritic, 2–5?mm grouped erythematous papules or papulovesicles or edematous plaques that are more than 5?cm in diameter. Most cases involve sensitivity to UVA radiation, although some are UVB induced. Therapeutic approaches include sun avoidance, broad-spectrum sunscreens, topical or systemic corticosteroids, ß-carotene, nicotinamide, antimalarials, or prophylactic UVB or PUVA phototherapy.

Cockayne Syndrome.

Onset of this autosomal recessive disorder is characterized by the appearance, at approximately 1 yr of age, of facial erythema in a butterfly distribution after sun exposure, followed by loss of adipose tissue and development of thin, atrophic, hyperpigmented skin, particularly over the face. Associated features include dwarfism; mental retardation; large, protuberant ears; long limbs; disproportionately large hands and feet, which are sometimes cool and cyanotic; pinched nose; carious teeth; unsteady gait with tremor; limitation of joint mobility; progressive deafness; cataracts; retinal degeneration; optic atrophy; decreased sweating and tearing; and premature graying of the hair. Diffuse extensive demyelination of the peripheral and central nervous systems ensues, and patients generally die of atheromatous vascular disease before the 3rd decade. Photosensitivity is due to deficient rates of repair of UV-induced damage, specifically within actively transcribing regions of DNA. The syndrome is distinguished from progeria (see Chapter 79) by photosensitivity and the ocular abnormalities.

Xeroderma Pigmentosum.

This is a rare autosomal recessive disorder that results from a defect in nucleotide excision repair. Ten complementation groups have been recognized, based on each group's separate defect in the ability to repair damaged DNA. The wavelength of light that induces the DNA damage ranges from 280–340?nm. Skin changes are first noted during infancy or early childhood in sun-exposed areas such as the face, neck, hands, and arms; lesions may occur, however, at other sites, including the scalp. The skin lesions consist of erythema, scaling, bullae, crusting, ephelides, telangiectasia, keratoses, basal and squamous cell carcinomas, and malignant melanomas. Ocular manifestations include photophobia, lacrimation, blepharitis, symblepharon, keratitis, corneal opacities, tumors of the lids, and possible eventual blindness. Neurologic abnormalities such as mental deterioration and sensorineural deafness may develop in approximately 20% of patients. Some patients with xeroderma pigmentosum have the clinical phenotype of Cockayne syndrome, suggesting that these two disorders may represent an overlapping spectrum of excision-repair defects. The association of xeroderma pigmentosum with microcephaly, mental retardation, dwarfism, and hypogonadism is known as *De Sanctis-Cacchione syndrome*.

This disease is a serious mutilating disorder, and the life span is often brief. Affected families should have genetic counseling. The disorder is detectable in cells cultured from amniotic fluid. Affected children should be totally protected from sun exposure; protective clothing, eyeglasses, and opaque broad-spectrum sunscreens should be used even for mildly affected children. Light from unshielded fluorescent bulbs and sunlight passing through glass windows are also harmful. Early detection and removal of malignancies is mandatory. Grafting of skin from non–light-exposed areas may be helpful, as is the use of topical antimitotic agents such as 5-fluorouracil.

Rothmund-Thomson Syndrome.

This syndrome is also known as *poikiloderma congenitale* because of the striking skin changes; it is inherited as an autosomal recessive trait, although a preponderance of affected females has been reported. Skin changes are noted as early as 3 mo of age. Plaques of erythema and edema appear on the cheeks, forehead, ears, neck, dorsal portions of the hands, extensor surfaces of the arms, and buttocks and are replaced gradually by reticulated, atrophic, hyperpigmented, telangiectatic plaques. Light sensitivity is present in many cases, and exposure to the sun may provoke formation of bullae. Areas of involvement, however, are not strictly photodistributed. Short stature; frontal bossing; saddle nose; prognathism; small hands and feet; sparse eyebrows, eyelashes, pubic and axillary hair; sparse, fine, prematurely gray hair or alopecia; dystrophic nails; defective dentition; bony defects; and hypogenitalism are common. Cataracts commonly become apparent at 2–7 yr of age. Most patients have normal mental development and life expectancy. Keratoses and later squamous cell carcinomas may develop on exposed skin. In addition, the incidence of noncutaneous malignancies, particularly osteosarcoma, is higher than in the general population.

Hartnup Disease (see Chapter 74.5).

This is a rare inborn error of metabolism with autosomal recessive inheritance. Neutral amino acids, including tryptophan, are not transported across the brush border epithelium of the intestine and kidneys, resulting in deficiency of synthesis of nicotinamide and causing a photo-induced pellagra-like syndrome. The urine contains increased amounts of monoamine monocarboxylic amino acids. Cutaneous signs, which precede neurologic manifestations, initially develop during the early months of life when an eczematous, occasionally vesicobullous eruption is noted on the face and extremities in a glove-and-stocking photodistribution. Hyperpigmentation and hyperkeratosis may supervene and are intensified by further exposure to sunlight. Episodic flares may be precipitated by febrile illness, sun exposure, emotional stress, and poor nutrition. In most cases, mental development is normal, but some patients display emotional instability and episodic cerebellar ataxia. Neurologic symptoms are fully reversible. Administration of nicotinamide and protection from sunlight result in improvement of both cutaneous and neurologic manifestations. Neomycin may also be beneficial in abating neurologic symptoms by reducing the intestinal bacterial flora and minimizing formation of indole and indican.

Bloom Syndrome.

The defect in Bloom syndrome is inherited in an autosomal recessive manner on chromosome 15, perhaps owing to absence of a DNA helicase. Erythema and telangiectasia develop during infancy in a butterfly distribution on the face after exposure to sunlight. A bullous eruption on the lips and telangiectatic erythema on the hands and forearms may develop. Café-au-lait spots, ichthyosis, acanthosis nigricans, and hypertrichosis are less constant cutaneous manifestations. Prenatal and postnatal short stature and a distinctive facies consisting of a prominent nose and ears and a small, narrow face are generally found. Defective dentition, pilonidal

cysts, sacral dimples, syndactyly, polydactyly, clinodactyly of the fifth fingers, shortened lower extremities, and clubfeet are additional inconstant features. Intellect is normal. Patients frequently have low levels of IgA, IgM, and IgG and are susceptible to infections. They are sensitive to UV radiation, and their rate of chromosomal breaks and sister chromatid exchanges is markedly increased. Affected children have an unusual tendency to develop lymphoreticular malignancies.

Chapter 647 - Diseases of the Epidermis

Psoriasis.

This common, chronic skin disorder is first evident in approximately one third of affected individuals within the first 2 decades of life. When the onset occurs during childhood, about 50% have a positive family history of the disease, and girls are more frequently affected. The mode of transmission is unknown; a multifactorial type of inheritance has been proposed. There is an association with histocompatibility antigens (HLA)-BW17, -B13, -B16, -BW37, and most often -CW6. The disease develops in 10% of HLA-CW6–positive patients. These HLA types are not associated with the pustular form of the disease. The pathogenesis is also unknown; epidermal turnover time, however, is distinctly accelerated compared with that of normal epidermis. In addition, infiltrating effector T lymphocytes and tumor necrosis factor may be involved, as evidenced by improvement after therapy, which block these cellular or humoral aspects of inflammation.

CLINICAL MANIFESTATIONS.

The lesions consist of erythematous papules that coalesce to form plaques with sharply demarcated, irregular borders. If they are unaltered by treatment, a thick silvery or yellow-white scale (resembling mica) develops; removal of it may result in pinpoint bleeding (Auspitz sign). The *Koebner*, or isomorphic, *response*, in which new lesions appear at sites of trauma, is a valuable diagnostic feature. Lesions may occur anywhere, but preferred sites are the scalp, knees (Fig. 647–1*A*), elbows, umbilicus, superior intergluteal fold, and genitals. Scalp lesions may be confused with seborrheic dermatitis, atopic dermatitis, or tinea capitis. Small raindrop-like lesions on the face are moderately common. Nail involvement, a valuable diagnostic sign, is characterized by pitting of the nail plate (see Fig. 647–1*B*), detachment of the plate (onycholysis), yellowish-brown subungual discoloration, and accumulation of subungual debris.

Age is an important factor in determining the clinical pattern. Psoriasis is rare in neonates but may be severe and recalcitrant and pose a diagnostic problem. The initial lesions may involve the diaper area and mimic seborrheic dermatitis, eczematous diaper dermatitis, perianal streptococcal disease, or candidosis. Biopsy or prolonged observation may be required for definitive diagnosis. Other rare forms include psoriatic erythroderma, localized or generalized pustular psoriasis, and linear psoriasis. Hospitalization may be required for severe forms of the disease. *Guttate psoriasis*, a variant that occurs predominantly in children, is characterized by an explosive eruption of profuse, small, oval or round lesions that morphologically are identical to the larger plaques of psoriasis (see Fig. 647–1*C*). Sites of predilection

are the trunk, face, and proximal portions of the limbs. The onset frequently follows a recent streptococcal respiratory infection; a culture of the throat and serologic titers should be obtained. Guttate psoriasis has also been observed after perianal streptococcal infection, viral infections, sunburn, and withdrawal of systemic corticosteroid therapy. Psoriatic skin lesions may be induced, in a genetically susceptible host, by CD4+ T cells that were initially activated by streptococcal pyrogenic exotoxins acting as superantigens. The source of the streptococcal antigens can be the throat or the skin. Some of the superantigen-activated T cells recognize streptococcal M protein in the skin and appear to have cross reactivity with an abnormal keratin that has homology with streptococcal M protein. The autoreactive T cells may be responsible for the formation and maintenance of psoriatic skin lesions. The lesions may be confused with viral exanthems and guttate parapsoriasis (see later).

DIAGNOSIS.

This is based on the clinical manifestations. The differential diagnosis includes Reiter syndrome, which, in contrast to psoriasis, involves mucous membranes, and pityriasis rubra pilaris. When in doubt, histopathologic examination of an untreated lesion reveals characteristic changes of psoriasis.

TREATMENT.

The therapeutic approach varies with the age of the child, type of psoriasis, sites of involvement, and extent of the disease. Therapy is mainly palliative and should not be overly aggressive. Physical and chemical trauma to the skin should be avoided as much as possible (see the Koebner response discussed earlier).

Tar preparations may be used in the form of an emulsion added to the daily bath, gel preparations, or ointments such as crude coal tar (1–5%) and liquor carbonis detergens (5–15%) in an emollient base alone or in conjunction with ultraviolet (UV) B light or natural sunlight. Sunlight occasionally has an adverse rather than a beneficial effect, and the use of tar preparations may have to be decreased during the summer to avoid phototoxic reactions. Salicylic acid ointment (1–3%) may provide an alternative for removal of scale, but extensive application may result in toxicity, particularly in small children. Topical corticosteroid preparations are effective during the first several weeks of therapy for an individual lesion, and then their effectiveness tends to decrease. Topical corticosteroids must be used with caution. Fluorinated compounds produce cutaneous atrophy if applied excessively or if occluded with polyethylene film for prolonged periods, and adrenal suppression may occur if systemic absorption is excessive. The preparation that is least potent but effective should be applied one to two times daily. The topical vitamin D analog calcipotriene may also be effective for limited lesions. It appears to have much less impact on calcium metabolism (e.g., 100-fold less) than calcitriol. Calcipotriene can burn and sting, which limits its usefulness in children. In addition, several weeks of therapy are necessary before benefit is seen. For scalp lesions, applications of a phenol and saline solution (Baker P & S) followed by a tar shampoo are effective in the removal of scales. A corticosteroid in a solution, lotion, or gel base may be applied when the scaling is diminished. Rarely, the more severe forms of psoriasis may require systemic therapy.

The use of psoralens and UV light (PUVA) is effective in severe psoriasis in adults, but the safety of PUVA has not been established for children. Methotrexate, oral retinoids (in combination with PUVA), and cyclosporine are used for the rare severe and generalized forms of psoriasis. The retinoid etretinate is useful in severe disorders, has a half-life of approximately 120 days, and may have serious side effects; dermatologic consultation is essential when its use is being considered. Acitretin may hold more promise for pediatric patients, because the half-life of this synthetic retinoid is 2–4 days. Psoriasis in infants and acute guttate psoriasis may flare with vigorous treatment and should be managed conservatively. Nail lesions are usually recalcitrant to therapy. Potentially beneficial therapies include 308?nm excimer laser UV-B radiation, inhibition of tumor necrosis factor with infliximab, and inhibition of CD45RO+ memory T cells with alefacept.

PROGNOSIS.

This is best for children with limited disease. Psoriasis is characterized by remissions and exacerbations; if present during adolescence, it is a lifelong disease. Arthritis may be an extracutaneous complication.

Figure 647-1 *A*, Chronic psoriatic plaques on the knee. *B*, Psoriatic nail changes of pitting and dystrophy. *C*, Guttate psoriasis in widespread distribution over the trunk.

Pityriasis Lichenoides.

This has historically encompassed pityriasis lichenoides et varioliformis acuta (PLEVA, Mucha-Habermann disease), which tends to develop acutely, and pityriasis lichenoides chronica (PLC), which follows a chronic course. The designation of pityriasis lichenoides as acute or chronic may more properly refer to morphologic appearance of the lesions, which is often hemorrhagic or necrotic in PLEVA, than to the duration of the disease. No correlation is found between the type of lesion at the onset of the eruption and the duration of the disease. Many patients have both acute and chronic lesions simultaneously, and transition of lesions from one form into another occurs occasionally. There is a correlation between the distribution of lesions and the duration of disease: (1) disease characterized by diffusely distributed lesions may resolve relatively quickly (mean disease duration 11 mo); (2) centrally distributed lesions on the trunk, neck, and/or proximal extremities are intermediate in duration; and (3) disease located peripherally or acrally usually persists the longest (mean 31 mo). Pityriasis lichenoides most commonly presents in the 2nd and 3rd decades; approximately one third of cases present before age 20 yr.

CLINICAL MANIFESTATIONS.

PLC presents with generalized, multiple, asymptomatic 3–5?mm brown-red papules

that are covered by a grayish mica-like scale. A useful clinical sign is the easy detachment of the adherent scale, revealing a shining surface. Lesions may be asymptomatic or may cause minimal pruritus and occasionally become infiltrated, vesicular, hemorrhagic, and crusted. Individual papules become flat and brownish over 2–6 wk, ultimately leaving a hyperpigmented or hypopigmented macule. Scarring is unusual. Lesions are most common on the trunk and extremities and generally spare the face, palmoplantar surfaces, scalp, and mucous membranes. The eruption persists for months to years and is characterized by polymorphous lesions in various stages of evolution. PLC histologically shows a parakeratotic, thickened corneal layer; epidermal spongiosis; a superficial perivascular infiltrate of

macrophages and predominantly CD8+ lymphocytes, which may extend into the epidermis; and small numbers of extravasated erythrocytes in the papillary dermis.

PLEVA presents with an abrupt eruption of numerous papules that have a vesiculopustular and then a purpuric center, are covered by a dark adherent crust, and are surrounded by an erythematous halo. Constitutional symptoms of fever, malaise, headache, and arthralgias may be present for 2–3 days after the initial outbreak. Lesions are distributed diffusely on the trunk and extremities, as in PLC. Individual lesions heal within a few weeks, sometimes leaving a varioliform scar, and successive crops of papules produce the characteristic polymorphous appearance of the eruption. The condition is generally self-limited from several weeks to months. The histopathologic changes of PLEVA reflect its more severe nature compared with PLC. Intercellular and intracellular edema in the epidermis may lead to degeneration of keratinocytes. A dense perivascular mononuclear cell infiltrate that extends upward into the epidermis and downward into the reticular dermis, endothelial cell swelling, and extravasation of erythrocytes into the epidermis and dermis are additional characteristic features. Severe changes of vasculitis are exceptional. Differential diagnosis includes guttate psoriasis, pityriasis rosea, drug eruptions, secondary syphilis, viral exanthems, and lichen planus. The chronicity of pityriasis lichenoides helps to preclude pityriasis rosea, viral exanthems, and some drug eruptions. A skin biopsy helps to preclude other differential diagnoses.

A rare form of PLEVA has been described as presenting with fever and ulceronecrotic plaques up to 1?cm in diameter; those are most common on the anterior trunk and flexors of the proximal upper extremities. Arthritis and superinfection of cutaneous lesions with *Staphylococcus aureus* may also develop. The ulceronecrotic lesions appear within papules of PLEVA and heal with hypopigmented scarring in a few weeks. Leukocytoclastic vasculitis is occasionally seen histopathologically. The eruption may resemble erythema multiforme, but it generally spares the mucous membranes.

ETIOLOGY.

The cause of pityriasis lichenoides is unknown, but sporadic outbreaks have led to an unsuccessful search for an infectious agent; human-to-human transmission has not been documented. A popular hypothesis is that pityriasis lichenoides is a hypersensitivity reaction to an infectious organism. Cell-mediated mechanisms appear to be important in the pathogenesis because most infiltrating cells are cytotoxic-suppressor cells. Clonal gene rearrangement studies of the T-cell receptor and immunohistologic studies have led to the suggestion that PLEVA may be a T-cell lymphoproliferative process. The condition in two children with PLEVA was reported to evolve into cutaneous T-cell lymphoma. It has been postulated that the relatively greater proportion of cytotoxic-suppressor cells than helper-inducer T cells in lesions of PLEVA compared with those of lymphomatoid papulosis or T-cell lymphoma reflects the more effective host response in PLEVA.

TREATMENT.

In general, pityriasis lichenoides should be considered a benign condition that does not alter the health of the child. A lubricant to remove excessive scaling may be all that is necessary if the patient is asymptomatic. The most appropriate treatment includes erythromycin (30–50?mg/kg/24?hr for 2 mo) in combination with natural sunlight. If this regimen is effective, erythromycin should then be tapered slowly over several months. The rare febrile ulceronecrotic form may be controlled effectively by systemic corticosteroids. Additional modalities that have been effective in some adult patients but are rarely appropriate for children include PUVA, tetracycline, dapsone, and methotrexate.

Keratosis Pilaris.

This moderately common papular eruption may vary in extent from sparse lesions over the extensor aspects of the limbs to involvement of most of the body surface; typical areas of involvement include the upper extensor arms and the thighs, cheeks, and buttocks. The lesions may resemble gooseflesh; they are noninflammatory, scaly, follicular papules that do not coalesce. Irritation of the follicular plugs occasionally causes folliculitis. Because the lesions are associated with and accentuated by dry skin, they are often more prominent during the winter. They are more frequent in patients with atopic dermatitis and are most common during childhood and early adulthood, tending to subside during the 3rd decade of life. Mild or localized eruptions respond to lubrication with a bland emollient; more pronounced or widespread lesions require regular applications of a 10–25% urea cream, an a-hydroxy acid preparation such as lactic acid in an emollient or in combination with a corticosteroid, or topical retinoic acid. Therapy may improve the condition but does not cure it.

Lichen Spinulosus.

This uncommon disorder occurs principally in children and more frequently in boys. The cause is unknown. The lesions consist of sharply circumscribed irregular plaques of spiny, keratinous projections that protrude from the orifices of the pilosebaceous canals (Fig. 647–2). Plaques may occur anywhere on the body and are often distributed symmetrically on the trunk, elbows, knees, and extensor surfaces of the limbs. Although sometimes erythematous, the lesions are usually skin colored. They are readily palpable and represent keratotic follicular plugs. Lichen spinulosus is easily differentiated from keratosis pilaris because the latter lesions are never grouped to form plaques. More commonly, it is confused with papular eczema.

Treatment is usually unnecessary. For patients who regard the eruption as a cosmetic defect, keratolytic agents such as salicylic acid ointment (3–7%), urea-containing lubricants (10–25%), and retinoic acid preparations are often effective in flattening the projections. The plaques usually disappear spontaneously after several months or years.

Pityriasis Rosea.

This benign, common eruption occurs most frequently in children and young adults. Although a prodrome of fever, malaise, arthralgia, and pharyngitis may precede the eruption, children rarely complain of such symptoms. The cause of pityriasis rosea is unknown; a viral agent is suspected.

CLINICAL MANIFESTATIONS.

A *herald patch*, a solitary, round or oval lesion that may occur anywhere on the body and is often but not always identifiable by its large size, usually precedes

Figure 647-2 Sharply circumscribed plaque of follicular papules characteristic of lichen spinulosus.

---

the generalized eruption. Herald patches vary from 1–10?cm in diameter; they are annular in configuration and have a raised border with fine, adherent scales. Approximately 5–10 days after the appearance of the herald patch, a widespread, symmetric eruption becomes evident involving mainly the trunk and proximal limbs (Fig. 647–3). When the disease is extensive, the face, scalp, and distal limbs may be involved, or, in the inverse form of pityriasis rosea, only those sites may be affected. Lesions may appear in crops for several days. Typical lesions are oval or round, less than 1?cm in diameter, slightly raised, and pink to brown. The developed lesion is covered by a fine scale that gives the skin a crinkly appearance; some lesions clear centrally, producing a collarette of scale that is attached only at the periphery. Papular, vesicular, urticarial, hemorrhagic, and large annular lesions are unusual variants. The long axis of each lesion is usually aligned with the cutaneous cleavage lines, a feature that creates the so-called Christmas tree pattern on the back. Actually, conformation to skin lines is often more discernible in the anterior and posterior axillary folds and supraclavicular areas. Duration of the eruption varies from 2–12 wk. The lesions may be asymptomatic or mildly to severely pruritic.

DIAGNOSIS.

This is clinical. The herald patch may be mistaken for tinea corporis, a pitfall that can be avoided if testing with a potassium hydroxide preparation is carried out. The generalized eruption resembles a number of other diseases; of these, secondary syphilis is the most important. Drug eruptions, viral exanthems, guttate psoriasis, PLC, and eczema can also be confused with pityriasis rosea.

TREATMENT.

Therapy is unnecessary for asymptomatic patients. If scaling is prominent, a bland emollient may suffice. Pruritus may be suppressed by a lubricating lotion containing menthol and camphor or by an oral antihistamine for sedation, particularly at night, when itching may be troublesome. Occasionally, a nonfluorinated topical corticosteroid preparation may be necessary to alleviate pruritus. After the eruption has resolved, postinflammatory hypopigmentation or hyperpigmentation may be pronounced, particularly in black patients; these changes disappear during subsequent weeks to months.

Pityriasis Rubra Pilaris.

This rare chronic dermatosis often has an insidious onset with diffuse scaling and erythema of the scalp, which is indistinguishable from seborrheic dermatitis, and with thick hyperkeratosis of the palms and soles. The characteristic primary lesion is a firm, dome-shaped, tiny, acuminate papule,

Figure 647-3 Ovoid, maculopapular lesions of pityriasis rosea. Note the distribution along the skin lines and the herald patch on the chest.

which is pink to red and has a central keratotic plug pierced by a vellus hair. Masses of these papules coalesce to form large, erythematous, sharply demarcated orangish plaques, within which islands of normal skin can be distinguished, creating a bizarre effect. Typical papules on the dorsum of the proximal phalanges are readily palpated. Gray plaques or papules resembling lichen planus may be found in the oral cavity. Dystrophic changes in the nails may occur and mimic those of psoriasis. In advanced stages, marked hyperkeratosis of the scalp and face may cause alopecia and ectropion. Differential diagnosis includes ichthyosis, seborrheic dermatitis, keratoderma of the palms and soles, and psoriasis.

ETIOLOGY.

The cause is unknown. A genetic form with autosomal dominant transmission may account for some cases in childhood, but most appear to be sporadic. Attempts to link the disease with a defect in vitamin A metabolism have not been definitive. Skin biopsy may help to differentiate this condition from psoriasis and seborrheic dermatitis, which it resembles most closely.

TREATMENT.

The numerous therapeutic regimens recommended are difficult to evaluate because the disease has a capricious course with exacerbations and remissions. Oral and topical retinoids and vitamin A have been used most frequently. When vitamin A or synthetic retinoids are administered orally, the child should be observed carefully for signs of toxicity (see earlier discussion on treatment of psoriasis). In childhood, the *prognosis* for eventual resolution is relatively good.

Darier Disease (Keratosis Follicularis).

This rare genetic disorder is inherited as an autosomal dominant trait. Onset occurs usually during late childhood. Typical lesions are small, firm, skin-colored papules that are not always follicular in location. The lesions eventually acquire yellow, malodorous crusts; coalesce to form large, gray-brown, vegetative plaques; and usually involve the face, neck, shoulders, chest, back, and limb flexures in a symmetric distribution. Papules, fissures, crusts, and ulcers may appear on the mucous membranes of the lips, tongue, buccal mucosa, pharynx, larynx, and vulva. Hyperkeratosis of the palms and soles and nail dystrophy with subungual hyperkeratosis are variable features. Severe pruritus, secondary infection, offensive odor, and aggravation of the dermatosis on exposure to sunlight may occur. Darier disease is most likely to be confused with seborrheic dermatitis or juvenile flat warts. Histologic changes are diagnostic: Hyperkeratosis, intraepidermal separation with formation of suprabasal clefts, and dyskeratotic epidermal cells are characteristic features.

Treatment is nonspecific. Some patients have responded to topical vitamin A or retinoic acid, with or without occlusive dressings. Severe disease may be controlled with oral synthetic retinoids. Secondary infection may require local cleansing and systemically administered antibiotics. Affected individuals usually suffer more during the summer.

Lichen Nitidus.

This chronic, benign, papular eruption is characterized by minute (1–2?mm), flat-topped, shiny, firm papules of uniform size; these are most often skin colored but may be pink or red. In black individuals, they are usually hypopigmented. Sites of predilection are the genitals, abdomen, chest, forearms, wrists, and inner aspects of the thighs. The lesions may be sparse or numerous and form large plaques; careful examination usually discloses linear papules in a line of scratch (Koebner phenomenon), a valuable clue to the diagnosis because it occurs in only a few diseases (Fig. 647–4). Lichen nitidus occurs in all age groups. The cause is unknown. Patients are usually asymptomatic and constitutionally well. The lesions may be confused with those of lichen planus and rarely coexist with them.

Widespread keratosis pilaris can also be confused with lichen nitidus, but the follicular localization of the papules and the absence of Koebner phenomenon in the former distinguish them. Verruca plana (flat warts), if small and uniform in size,

Figure 647-4 Tiny flat-topped papules of lichen nitidus on the arm and trunk. Note the Koebner response on the arm (papules in a line of scratch).

may occasionally resemble lichen nitidus. Although the diagnosis can be made clinically, a biopsy is occasionally indicated. Histopathologically, the lichen nitidus papule consists of sharply circumscribed nests of lymphocytes and histiocytes in the upper dermis enclosed by clawlike epidermal rete ridges. The course of lichen nitidus spans months to years, but the lesions eventually involute completely. There is no effective therapy.

Lichen Striatus.

This benign, self-limited eruption consists of a continuous or discontinuous linear band of papules in a zosteriform distribution. The primary lesion is a flat-topped, red to violaceous papule covered with fine scale. Aggregates of these papules form multiple bands or plaques (Fig. 647–5). In black patients, the lesions may be hypopigmented. The cause and explanation for the linear distribution are unknown. The eruption evolves over a period of days or weeks in an otherwise

Figure 647-5 Multiple linear plaques and streaks of lichen striatus.

healthy child, remains stationary for weeks to months, and finally remits without sequelae. Symptoms are usually absent; some children complain of itching. Nail dystrophy may occur when the eruption involves the posterior nail fold and matrix.

Lichen striatus is occasionally confused with other disorders. The initial plaque may resemble papular eczema or lichen nitidus until the linear configuration becomes apparent. Linear lichen planus and linear psoriasis are usually associated with typical individual lesions elsewhere on the body. Linear epidermal nevi are permanent lesions that often become more hyperkeratotic and hyperpigmented than those of lichen striatus. A lubricating lotion containing menthol and camphor or a mild corticosteroid preparation provides sufficient relief when pruritus is a problem.

Lichen Planus.

This is a rare disorder in young children and uncommon in older ones. The primary lesion is a violaceous, sharply demarcated, polygonal papule with fine lines or thin white scales on the surface; papules may coalesce to form large plaques. The papules are intensely pruritic, and additional ones are often induced by scratching (Koebner phenomenon) so that lines of them are often detected (Fig. 647–6). Sites of predilection are the flexor surfaces of the wrists, forearms, and inner aspects of the thighs. Characteristic lesions of mucous membranes consist of pinhead-sized white papules that coalesce to form reticulated and lacy patterns on the oral mucosa and sometimes on the lips and tongue.

Acute eruptive lichen planus is probably the most common form in children. The lesions erupt in an explosive fashion, much like a viral exanthem, and spread to involve most of the body surface. Hypertrophic, linear, bullous, atrophic, annular, follicular, erosive, and ulcerative forms of lichen planus may also occur. Nail involvement may develop in the chronic forms but is rarely evident in children (see Chapter 653). The disorder may persist for months to years, but the acute eruptive form is most likely to involute permanently. Intense hyperpigmentation frequently persists for a long time after the resolution of lesions. The histopathologic findings of lichen planus are specific, and a biopsy is indicated if the diagnosis is unclear.

Treatment is directed at alleviation of the intense pruritus and amelioration of the

skin lesions. Oral antihistamines and/or

Figure 647-6 Violaceous polygonal papules of lichen planus. Note the striking Koebner response.

---

tranquilizers are often helpful. The skin lesions respond best to regular applications of a topical corticosteroid preparation. Rarely, systemic corticosteroid therapy is necessary to gain control of widespread, intractable lesions.

Porokeratosis.

This rare, chronic, progressive disease is inherited as an autosomal dominant trait. Several forms have been delineated: solitary plaques, linear porokeratosis, hyperkeratotic lesions of the palms and soles, disseminated eruptive lesions, and superficial actinic porokeratosis. The last form, probably induced by excessive sun exposure, occurs more commonly in women. Other types of porokeratosis are more common in males and begin during childhood. Sites of predilection are the limbs, face, neck, and genitals. The primary lesion is a small, keratotic papule that enlarges peripherally so that the center becomes depressed, with the edge forming an elevated wall or collar. The configuration of the plaque may be round, oval, or gyrate; its elevated border is split by a thin groove from which minute cornified projections protrude. The enclosed central area is yellow, gray, or tan and sclerotic, smooth, and dry, whereas the hyperkeratotic border is a darker gray, brown, or black.

The differential diagnosis includes warts, epidermal nevi, lichen planus, granuloma annulare, and elastosis perforans serpiginosa. A skin biopsy discloses the characteristic cornoid lamella (plug of stratum corneum cells with retained nuclei), which is responsible for the invariable linear ridge of the lesion. The disease is slowly progressive but relatively asymptomatic. Lesions are sometimes responsive to applications of liquid nitrogen or occasionally may be surgically excised. Topical agents such as retinoic acid and 5-fluorouracil may be effective in some patients.

Papular Acrodermatitis of Childhood (Gianotti-Crosti Syndrome).

This distinctive eruption is occasionally associated with malaise and low-grade fever but few other constitutional symptoms. The incidence peaks in early childhood. Occurrences are usually sporadic, but epidemics have been recorded. The skin lesion is a monomorphous, usually nonpruritic, dusky or coppery red, flat-topped, firm papule ranging in size from 1–5?mm. The papules appear in crops and may become profuse but remain discrete, forming a symmetric eruption on the face, buttocks, and limbs, including the palms and soles. The papules often have the appearance of vesicles; when opened, however, no fluid is obtained. The papules sometimes become hemorrhagic. Lines of papules (Koebner phenomenon) may be noted on the extremities. The trunk is relatively spared, as are the scalp and mucous membranes. Generalized lymphadenopathy and hepatomegaly (in those with hepatitis B viremia) constitute the only other abnormal physical findings. The eruption resolves spontaneously in about 15–60 days. Lymphadenopathy and hepatomegaly, if present, may persist for several months. This eruption in Italy was initially associated with primary liver infection by hepatitis B virus and surface antigenemia. Elevation of serum transaminase and alkaline phosphatase values without concomitant hyperbilirubinemia was usual. Skin biopsy was characterized by a perivascular mononuclear cell infiltrate and capillary endothelial swelling.

Generally, the disease is benign and is not associated with hepatitis in the United States. This eruption has been seen in children infected with Epstein-Barr virus, coxsackievirus A16, parainfluenza virus, and other viral infections. Papular acrodermatitis can be confused with lichen planus, erythema multiforme, histiocytosis X, and Henoch-Schönlein purpura.

Acanthosis Nigricans.

This is characterized by hyperpigmented, velvety, hyperkeratotic plaques that are most often localized to the neck, axillae, inframammary areas, groin, inner thighs, and anogenital region. The histologic changes are those of papillomatosis and hyperkeratosis rather than acanthosis or excessive pigment formation. Acanthosis nigricans has classically been associated with obesity; drugs such as nicotinic acid; endocrinopathies, including diabetes mellitus, Addison disease, Cushing syndrome, acromegaly, hypothyroidism, hyperthyroidism, Stein-Leventhal syndrome, and hyperandrogenic or hypogonadal syndromes; many different syndromes such as Bloom, Crouzon, or Rud syndromes, Wilson disease, lipoatrophic diabetes, partial lipodystrophy, and leprechaunism; and malignancies, usually in adults with an abdominal adenocarcinoma. It may occasionally be familial, with autosomal dominant inheritance. Acanthosis nigricans is found in 7% of children and is usually associated with obesity; this form is termed pseudoacanthosis nigricans.

The skin lesions appear to be a manifestation of insulin resistance. The clinical severity and histopathologic features of acanthosis nigricans correlate positively with the degree of hyperinsulinism. It has been hypothesized that insulin resistance, with compensatory hyperinsulinism, leads to insulin binding to and activation of insulin-like growth factor receptors, promoting epidermal growth. In the malignant form, tumor-secreted growth factors and hyperinsulinemia could be pathogenic.

This skin disorder is extremely difficult to treat but may be improved by palliation of the underlying disorder, weight loss in the case of pseudoacanthosis nigricans, reduction in insulin resistance, and topical or oral retinoids.

Chapter 648 - Disorders of Keratinization

Disorders of Cornification.

Disorders of cornification (ichthyoses) are a primary group of inherited conditions characterized clinically by patterns of scaling and histopathologically by hyperkeratosis. They are usually distinguishable on the basis of inheritance patterns, clinical features, associated defects, and histopathologic changes. Because some of these conditions cause disfigurement and considerable psychosocial stress, early diagnosis is helpful to predict probable course and prognosis and to provide supportive management for patients and families.

Harlequin Fetus.

This rare keratinizing disorder probably represents several genotypes with similar clinical manifestations. At birth, markedly thickened, ridged, and cracked skin forms horny plates over the entire body, disfiguring the facial features and constricting the digits. Severe ectropion and chemosis obscure the orbits, the nose and ears are flattened, and the lips are everted and gaping. Nails and hair may be absent. Joint mobility is restricted, and the hands and feet appear fixed and ischemic. Affected neonates have respiratory difficulty, suck

poorly, and are subject to severe cutaneous infection. Most die within the 1st days to weeks of life, but patients occasionally survive beyond infancy and have severe ichthyosis and variable neurologic impairment. Ectropion and eclabium resolve, and the cracked, horny plated skin is replaced by large, thin scales with surrounding erythema.

Inheritance is autosomal recessive. Common morphologic abnormalities include hyperkeratosis, accumulation of lipid droplets within corneocytes, and absence of normal lamellar granules. One type has an altered catalytic subunit of 2A protein phosphorylase, which is encoded on chromosome 11. The basic defect of all types is suggested to be an abnormality of lamellar granules, which have an important role in desquamation.

Initial treatment includes high fluid intake to avoid dehydration from transepidermal water loss and use of a humidified heated incubator, emulsifying ointments, careful attention to hygiene, and oral retinoids such as etretinate. Survivors after retinoid

therapy have shown severe congenital ichthyosiform erythroderma. Prenatal diagnosis has been accomplished by fetoscopy, fetal skin biopsy, and microscopic examination of cells from amniotic fluid taken at the 17th and 21st wk of gestation.

Collodion Baby.

These infants are covered at birth by a thick, taut membrane resembling oiled parchment or collodion, which is subsequently shed. The condition is usually a manifestation of congenital ichthyosiform erythroderma or lamellar ichthyosis; like a harlequin fetus, a collodion baby appears to be one phenotype for several genotypes. Less commonly collodion babies evolve into other forms of ichthyosis, Gaucher disease, and a small subset is otherwise healthy without chronic skin disease. Infrequently, an affected infant has normal skin after the membrane is shed. Affected neonates have ectropion, flattening of the ears and nose, and fixation of the lips in an O-shaped configuration

Figure 648-1 Typical facial appearance of a collodion baby.

(Fig. 648–1). Hair may be absent or may perforate the horny covering. The membrane cracks with initial respiratory efforts and, shortly after birth, begins to desquamate in large sheets. Complete shedding may take several weeks, and a new membrane may occasionally form in localized areas.

Neonatal morbidity and deaths may be due to cutaneous infection, aspiration pneumonia (squamous material), hypothermia, or hypernatremic dehydration from excessive transcutaneous fluid losses as a result of increased skin permeability. The outcome is uncertain, and accurate prognosis is impossible with respect to the subsequent development of ichthyosis. Treatment with a high-humidity environment and application of nonocclusive lubricants may facilitate shedding of the membrane.

Lamellar Ichthyosis and Congenital Ichthyosiform Erythroderma (Nonbullous Congenital Ichthyosiform Erythroderma).

There are two major forms of autosomal recessively inherited ichthyosis. Both forms are present soon or shortly after birth and are the most common forms of ichthyosis to present as collodion babies, although most infants present with erythroderma and scaling.

After shedding of the collodion membrane, if present, *lamellar ichthyosis*, evolves into large, quadrilateral dark scales that are free at the edges and adherent at the center. Scaling is often pronounced and involves the entire body surface, including flexural surfaces (Fig. 648–2). The face is often markedly involved, including ectropion and crumpled, small ears. The palms and soles are generally hyperkeratotic. The hair may be sparse and fine, but the teeth and mucosal surfaces are normal. In contrast to congenital ichthyosiform erythroderma, there is little erythema. Neither form includes blistering. Autosomal recessive lamellar ichthyosis (ARLI) is a clinically and genetically heterogeneous disorder. In many cases, mutations in TGM1 gene encoding transglutaminase have been found.

In *congenital ichthyosiform erythroderma*, erythroderma tends to be persistent, and scales, although they are generalized, are finer and whiter than in lamellar ichthyosis. Erythema decreases in later life and may disappear in middle age, whereas scaling persists and may even worsen with age. Hyperkeratosis is particularly

Figure 648-2 Generalized scaling of lamellar ichthyosis. Note the involvement of the axillary areas.

noticeable around the knees, elbows, and ankles. Palms and soles are uniformly hyperkeratotic. Some patients have sparse hair; cicatricial alopecia and nail dystrophy are found occasionally.

On histopathologic examination, lamellar ichthyosis is characterized by a markedly thickened stratum corneum and mild irregular epidermal thickening. Congenital ichthyosiform erythroderma has more epidermal thickening with parakeratosis but less hyperkeratosis and hypergranulosis than in lamellar ichthyosis. In congenital ichthyosiform erythroderma, there is a marked increase in the rate of epidermal cell production, considerably greater than the slightly increased rate observed in patients with lamellar ichthyosis.

Pruritus may be severe and responds minimally to antipruritic therapy. The unattractive appearance of the child and the malodor from bacterial colonization of macerated scales may create serious psychologic problems. Effective *treatment* includes prolonged baths with bath oil to remove excessive scales. Restriction of bathing, on the erroneous premise that accentuation of dryness will occur, only promotes malodor and accumulation of keratinous debris and contributes to pruritus and discomfort. A high-humidity environment in winter and air conditioning in summer reduce discomfort. Generous and frequent applications of emollients and keratolytic agents such as lactic or glycolic acid (5%), urea (10–25%), and retinoic acid (0.1% cream) may lessen the scaling to some extent, although these agents produce stinging if applied to fissured skin. Oral retinoids have a beneficial effect in these conditions but do not alter the underlying defect and, therefore, must be administered indefinitely. The long-term risks of these compounds (e.g., teratogenic effects and toxicity to bone) limit their usefulness. Ectropion requires ophthalmologic care and, at times, plastic procedures. Genetic counseling should be provided.

Ichthyosis Vulgaris.

This autosomal dominant ichthyosis is the most common of the disorders of keratinization, with an incidence of approximately 1/300 live births. Onset generally occurs sometime after birth during the 1st yr of life and, in most cases, is trivial, consisting only of slight roughening of the skin surface. In rare cases, infants have presented as collodion babies. Scaling is most prominent on the extensor aspects of the extremities, particularly the legs and back. Flexural surfaces are spared, and the abdomen, neck, and face are relatively uninvolved. Keratosis pilaris, particularly on the upper arms and thighs, accentuated markings and hyperkeratosis on the palms and soles, and atopy are relatively common. Scaling is most pronounced during the winter months and may abate completely during warm weather. The condition may

improve and even disappear with age. There is no accompanying disorder of hair, teeth, mucosal surfaces, or other organ systems.

The histopathologic changes differ from those of other types of ichthyosis in that the hyperkeratosis is associated with a decreased or absent granular layer. Abnormally small and crumbly keratohyalin granules are found in epidermal cells on electron microscopy. The rate of epidermal proliferation is normal; rather, the hyperkeratosis is due to defective desquamation. Profilaggrin, which has a role in desmosome dissolution, is deficient.

Scaling may be diminished by use of bath oil and daily applications of an emollient or a lubricant containing urea, salicylic acid, or an a-hydroxy acid, such as lactic acid.

X-Linked Ichthyosis.

X-linked ichthyosis is largely limited to males, although female carriers may display some clinical manifestations of the disorder. Skin peeling may be present at birth but typically abates until 3–6 mo of life. Scaling is most pronounced on the sides of the neck, lower face, preauricular areas, anterior trunk, and the limbs, particularly the legs. The elbow and knee flexures are generally spared but may be mildly involved. The palms and soles may be slightly thickened but are also usually spared. The condition gradually worsens in severity and extent. Keratosis pilaris is not present, and there is no increased incidence of atopy. Deep corneal opacities that do not interfere with vision develop during late childhood or adolescence and are a useful marker for the disease because they may also be present in carrier females. Cryptorchidism occurs in approximately 25% of affected males, although this may reflect an association with Kallmann syndrome, which also involves deletion on the short arm of the X chromosome. Testicular carcinoma occurs in some patients. Histologic changes include hyperkeratosis of the stratum corneum, a well-developed granular layer, and a hyperplastic epidermis.

The rate of epidermal proliferation is normal, and the hyperkeratosis is due to retention of corneocytes and delayed dissolution of the desmosomal disks. X-linked ichthyosis, however, involves a deficiency of steroid sulfatase, which hydrolyzes cholesterol sulfate and other sulfated steroids to cholesterol; cholesterol sulfate accumulates in the stratum corneum and plasma and may cause hyperkeratosis by inhibiting desmosomal proteolysis. Elevated cholesterol sulfate levels can be demonstrated in the serum, erythrocyte membranes, and epidermal cells and scales of affected males. Reduced enzyme activity can be detected in fibroblasts, keratinocytes, and leukocytes and, prenatally, in amniocytes or chorionic villus cells. In affected families, an affected male can be detected by restriction enzyme analysis of cultured chorionic villus cell DNA or amniocytes or by in situ hybridization, which identifies steroid sulfatase gene deletions prenatally in chorionic villus cells. A placental steroid sulfatase deficiency in carrier mothers results in low urinary and serum estriol values, prolonged labor, and insensitivity of the uterus to oxytocin and prostaglandins. The gene for steroid sulfatase is located on the short arm of the X chromosome (Xp22.3). Correction of steroid sulfatase deficiency is accomplished by gene transfer into tissue-cultured keratinocytes.

Hydration by bathing with bath oil and daily application of emollients and a urea-containing lubricant are usually effective *treatments*. Glycolic or lactic acid (5%) in an emollient base and propylene glycol 40–60% in water with occlusion overnight are alternative forms of therapy.

Epidermolytic Hyperkeratosis (Bullous Congenital Ichthyosiform Erythroderma).

Epidermolytic hyperkeratosis is inherited as an autosomal dominant trait, although many cases are sporadic. The *clinical manifestations* are characterized by the onset at birth of generalized erythroderma and severe hyperkeratosis. The scales are small, hard, and verrucous; distinctive, parallel hyperkeratotic ridges develop over the joint flexures, including the axillary, popliteal, and antecubital fossas, and on the neck and hips. Erythema becomes less prominent after infancy; however, the hyperkeratosis persists throughout adult life. Recurrent blistering may be widespread in neonates and may cause diagnostic confusion with other blistering disorders. Blistering becomes accentuated at sites of trauma such as the knees, elbows, and lower limbs but is not problematic after age 7–8 yr. The palms and soles may be thickened, but the hair, nails, mucosa, and sweat glands are normal. Secondary bacterial infection is common and requires appropriate antibiotic therapy. Severely affected patients may have crumpled ears and ectropion.

The histopathologic pattern is *diagnostic* and consists of hyperkeratosis, a markedly thickened granular layer with an increased number of keratohyalin granules, clear spaces around nuclei, and indistinct cellular boundaries of cells in the upper epidermis. On electron microscopic examination, keratin intermediate

filaments are clumped, and many desmosomes are attached to only one keratinocyte instead of connecting neighboring keratinocytes. Epidermolytic hyperkeratosis has been shown to be due to defects in either keratin 1 or 10 encoded in chromosome 12p, where the type II keratin genes are clustered. These keratins are required to form the keratin intermediate filaments in cells of the suprabasilar layers of the epidermis. Localized forms of the disease may resemble epidermal nevi (ichthyosis hystrix) or keratoderma of the palms and soles but share the distinctive histopathologic changes of epidermolytic hyperkeratosis. Prenatal diagnosis for affected families is possible by examination of DNA extracts from chorionic villus cells or amniocytes, provided that the specific mutation in the affected parent is known.

Treatment is difficult. Morbidity is increased in the neonatal period as a result of prematurity, sepsis, and fluid and electrolyte imbalance. Bacterial colonization of macerated scales produces a distinctive malodor that can be controlled somewhat by use of an antibacterial cleanser. Intermittent oral antibiotics generally are necessary. Keratolytic agents are often poorly tolerated. Oral retinoids (e.g., etretinate, acitretin, isotretinoin) may produce significant improvement, even at relatively low doses. Genetic counseling should be provided.

Ichthyosis Linearis Circumflexa.

This rare autosomal recessive disorder presents at birth or in the first few months of life with generalized erythema and scaling. The trunk and limbs have diffuse

erythema and superimposed migratory, polycyclic, and serpiginous hyperkeratotic lesions, some with a distinctive double-edged margin of scale. Lichenification or hyperkeratosis tends to persist in the antecubital and popliteal fossas. The face and scalp may remain erythematous and scaling. Many hair shaft deformities, most notably trichorrhexis invaginata, have been described in more than half of patients. This type of ichthyosis is characteristic of patients with Netherton syndrome (see later). Nonspecific psoriasiform changes are found on histopathologic examination.

Erythrokeratoderma Variabilis.

This autosomal dominant disorder with genetic linkage to the Rh blood group usually presents in the early months of life, progresses in childhood, and stabilizes in adolescence. It is characterized by sharply demarcated hyperkeratotic plaques with geographic borders that develop in areas of normal skin or within discrete erythematous patches. Patches of erythema change shape or size within minutes to hours or days or migrate, and they may gradually became hyperkeratotic and fixed. The distribution is generalized but sparse; sites of predilection are the face, buttocks, axillae, and extensor surfaces of the limbs. The palms and soles may be thickened, but hair, teeth, and nails are normal. Histopathologic changes include hyperkeratosis, papillomatosis, and irregular hyperplasia of the epidermis.

Symmetric progressive erythrokeratoderma is an autosomal dominant disorder that presents in childhood with large, fixed, geographic and symmetric fine, scaling, hyperkeratotic, erythematous plaques primarily on the extremities, buttocks, face, ankles, and wrists. Palmoplantar keratoderma is also present. The primary feature distinguishing this from erythrokeratoderma variabilis is the lack of variable erythema, as seen in the latter condition. These two conditions may be manifestations of the same disorder.

Ichthyosiform Dermatoses.

Several syndromes that include ichthyosis as a constant feature have been established as rare but distinct entities.

SJÖGREN-LARSSON SYNDROME.

This autosomal recessive inborn error of metabolism consists of ichthyosis of the lamellar or congenital ichthyosiform erythroderma types, mental retardation, and spasticity. The ichthyosis is generalized but is accentuated on the flexures and the lower abdomen and consists of erythroderma, fine scaling, larger platelike scales, and dark hyperkeratosis. A degenerative defect of retinal pigment epithelium has been detected in 20–30% of affected individuals. Glistening dots in the foveal area are a cardinal ophthalmologic sign. Motor and speech developmental delays are usually noted before 1 yr of age, and spastic diplegia or tetraplegia, epilepsy, and mental retardation generally become evident within the first 3 yr of life. Some patients may walk with the aid of braces, but most are confined to a wheelchair. The primary defect is an abnormality of fatty alcohol oxidation as a result of a deficiency of fatty aldehyde dehydrogenase, a component of the fatty alcohol-nicotinamide adenine dinucleotide oxidoreductase enzyme complex. This deficiency can be demonstrated in cultured skin fibroblasts of affected patients and carriers and, prenatally, in cultured chorionic villus cells and amniocytes from affected fetuses.

Elevation of urinary leukotriene B4 (LTB4) may provide an easier approach to diagnosis.

NETHERTON SYNDROME.

This autosomal recessive disorder is characterized by ichthyosis (usually ichthyosis linearis circumflexa but, occasionally, the lamellar or congenital ichthyosiform erythroderma types), trichorrhexis invaginata, and other hair shaft anomalies such as pili torti or trichorrhexis nodosa, and atopic diathesis (see Chapter 652). Mutations in the gene SPINK 5, which encodes a serine protease inhibitor, have been identified in patients with Netherton syndrome. The ichthyosis is present in the first 10 days of life and may be especially marked around the eyes, mouth, and perineal area. The erythroderma often is intensified after infection. Infants may suffer from failure to thrive, recurrent bacterial and candidal infections, elevated serum IgE levels, and marked hypernatremic dehydration. Scalp hair is sparse and short and fractures easily; eyebrows, eyelashes, and body hair are also abnormal. The most frequent allergic manifestations are urticaria, angioedema, atopic dermatitis, and asthma. Some patients are mentally retarded. The characteristic hair abnormality is seen on electron microscopy as invagination of the distal end of the hair shaft into the proximal end.

REFSUM SYNDROME (see Chapter 75.2).

This multisystem disorder is inherited as an autosomal recessive trait and becomes symptomatic during the 2nd or 3rd decade of life. The ichthyosis may be generalized, is relatively mild, and resembles ichthyosis vulgaris. The ichthyosis may also be localized to the palms and soles. Chronic polyneuritis with progressive paralysis and ataxia, atypical retinitis pigmentosa, anosmia, deafness, bony abnormalities, and electrocardiographic changes are the most characteristic features. This condition is diagnosed by lipid analysis of the blood or skin, which shows elevated phytanic acid levels. Dietary avoidance of phytanic acid-containing green vegetables and dairy products produces clinical improvement.

CHONDRODYSPLASIA PUNCTATA (see Chapter 75.2).

This includes several genetically heterogeneous disorders marked by ichthyosis and bone changes, principally *Conradi-Hunermann syndrome*, an X-linked dominant form affecting females only, and *rhizomelic dwarfism*, transmitted as an autosomal recessive trait. Nearly all with the X-linked dominant form and approximately 25% of patients with the recessive type have cutaneous lesions, ranging from severe, generalized erythema and scaling to mild hyperkeratosis. Rhizomelic chondrodysplasia punctata is associated with cataracts, hypertelorism, optic nerve atrophy, disproportionate shortening of the proximal extremities, psychomotor retardation, failure to thrive, and spasticity; most patients die during infancy. Numerous dysfunctional peroxisomal enzymes are found in patients with rhizomelic chondrodysplasia. Patients with the X-linked dominant form have asymmetric, variable shortening of the limbs and a distinctive ichthyosiform eruption at birth. Thick, yellow, tightly adherent keratinized plaques are distributed in a whorled pattern over the entire body, which may be intensely erythematous. The histologic changes include hyperkeratosis that penetrates to the depths of the hair follicles. The eruption typically resolves during infancy and may be superseded by a follicular

atrophoderma and patchy alopecia.

Additional features in all variants include cataracts and abnormal facies with saddle nose and frontal bossing. The pathognomonic defect, termed chondrodysplasia punctata, is stippled

---

epiphyses in the cartilaginous skeleton. This defect, which is seen in various settings and inherited disorders, often in association with peroxisomal deficiency, disappears by approximately age 3–4 yr.

Recessive X-linked chondrodysplasia punctata is due to a contiguous gene deletion affecting the recessive X-linked ichthyosis locus. These patients are deficient in steroid sulfatase activity, and their scaling resembles that in X-linked ichthyosis; peroxisomal function is normal.

RUD SYNDROME.

This consists of mental retardation, epilepsy, ichthyosis (type uncertain), and sexual infantilism. Associated defects of the skeleton, eyes, dentition, and hearing have also been reported.

A number of other rare syndromes with ichthyosis as a consistent feature include the following: ichthyosis with keratitis and deafness (KID syndrome); ichthyosis with defective hair having a banded pattern under polarized light and a low sulfur content (trichothiodystrophy), hypogonadism, and mental and growth retardation (Tay syndrome); multiple sulfatase deficiency; neutral lipid storage disease with ichthyosis (Chanarin-Dorfman syndrome); and CHILD syndrome (congenital hemidysplasia with ichthyosiform erythroderma and limb defects).

Keratoderma of Palms and Soles (Keratosis Palmaris et Plantaris).

Excessive hyperkeratosis of the palms and soles may occur as a manifestation of a focal or generalized congenital hereditary skin disorder or may result from such chronic skin diseases as psoriasis, eczema, pityriasis rubra pilaris, lupus erythematosus, or Reiter disease. The names of individual disorders have been based on descriptive titles, modes of inheritance, histopathologic findings, and biochemical defects.

DIFFUSE HYPERKERATOSIS OF PALMS AND SOLES (UNNA-THOST SYNDROME, TYLOSIS).

This autosomal dominant disorder presents in the first few months of life with erythema that gradually progresses to sharply demarcated hyperkeratotic scaling plaques over the palms and soles. The margins of the plaques often remain red; plaques may extend along the lateral aspects of the hands and feet and onto the volar wrists and the heels. Hyperhidrosis is usually present, but hair, teeth, and nails are usually normal. Dermatophyte infections are common and difficult to treat. Mutations in the gene for keratin 1 on chromosome 12 appear to underlie the disorder. Striate and punctate forms of palmar and plantar hyperkeratosis represent distinct entities.

EPIDERMOLYTIC HYPERKERATOSIS.

This type of hyperkeratosis, which is localized to the palms and soles, is an autosomal dominant defect involving mutations in the gene for keratin 9 with clinical findings identical to those of the Unna-Thost type. There is no hyperhidrosis, however, and affected areas may blister. Histopathologic changes are characteristic.

MAL DE MELEDA (KERATODERMA PALMOPLANTARIS TRANSGREDIENS).

This rare, progressive autosomal recessive condition is characterized by erythema and thick scales on the palms, fingers, soles, and flexor aspects of the wrists, knees, and elbows. Hyperhidrosis, nail thickening or koilonychia, and eczema may also occur.

MUTILATING KERATODERMA (VOHWINKEL SYNDROME).

This is a progressive autosomal dominant disease with honeycombed hyperkeratosis of palms and soles, sparing the arches; starfish-like and linear keratoses on the dorsum of the hands, fingers, feet, and knees; and ainhum-like constriction of the digits that sometimes leads to autoamputation. This disorder may be associated with alopecia and hearing loss. Mutations of the gene for loricrin, a major protein of the cornified cell envelope, have been identified.

PAPILLON-LEFÈVRE SYNDROME.

This autosomal recessive erythematous hyperkeratosis of the palms and soles sometimes extends to the dorsal hands and feet, elbows, and knees later in childhood. This syndrome is characterized by periodontal inflammation, leading to loss of teeth by age 4–5 yr if untreated; a tendency to frequent pyogenic skin infections; nail dystrophy, including transverse nail grooves; hyperhidrosis; and ectopic calcification of the dura.

Keratoderma of palms and soles also occurs as a feature of some forms of ichthyosis and ectodermal dysplasia. *Richner-Hanhart syndrome* is an autosomal recessive palmoplantar keratoderma with corneal ulcers, progressive mental impairment, and a deficiency of tyrosine aminotransferase, which leads to tyrosinemia. *Pachyonychia congenita* is transmitted as an autosomal dominant trait with variable expressivity. The classic type I form *(Jadassohn-Lewandowski syndrome)* is due to mutations in the gene for keratin 16. Major features of the syndrome are onychogryphosis; palmoplantar keratoderma; follicular hyperkeratosis, especially of the elbows and knees; and oral leukokeratosis. The nail dystrophy is the most striking feature and may be present at birth or develop early in life. The nails are thickened and tubular, projecting upward at the free edge to form a conical roof over a mass of subungual keratotic debris. Repeated paronychial inflammation may result in shedding of the nails. The feature seen most consistently among patients with this condition is keratoderma of the palms and soles. Additional associated features include hyperhidrosis of the palms and soles, and bullae and

erosions on the palms and soles. Some patients have shown a selective cell-mediated defect in recognition and processing of candida. Surgical removal of the nails and excision of the nail matrix have been helpful in some patients.

Patients with palmoplantar hyperhidrosis may have macerated plaques that become secondarily infected and malodorous. Morbidity is lessened if the hyperkeratosis can be controlled by *treatment*; however, only mild palliation is achieved with applications of lubricants, keratolytic agents (urea, salicylic acid, lactic acid), and oral retinoids including etretinate, isotretinoin, and acitretin. Soaking in saline solution followed by debridement is a mainstay of treatment.

Chapter 649 - Diseases of the Dermis

Keloid.

A keloid is a sharply demarcated, benign, dense growth of connective tissue that forms in the dermis after trauma. The lesions are firm, raised, pink, and rubbery; they may be tender or pruritic. Sites of predilection are the face, earlobes, neck, shoulders, upper trunk, sternum, and lower legs. Keloids are usually induced by trauma and commonly follow ear piercing, burns, scalds, and surgical procedures. Certain individuals, especially blacks, seem predisposed to keloid formation. In some

---

cases, a familial tendency (recessive or dominant inheritance) or the presence of foreign material in the wound appears to have a pathogenic role. Keloids are a rare feature of Ehlers-Danlos syndrome, Rubinstein-Taybi syndrome, and pachydermoperiostosis. In both keloids and hypertrophic scars, new collagen forms over a much longer period than in wounds that heal normally. Histopathologically, a keloid consists of whorled and interlaced hyalinized collagen fibers.

Keloids should be differentiated from hypertrophic scars, which remain confined to the site of injury and gradually involute over time. Young keloids may diminish in size if injected intralesionally at 4-wk intervals with triamcinolone suspension (10?mg/mL). At times, a more concentrated suspension is required. Large or old keloids may require surgical excision followed by intralesional injections of corticosteroid. The risk of recurrence at the same site argues against surgical excision alone. Placement of topical silicon gel sheeting over the keloid for several hours per day for several weeks may help some patients.

Striae Cutis Distensae.

These thinned, depressed, erythematous bands of atrophic skin eventually become silvery, opalescent, and smooth. They occur most frequently in areas that have been subject to distention, such as the lower back, buttocks, thighs, breasts, abdomen, and shoulders. The most frequent causes are rapid growth, pregnancy, obesity, Cushing disease, or prolonged corticosteroid therapy. Adolescent striae tend to become less conspicuous with time. Histopathologically, striae distensae resemble scars.

Corticosteroid-Induced Atrophy.

Both topical and systemic corticosteroid treatment can result in cutaneous atrophy. This is particularly common when a potent topical corticosteroid is applied under occlusion or to the intertriginous areas for a prolonged period. Affected skin is thin, fragile, smooth, and semitransparent, with telangiectasias and loss of normal skin markings. Histopathologically, one sees thinning of the stratum corneum and malpighii. Spaces between dermal collagen and elastic fibers are small, producing a more compact but thin dermis. The mechanism involves inhibition of synthesis of collagen type I, noncollagenous proteins, and total protein content of the skin; progressive reduction of dermal proteoglycans and glycosaminoglycans; and possibly prolonged vasoconstriction-induced ischemia. Retinoids applied topically restore these steroid-induced biochemical changes in the dermal connective tissue of the hairless mouse, without abrogating the beneficial anti-inflammatory effects.

Granuloma Annulare.

This common dermatosis occurs predominantly in children and young adults. Typical lesions begin as erythematous, firm, smooth papules; they gradually enlarge to form annular plaques with a papular border and a normal, slightly atrophic or discolored central area (Fig. 649–1) up to several centimeters in size. Lesions may occur anywhere on the body, but mucous membranes are spared. Favored sites include the dorsum of the hands and feet. *Annular lesions* are often mistaken for tinea corporis because of the elevated advancing border; they differ in that they are not scaly. *Papular lesions*, another variant, may simulate rheumatoid nodules, particularly when grouped on the fingers and elbows. The disseminated papular form, which is provoked by light in some cases, is rare in children. *Subcutaneous granuloma annulare* is especially common in children; it tends to develop on the scalp and limbs, particularly in the pretibial area. These lesions are firm, usually nontender, skin-colored nodules. *Perforating granuloma annulare* is characterized by the development of a yellowish center in some of the superficial papular lesions as a result of transepidermal elimination of altered collagen.

A biopsy is occasionally required for diagnosis. The lesions consist of a granuloma with a central area of necrotic collagen;

Figure 649-1 Annular lesion with a raised papular border and depressed center, characteristic of granuloma annulare.

mucin deposition; and a peripheral palisading infiltrate of lymphocytes, histiocytes, and foreign body giant cells. The pattern resembles that of necrobiosis lipoidica and rheumatoid nodule (see Chapter 145), but subtle histologic differences usually permit differentiation. The cause of granuloma annulare is unknown. Affected children are usually healthy. Some cases of granuloma annulare, particularly the generalized form, may be associated with diabetes mellitus. The eruption persists for months to years, but spontaneous resolution without residual change is usual; 75% of lesions clear within 2 yr. Application of a potent topical corticosteroid preparation or intralesional injections of corticosteroid may hasten involution, but nonintervention is acceptable.

Necrobiosis Lipoidica.

This rare disorder presents as erythematous papules that evolve into irregularly shaped, sharply demarcated, yellow, sclerotic plaques with central telangiectasia and a violaceous border. Scaling, crusting, and ulceration are frequent. Lesions develop most commonly on the shins. Slow extension of a given lesion over the years is usual, but long periods of quiescence or complete healing with scarring may occur.

Histopathologically, poorly defined areas of necrobiotic collagen are seen throughout, but primarily low in the dermis, associated with mucin deposition. Surrounding the necrobiotic, disordered areas of collagen is a palisading lymphohistiocytic granulomatous infiltrate. Some lesions are more characteristically granulomatous, with limited necrobiosis of collagen. Necrobiosis lipoidica must be differentiated clinically from xanthomas, morphea, granuloma annulare, and pretibial myxedema. Fifty to 75% of patients have diabetes mellitus; necrobiosis lipoidica occurs in 0.3% of all diabetic patients. The lesions persist despite good control of the diabetes but may improve minimally after applications of high-potency topical steroids or local injection of a corticosteroid.

Lichen Sclerosus et Atrophicus.

This presents initially with ivory-colored, shiny, indurated papules, often with a violaceous halo. The surface shows prominent dilated pilosebaceous or sweat duct orifices that often contain yellow or brown horny plugs. The papules coalesce to form irregular plaques of variable size, which may develop hemorrhagic bullae in their margins. In the latter stages, atrophy results in a depressed plaque with a wrinkled surface. This disorder occurs more commonly in girls than in boys. Sites of predilection in girls are the vulvar, perianal, and perineal skin. Extensive involvement may produce a sclerotic,

---

atrophic plaque of hourglass configuration; shrinkage of the labia and stenosis of the introitus may result. Vaginal discharge precedes vulvar lesions in approximately 20% of patients. In boys, the prepuce and glans penis are often involved, usually in association with phimosis; most boys with the disorder were not circumcised early in life. Sites elsewhere on the body that are most commonly involved include the upper trunk, the neck, the axillae, the flexor surfaces of wrists, and the areas around the umbilicus and the eyes. Pruritus may be severe.

In children, this disorder is most frequently confused with focal scleroderma (morphea) (see Chapter 150), with which it may coexist. In the genital area, it may be mistakenly attributed to sexual abuse. Biopsy is diagnostic, revealing hyperkeratosis with follicular plugging, hydropic degeneration of basal cells, a bandlike dermal lymphocytic infiltrate, homogenized collagen, and thinned elastic fibers in the upper dermis. The lesions may involute spontaneously, usually before or at the time of menarche; involution is more likely to occur in those in whom the disorder developed at a younger age. Leukoplakia and squamous cell carcinoma

may rarely develop. Potent topical corticosteroids may provide relief from pruritus and produce clearing of lesions, including those in the genital area. Topical progesterone 1% and testosterone 2% preparations have also been used for genital lesions.

Scleredema (Scleredema Adultorum, Scleredema of Buschke).

Approximately 30% of cases of scleredema develop before the age of 10 yr. Onset is sudden, with brawny edema of the face and neck that spreads rapidly to involve the thorax and arms in a sweater distribution; the abdomen and legs are usually spared. The face acquires a waxy, masklike appearance; the involved areas feel indurated and woody, are nonpitting, and are not sharply demarcated from normal skin. The overlying skin is normal in color and is not atrophic. Systemic involvement, which is uncommon, is marked by thickening of the tongue; dysarthria; dysphagia; restriction of eye and joint movements; and pleural, pericardial, and peritoneal effusions. Electrocardiographic changes may also be observed.

In 65–90% of cases, the disease follows an infection such as tonsillitis, pharyngitis, influenza, scarlet fever, measles, mumps, impetigo, or cellulitis after an interval of days or weeks; most cases follow a streptococcal infection. Onset may be heralded by a prodrome of fever, arthralgia, myalgia, and malaise. Onset in diabetic patients may occur insidiously. Laboratory data are not helpful. Some cases, however, are associated with immunoglobulin (Ig)G or IgA paraproteinemia. Skin biopsy demonstrates an increase in dermal thickness as a result of swelling and homogenization of the collagen bundles, which are separated by large interfibrous spaces. Increased amounts of mucopolysaccharides in the dermis can be identified by special stains.

The active phase of the disease persists for 2–8 wk; spontaneous and complete resolution usually occurs in 6 mo–2 yr. Recurrent attacks are unusual. The disorder must be differentiated from scleroderma, morphea, myxedema, trichinosis, dermatomyositis, sclerema neonatorum, and subcutaneous fat necrosis. There is no specific therapy.

Lipoid Proteinosis (Urbach-Wiethe Disease, Hyalinosis Cutis et Mucosae).

This autosomal recessive disorder consists of infiltration of hyaline material into the skin, oral cavity, larynx, and internal organs. It may be noted initially in early infancy as hoarseness. Skin lesions appear during childhood and consist of yellowish papules and nodules that may coalesce to form plaques on the face, forearms, neck, genitals, dorsum of the fingers, and scalp, where they result in patchy alopecia. Similar deposits are found on the lips, undersurface of the tongue, fauces, uvula, epiglottis, and vocal cords. The tongue becomes enlarged and feels firm on palpation; patients may be unable to protrude their tongue. Translucent nodules along the margins of the eyelids, causing thickening of the eyelids, are the most characteristic clinical manifestation. Pock-like atrophic scars may develop on the face. Hypertrophic, hyperkeratotic nodules occur at sites of friction such as the elbows and knees; the palms may be diffusely thickened. The disease progresses until early adult life, but the prognosis is good. Involvement of the larynx can lead to respiratory compromise, particularly in infancy, necessitating tracheostomy. Associated anomalies include dental abnormalities, epilepsy, and recurrent parotitis as a result of infiltrates in the Stensen duct; virtually any organ can be involved. There is no specific treatment.

The distinctive histologic pattern includes dilatation of dermal blood vessels and infiltration of homogeneous eosinophilic extracellular hyaline material along capillary walls and around sweat glands. Hyaline material in homogeneous bundles, diffusely arranged in the upper dermis, produces a thickened dermis. The infiltrates appear to contain both lipid and mucopolysaccharide substances. Symmetric ossification lateral to the sella turcica in the medial temporal region, identifiable roentgenographically, is pathognomonic but is not always present. The biochemical defect is unknown but may represent a lysosomal storage disorder caused by single or numerous enzyme defects. Alterations in the distribution of collagens I, III, IV, and V have also been described.

Macular Atrophy (Anetoderma).

Anetoderma is characterized by circumscribed areas of slack skin associated with loss of dermal substance. This disorder may have no associated underlying disease (primary macular atrophy) or may develop after an inflammatory skin condition (secondary macular atrophy) such as syphilis, lupus erythematosus, acne, varicella, leprosy, urticaria pigmentosa, or *Staphylococcus epidermidis* folliculitis. Lesions vary from 0.5–1?cm in diameter and, if inflammatory, may initially be erythematous. They subsequently become thin, wrinkled, and blue-white or hypopigmented. The lesions often protrude as small outpouchings that, on palpation, may be readily indented into the subcutaneous tissue because of the dermal atrophy. Sites of predilection include the trunk, thighs, upper arms, and less commonly the neck and face. Lesions remain unchanged for life; new lesions often continue to develop for years. There is no effective therapy, although some authorities have reported benefit from penicillin or pentoxifylline.

All types of macular atrophy show focal loss of elastic tissue on histopathologic examination, a change that is not recognizable unless special stains are used. The elastolysis may be due to release of elastase from inflammatory cells, such as macrophages, in contact with elastic fibers. Lesions of anetoderma occasionally resemble morphea, lichen sclerosus et atrophicus, focal dermal hypoplasia, atrophic scars, or end-stage lesions of chronic bullous dermatoses.

Cutis Laxa (Dermatomegaly, Generalized Elastolysis).

Cutis laxa is a congenital autosomal recessive or autosomal dominant disorder. Affected newborn infants may appear prematurely aged. When onset appears to occur during childhood or adulthood, the disorder is termed *acquired cutis laxa*. Cutis laxa has developed after a febrile illness, inflammatory skin diseases such as lupus erythematosus or erythema multiforme, amyloidosis, urticaria, angioedema, and hypersensitivity reactions to penicillin, and in infants born to women who were taking penicillamine.

CLINICAL MANIFESTATIONS.

There may be widespread folds of lax skin, or changes may be mild and limited in extent, resembling anetoderma. Patients with severe cutis laxa have characteristic

facial features, including an aged appearance with sagging jowls (bloodhound appearance), a hooked nose with everted nostrils, a short columella, a long upper lip, and everted lower eyelids. The skin is also lax elsewhere on the body and may resemble an ill-fitting suit (Fig. 649–2). Hyperelasticity and hypermobility of the joints are not present as they are in the Ehlers-Danlos syndrome. Many infants have a hoarse cry, probably as a

Figure 649-2 Pendulous folds of skin of an infant with cutis laxa. Note the long upper lip and upturned nose.

result of laxity of the vocal cords. Tensile strength of the skin is normal. Histologically, elastic tissue is reduced throughout the dermis, with fragmentation, distention, and clumping of the elastic fibers.

The dominant form of cutis laxa may develop at any age and is generally benign and mainly of cosmetic significance. When it presents in infancy, it may be associated with intrauterine growth retardation, ligamentous laxity, and delayed closure of fontanels. Affected males may be impotent and have infantile genitals and scanty body hair. Pulmonary emphysema and mild cardiovascular manifestations may also occur. In contrast, those with the more common recessive form of the disease are susceptible to severe complications, such as multiple hernias, rectal prolapse, diaphragmatic atony, diverticula of the gastrointestinal and genitourinary tracts, cor pulmonale, emphysema, pneumothoraces, peripheral pulmonary artery stenosis, and aortic dilatation. Characteristic facial features include downward slanting palpebral fissures; a broad, flat nose; and large ears. Skeletal anomalies, dental caries, growth retardation, and developmental delay also occur. Such patients often have a shortened life span.

The *pathogenesis* of cutis laxa is not well known. Abnormalities that have been described include excessive enzymatic destruction of elastin, decreased elastase inhibitor levels, and decreased elastin messenger RNA levels in fibroblasts.

Ehlers-Danlos Syndrome.

This is a group of genetically (usually autosomal dominant) heterogeneous connective tissue disorders. Affected children appear normal at birth, but skin hyperelasticity, fragility of the skin and blood vessels, delayed wound healing, and joint hypermobility develop. The essential defect is a quantitative deficiency of fibrillar collagen. Many patients have haploinsufficiency of the type V collagen (*COL5A1*) gene. Others may have mutations in collagen modifying genes such as a recessive form with tenascin-X deficiency. Ehlers-Danlos syndrome has been classified into 10 clinical forms.

I. GRAVIS TYPE.

This autosomal dominant disorder is characterized by premature birth caused by rupture of membranes, skin hyperelasticity and fragility, easy bruising, generalized and severe joint hypermobility, scoliosis, and mitral valve prolapse. Insignificant lacerations may form gaping wounds that leave broad, atrophic, papyraceous scars. Additional cutaneous manifestations include molluscoid pseudotumors over pressure points from accumulations of connective tissue. Life expectancy is not reduced.

II. MITIS TYPE.

This autosomal dominant form is characterized by mild skin and joint manifestations, the latter limited to hands and feet. The incidence of premature birth is not increased.

III. BENIGN, HYPERMOBILE TYPE.

This disorder has autosomal dominant inheritance and is manifested as generalized severe joint hypermobility and minimal skin manifestations. Osteoarthritis may develop prematurely.

IV. ECCHYMOTIC (SACK) TYPE.

This form may have autosomal dominant or autosomal recessive inheritance and shows the most pronounced dermal thinning of all; consequently, the underlying venous network is prominent. The skin has minimal hyperextensibility, and the joints are not hypermobile, except perhaps during childhood. Premature birth; extensive ecchymoses from trauma; a high incidence of keloids; rupture of the bowel, especially the colon; uterine rupture during pregnancy; rupture of the great vessels; dissecting aortic aneurysm; and stroke all contribute to the increased morbidity and shortened life span. Patients should be advised to avoid becoming pregnant, avoid activities such as trumpet playing that raise intracranial pressure as a result of a Valsalva maneuver, and minimize trauma to the skin. Defects that have been identified in affected patients include multiple deletions, exon skipping, or point mutations in the *COL3A1* gene of collagen III.

V. X-LINKED TYPE.

This is characterized by minimal joint hypermobility and skin hyperelasticity and moderate bruising, skin fragility, and scarring. The life span is normal. Lysyl oxidase was deficient in one family with this disorder.

VI. AUTOSOMAL RECESSIVE OCULAR TYPE.

These patients have joint hyperextensibility, hypotonia, kyphoscoliosis, fragile cornea, keratoconus, skin hyperelasticity, and fragile bones. There is a mutation affecting a collagen structural protein. Patients lack lysyl hydroxylase, a crucial enzyme in collagen biosynthesis that catalyzes the formation of hydroxylysine, which cross-links collagen. Prenatal diagnosis is available by measuring lysyl hydroxylase activity in amniocytes. The diagnosis can also be confirmed by detecting decreased lysyl hydroxylase activity in cultured dermal fibroblasts. This form may respond to oral ascorbic acid.

VII. ARTHROCHALASIS MULTIPLEX CONGENITA.

The A type is an autosomal recessive disorder characterized by short stature, marked joint hyperextensibility and dislocation, and moderate hyperelasticity and bruisability of skin. The defect is a failure of cleavage of the N-terminus propeptide of type I procollagen chains by procollagen N-proteinase caused by a mutation in the *COL1A1* gene that results in loss of the procollagen N-proteinase cleavage site. The B type, possibly autosomal dominant, is characterized by skin hyperelasticity and marked joint hypermobility. Mutations in the *COL1A2* gene cause loss of the N-proteinase cleavage site in the pro-a_2 (I) collagen chain. The type C disorder, known as dermatosparaxis, includes premature rupture of membranes; delayed closure of fontanels; skin fragility and laxity; easy bruisability; growth retardation; short limbs; umbilical hernia; and characteristic facies with micrognathia, jowls, and prominent, puffy eyelids. This disorder is due to a lack of N-proteinase activity.

VIII. PERIODONTITIS TYPE.

This autosomal dominant disorder is characterized by mild skin hyperelasticity, small joint hypermobility, bruisability, moderate cutaneous fragility, abnormal scarring, and severe periodontitis, leading to premature loss of teeth and alveolar bone. The proportion of type III collagen is reduced.

IX. X-LINKED RECESSIVE SKELETAL TYPE.

This form is characterized by occipital exostoses; widening and bowing of long bones at tendinous and ligamentous insertion sites; short, broad clavicles; mild skin hyperelasticity; bladder diverticula with spontaneous rupture; inguinal hernias; and chronic diarrhea. Defective copper transport results in low serum copper and ceruloplasm levels and diminished lysyl oxidase activity, an important copper-dependent enzyme required for collagen cross-linking. Menkes disease and X-linked cutis laxa also have

altered copper metabolism and defective collagen fibril formation; these may be examples of type IX Ehlers-Danlos syndrome.

X. DYSFIBRONECTINEMIC TYPE.

This autosomal recessive disorder is characterized by fibronectin-correctable failure of platelet aggregation, easy bruisability, joint hypermobility, and skin hyperextensibility.

DIFFERENTIAL DIAGNOSIS.

Ehlers-Danlos syndrome has been confused with cutis laxa, but the features of the two disorders differ considerably. The skin of patients with cutis laxa hangs in redundant folds, whereas the skin in Ehlers-Danlos syndrome is hyperextensible and snaps back into place when stretched. Because of the marked skin fragility in Ehlers-Danlos syndrome, minor trauma results in ecchymoses, bleeding, and poor healing with atrophic cigarette-paper scars, which are most prominent on the forehead and lower legs, and over pressure points. Surgical procedures are fraught with risk; dehiscence of wounds is common.

Pseudoxanthoma Elasticum.

This disorder of elastic tissue primarily affects the dermis, retina, and cardiovascular system.

CLINICAL MANIFESTATIONS.

Onset of skin manifestations often occurs during childhood, but the changes produced by early lesions are subtle and may not be recognized. The characteristic pebbly “plucked chicken skin” cutaneous lesions are asymptomatic, 1–2-mm yellow papules that are arranged in a linear or reticulated pattern or in confluent plaques. Preferred sites are the flexural neck, axillary and inguinal folds, umbilicus, thighs, and antecubital and popliteal fossas. As the lesions become more pronounced, the skin acquires a velvety texture and droops in lax, inelastic folds. The face is usually spared. Mucous membrane lesions may involve the lips, buccal cavity, rectum, and vagina. Involvement of the connective tissue of the media and intima of blood vessels, Bruch membrane of the eye, and endocardium or pericardium may result in visual disturbances, angioid streaks in Bruch membrane, intermittent claudication, cerebral and coronary occlusion, hypertension, and hemorrhage from the gastrointestinal tract, uterus, or mucosal surfaces. Affected women have an increased risk of miscarriage in the first trimester. Arterial involvement generally presents in adulthood, but claudication and angina have occurred in early childhood. There is no effective *treatment*, although laser therapy may help to prevent retinal hemorrhage.

PATHOLOGY AND PATHOGENESIS.

Histopathologic examination shows fragmented, swollen, and clumped elastic fibers in the middle and lower third of the dermis. The fibers stain positively for calcium. Collagen in the vicinity of the altered elastic fibers is reduced in amount and is split into small fibers. Aberrant calcification of the elastic fibers of the internal elastic lamina of arteries leads to narrowing of vessel lumina. It is hypothesized that an abnormal glycosaminoglycan is secreted by fibroblasts and deposited on the surface of elastic fibers, leading to fragmentation and calcification of the coated fibers. Candidate genes for pseudoxanthoma elasticum include the genes encoding elastin; the fibrillins, which form a microfibrillar coating around elastin; and lysyl oxidase, which catalyzes formation of the desmosines, the covalent interchain cross links that stabilize elastin polypeptides into their fibrillar structure. There are two autosomal dominant and two autosomal recessive forms of the disease. However, all affected patients tend to merge into a single classic phenotype involving the skin, eyes, and cardiovascular system, with considerable variability in expression of the disorder, particularly in the vascular and ophthalmologic complications.

Elastosis Perforans Serpiginosa.

This is an unusual skin disorder in which 1–3?mm, skin-colored, keratotic, firm papules tend to cluster in arcuate and annular patterns on the posterolateral neck and limbs and, occasionally, on the face and trunk. Onset usually occurs during childhood or adolescence. Histopathologically, a papule consists of a circumscribed area of epidermal hyperplasia that communicates with the underlying dermis by a narrow channel. Elastotic material is extruded from the channel. There is a great increase in the amount and size of elastic fibers in the upper dermis, particularly in the dermal papillae. The primary abnormality is probably in the dermal elastin, which provokes a cellular response that ultimately leads to extrusion of the abnormal elastic tissue. Approximately one third of cases occur in association with osteogenesis imperfecta, Marfan syndrome, pseudoxanthoma elasticum, Ehlers-Danlos syndrome, Rothmund-Thomson syndrome, and Down syndrome. It has also occurred in association with penicillamine therapy. Differential diagnosis includes tinea corporis, perforating granuloma annulare, reactive perforating collagenosis, lichen planus, creeping eruption, and porokeratosis of Mibelli. Treatment is ineffective; however, the lesions are asymptomatic and disappear spontaneously.

Reactive Perforating Collagenosis.

This usually presents in early childhood with small papules on the dorsal areas of the hands and forearms, elbows, knees, and sometimes face and trunk. The condition is often familial and may be inherited in an autosomal recessive pattern. Over a period of several weeks, the papules increase in size to 5–10?mm, become umbilicated, and develop a keratotic plug in the center. Individual lesions resolve spontaneously in 2–4 mo, leaving a hypopigmented macule or scar. Lesions may recur in crops; may undergo a linear Koebner reaction; and may form in response to cold temperatures or superficial trauma such as abrasions, insect bites, and acne lesions. Histopathologically, collagen in the papillary dermis is engulfed within a cup-shaped perforation in the epidermis. The central crater contains pyknotic inflammatory cells and keratinous debris. The process appears to represent transepidermal elimination of altered collagen. Topical retinoic acid may reduce the number of lesions.

Xanthomas.

See Chapter 75.3 .

Fabry Disease.

See Chapter 75.4 .

Mucopolysaccharidoses.

See Chapter 77 . In several of these disorders, thick, inelastic, rough skin, particularly on the extremities, and generalized hirsutism are characteristic but nonspecific features. Telangiectasias on the face, forearms, trunk, and legs have been observed in Scheie and Morquio syndromes. In some patients with Hunter syndrome, distinctive ivory-colored, firm papulonodules with a corrugated surface texture are grouped into symmetric plaques on the upper trunk, arms, and thighs. Onset of these unusual lesions occurs during the 1st decade of life, and spontaneous disappearance has been noted.

Mastocytosis.

Mastocytosis encompasses a spectrum of disorders that range from solitary cutaneous nodules to diffuse infiltration of skin associated with involvement of other organs (Box 649–1). All the disorders are characterized by aggregates of mast cells in the dermis. Mast cell growth factor, which can be secreted by keratinocytes, stimulates the proliferation of mast cells and increases the production of melanin by melanocytes. Mastocytosis may be due to altered cutaneous metabolism of mast cell growth factor and, thus, may represent a hyperplastic rather than a neoplastic disorder. Mutations in c-KIT are seen in pediatric onset mastocytosis with extracutaneous involvement.

CLINICAL MANIFESTATIONS.

Affected children can have intense pruritus. Systemic signs of histamine release, such as hypotension, syncope, headache, episodic flushing, tachycardia, wheezing, colic, and diarrhea, occur most frequently in the more severe types of mastocytosis. The local and systemic manifestations of the disease are due, at least partially, to release of histamine and heparin from mast cell granules; although heparin is present in significant amounts in mast cells, coagulation disturbances occur only rarely. The vasodilator prostaglandin D_2 or its

metabolite appears to exacerbate the flushing response. Serum trypase levels are often elevated.

Mastocytomas are solitary lesions 1–5?cm in diameter. Lesions may be present at birth or arise during early infancy at any site; the wrist, neck, and trunk are sites of predilection. The lesions may present as recurrent, evanescent wheals or bullae; in time, however, an infiltrated, rubbery, pink, yellow, or tan plaque develops at the site of whealing or blistering (Fig. 649–3*A*). The surface acquires a pebbly, orange peel-like texture, and hyperpigmentation may become prominent. Stroking or trauma to the nodule may result in urtication (Darier sign) as a result of local histamine release; rarely, systemic signs of histamine release become apparent. The differential diagnosis includes recurrent bullous impetigo, nevi, and juvenile xanthogranuloma. Mastocytomas usually involute spontaneously during early childhood; troublesome lesions can be excised and do not recur. Only rarely do multiple cutaneous lesions develop.

Urticaria pigmentosa is the most common form of mastocytosis and occurs primarily in infants and children. Lesions may be present at birth but more often erupt in crops during the first several months to 2 yr of age. In some cases, early bullous or urticarial lesions fade, only to recur at the same site, ultimately becoming fixed and hyperpigmented; in others, the initial lesions are hyperpigmented. Vesiculation usually abates by 2 yr of age. Individual lesions range in size from a few millimeters to

Figure 649-3 *A*, Solitary mastocytoma that is partially blistered. *B*, Hyperpigmented papular lesions of urticaria pigmentosa, some of which exhibit a surrounding flare. *C*, Infiltrated plaques of urticaria pigmentosa.

several centimeters and may be macular, papular, or nodular; they range in color from yellow-tan to chocolate brown and often have ill-defined borders (see Fig. 649–3*B*). Larger nodular lesions, like mastocytomas, may have a characteristic orange peel texture (see Fig. 649–3*C*). Lesions of urticaria pigmentosa may be sparse or numerous and are often symmetrically distributed. Palms, soles, and face are sometimes spared, as are the mucous membranes. The rapid appearance of erythema and whealing in response to vigorous stroking of a lesion can usually be elicited; dermographism of intervening normal skin is also common. Urticaria pigmentosa can be confused with drug eruptions, postinflammatory pigmentary change, juvenile xanthogranuloma, pigmented nevi, ephelides, xanthomas, chronic urticaria, insect bites, and bullous impetigo.

PROGNOSIS.

Spontaneous involution occurs in about 50% of patients by puberty; another 25% have partial resolution by adulthood. The incidence of systemic manifestations is very low.

Diffuse Cutaneous Mastocytosis.

This variant is characterized by diffuse involvement of the skin rather than discrete hyperpigmented lesions. Affected patients are usually normal at birth and develop features of the disorder after the first few months of life. Rarely, the condition may present with intense generalized pruritus in the absence of visible skin changes. The skin usually appears thickened and pink to yellow and may have a doughy feel and a texture resembling an orange peel. Surface changes are accentuated in flexural areas. Recurrent bullae, intractable pruritus, and flushing attacks are common, as is systemic involvement.

Telangiectasia macularis eruptiva perstans is another variant that consists of telangiectatic hyperpigmented macules that are usually localized to the trunk. These lesions do not urticate when stroked. This form of the disease is seen in adolescents and adults primarily.

Systemic Mastocytosis.

This disorder is marked by an abnormal increase in the number of mast cells in other than cutaneous tissues. It occurs in approximately 5–10% of patients with mastocytosis and is more common in adults than in children. Bone lesions may be silent but are detectable radiologically as osteoporotic or osteosclerotic areas, principally in the axial skeleton. Gastrointestinal tract involvement may produce diarrhea and steatorrhea. Mucosal infiltrates may be detectable by barium studies or by small bowel biopsy. Peptic ulcers also occur. Hepatosplenomegaly as a result of mast cell infiltrates and fibrosis has been described, as has mast cell proliferation in lymph nodes, kidneys, periadrenal fat, and bone marrow. Abnormalities in the peripheral blood, such as anemia, leukocytosis, and eosinophilia, are noted in approximately one third of patients.

TREATMENT.

Flushing can be precipitated by excessively hot baths, vigorous rubbing of the skin, and certain drugs, such as codeine, aspirin, morphine, atropine, ketorolac, alcohol, tubocurarine, iodine-containing radiographic dyes, and polymyxin B. Avoidance of these triggering factors is advisable. For patients who are symptomatic, oral antihistamines may be palliative. H_1 receptor antagonists (hydroxyzine) are the initial drugs of choice for systemic signs of histamine release. If H_1 antagonists are unsuccessful, H_2 receptor antagonists may be helpful in controlling pruritus or gastric hypersecretion. Oral mast cell-stabilizing agents, such as cromolyn sodium or ketotifen, may also be effective for diarrhea or abdominal cramping and some systemic symptoms such as headache or muscle pain.

Chapter 650 - Diseases of Subcutaneous Tissue

Diseases involving the subcutis are usually characterized by necrosis and/or inflammation; they may occur either as a primary event or as a secondary response to various stimuli or disease processes. Unfortunately, these disorders cannot all be distinguished by their histopathologic changes, which may merely reflect the stage of the lesion at the time of biopsy. The principal diagnostic criteria are the appearance and distribution of the lesions, associated symptoms, results of laboratory studies, and the natural history and exogenous provocative factors of these conditions.

Corticosteroid-Induced Atrophy.

Injection of a corticosteroid intradermally can produce deep atrophy accompanied by surface pigmentary changes and telangiectasia. These changes occur approximately 2 wk after injection and may last for months. The deltoid area is most susceptible to this complication (see Chapter 649).

Panniculitis.

Inflammation of fibrofatty subcutaneous tissue may primarily involve the fat lobule or, alternatively, the fibrous septum that compartmentalizes the fatty lobules. Lobular panniculitis that spares the subcutaneous vasculature includes poststeroid panniculitis, lupus erythematosus profundus, relapsing nodular nonsuppurative panniculitis *(Weber-Christian syndrome)*, pancreatic panniculitis, a_1 -antitrypsin deficiency, subcutaneous fat necrosis of the newborn, sclerema neonatorum, cold panniculitis, subcutaneous sarcoidosis, and factitial panniculitis. Lobar panniculitis with vasculitis occurs in erythema induratum and occasionally as a feature of Crohn disease (see Chapter 317.2). Inflammation predominantly within the septum, sparing the vasculature, may be seen in erythema nodosum, necrobiosis lipoidica, scleroderma (see Chapter 150), and subcutaneous granuloma annulare (see Chapter 649). Septal panniculitis that includes inflammation of the vessels is found primarily in leukocytoclastic vasculitis and polyarteritis nodosa (see Chapter 157.3).

Poststeroid panniculitis has been observed in children who received high-dose corticosteroids orally for relatively short periods, usually for rheumatic fever. Within 1–2 wk after discontinuation of the drug, multiple subcutaneous nodules may appear on the cheeks, trunk, and arms. Nodules range in size from 0.5–4?cm, are erythematous or skin colored, and may be pruritic. The mechanism of the inflammatory reaction in the fat is unknown. Treatment is unnecessary because the lesions remit spontaneously over a period of months without scarring.

Lupus erythematosus profundus (lupus erythematosus panniculitis) presents with one to several firm, well-defined plaques or nodules 1 to several centimeters in diameter, most commonly on the face, buttocks, or proximal extremities. This condition may occur in patients with systemic or discoid lupus erythematosus and may precede or follow the development of other

cutaneous lesions. The overlying skin is usually normal but may be erythematous, atrophic, poikilodermatous, or hyperkeratotic. Lesions may be painful and may ulcerate. On healing, a shallow depression generally remains; rarely, soft pink areas of anetoderma may result. The histopathologic changes are distinctive and may allow one to make the diagnosis in the absence of other cutaneous lesions of lupus erythematosus. The lupus band and antinuclear antibody test results are usually positive. Nodules tend to be persistent but may respond to antimalarials, oral or intralesional corticosteroids, or, in debilitating cases, immunosuppressive agents such as azathioprine or cyclophosphamide. Avoidance of sun exposure and trauma is also important.

a_1 -*Antitrypsin deficiency* may present with cellulitis-like areas or red, tender nodules on the trunk or proximal extremities (see Chapter 393.4). Nodules tend to ulcerate spontaneously and discharge an oily yellow fluid. Trauma is an inciting factor in some patients. Affected individuals have severe homozygous deficiency or rarely a partial deficiency of the protease inhibitor a_1 -antitrypsin, which inhibits trypsin activity and the activity of elastase, serine proteases, collagenase, factor VIII, and kallikrein. Accordingly, panniculitis may be associated with panacinar emphysema, noninfectious hepatitis, cirrhosis, persistent cutaneous vasculitis, cold-contact urticaria, or acquired angioedema. Diagnosis can be substantiated by a decreased level of serum a_1 -antitrypsin activity, although, because the protein behaves as an acute-phase reactant, the level may be elevated spuriously during an acute attack of pancreatitis. Some patients respond to dapsone or infusion of random-donor–derived a_1 -protease inhibitor concentrate.

Pancreatic panniculitis presents most commonly on the pretibial regions, thighs, or buttocks as tender, erythematous nodules that may be fluctuant and occasionally discharge a yellowish oily substance. It presents most often in males with alcoholism but may also occur in patients with pancreatitis as a result of cholelithiasis or abdominal trauma, with rupture of a pancreatic pseudocyst, with pancreatic ductal adenocarcinoma, or with pancreatic acinar cell carcinoma. Associated features may include arthropathy and synovitis, particularly in the ankles; eosinophilia; polyserositis; and painful osteolytic bone lesions with medullary necrosis. Microscopic changes consist of multiple foci of fat necrosis that contain ghost cells with thick, shadowy walls and no nuclei. A polymorphous inflammatory infiltrate surrounds the areas of fat necrosis. Pathogenesis of the panniculitis appears to be multifactorial, involving liberation of the lipolytic enzymes lipase, trypsin, and amylase into the circulation, causing adipocyte membrane damage and intracellular lipolysis. There is no correlation, however, between the occurrence of pancreatitis and the

serum concentration of pancreatic enzymes.

Subcutaneous fat necrosis is an inflammatory disorder of adipose tissue that occurs primarily in the first 4 wk of life in full-term or post-term infants. Affected infants may have a history of perinatal asphyxia or a difficult labor and delivery. Typical lesions are asymptomatic, rubbery to firm, erythematous to violaceous plaques or nodules on the cheeks, buttocks, back, thighs, or upper arms (Fig. 650–1). Lesions may be focal or extensive and are generally asymptomatic, although they may be tender during the acute phase. Histopathologic changes are diagnostic and consist of necrosis of fat; a granulomatous cellular infiltrate composed of lymphocytes, histiocytes, multinucleated giant cells, and fibroblasts; and radially arranged clefts of crystalline triglyceride within fat cells and multinucleated giant cells. Calcium deposits are commonly found in areas of fat necrosis. Subcutaneous fat necrosis in infants may be due to ischemic injury under various circumstances such as maternal preeclampsia, birth trauma, asphyxia, and prolonged hypothermia; in many affected infants, however, no provocative factors are identified. Susceptibility has been attributed to differences in composition between the

Figure 650-1 Red-purple nodular infiltration of skin of back caused by subcutaneous fat necrosis.

subcutaneous tissue of young infants and that of older infants, children, and adults. Neonatal fat solidifies at a relatively high temperature because of its relatively greater concentration of high melting point saturated fatty acids such as palmitic and stearic acids.

Uncomplicated lesions involute spontaneously within weeks to months, usually without scarring or atrophy. Calcium deposition may occasionally occur within areas of fat necrosis, and this may sometimes result in rupture and drainage of liquid material. A rare but potentially life-threatening complication is *hypercalcemia*. This presents at 1–6 mo of age with lethargy, poor feeding, vomiting, failure to thrive, irritability, seizures, shortening of the QT interval, or renal failure. The origin of the hypercalcemia is unknown but is postulated to involve excess bone resorption through elevated levels of prostaglandin E or increased intestinal calcium uptake by unregulated extrarenal production of 1,25 dihydroxyvitamin D by macrophages in the granulomatous infiltrate. Subcutaneous fat necrosis can be confused with sclerema neonatorum, panniculitis, cellulitis, or hematoma. Because the lesions are self-limited, therapy is not required for uncomplicated cases. Needle aspiration of fluctuant lesions may prevent rupture and subsequent scarring. Treatment of hypercalcemia is aimed at enhancing renal calcium excretion by hydration and furosemide administration and at limiting dietary calcium and vitamin D intake. Reduction of intestinal calcium absorption and alteration of vitamin D metabolism may be accomplished by administration of corticosteroids.

Sclerema neonatorum is an uncommon disorder of adipose tissue that presents abruptly in preterm, gravely ill infants as

diffuse, yellowish-white woody induration of the skin. Affected skin becomes stony in consistency, cold, and nonpitting. The face assumes a masklike expression, and joint mobility may be compromised because of inflexibility of the skin. Histopathologic changes in sclerema neonatorum consist of an increase in the size of fat cells and an increase in the width of the fibrous connective tissue septa. In contrast to subcutaneous fat necrosis, with which it is most apt to be confused, fat necrosis, inflammation, giant cells, and calcium crystals are generally absent. Sclerema neonatorum almost always is associated with serious illness, such as sepsis, congenital heart disease, multiple congenital anomalies, or hypothermia. The appearance of sclerema in a sick infant should be regarded as an ominous prognostic sign. The outcome depends on the response of the underlying disorder to treatment.

Cold panniculitis may result in localized lesions in infants after prolonged cold exposure, especially on the cheeks, or after prolonged application of a cold object such as an ice cube, ice bag, or Popsicle to any area of the skin. Erythematous to bluish, indurated, ill-defined plaques or nodules arise within hours to a couple days of exposure, persist for 2–3 wk, and heal without residua. Recurrence of the lesions is common, however, thus emphasizing the importance of parental education in treating these patients. Histopathologic examination reveals an infiltrate of lymphoid and histiocytic cells around blood vessels at the dermal-subdermal junction; by the 3rd day, some of the fat cells in the subcutis may have ruptured and coalesced into cystic structures. Cold panniculitis may be confused with facial cellulitis caused by *Haemophilus influenzae* type b. Unlike the situation with buccal cellulitis, however, the area may be cold to the touch, and the patient is afebrile. Chilblains (pernio), a condition of acute or chronic cold injury, is characterized by localized symmetric erythematous to purplish edematous plaques and nodules in areas exposed to cold, typically acral areas (distal hands and feet, ears, face) (see Chapter 63). Lesions develop 12–24?hr after cold exposure and may be associated with itching, burning, or pain. Blister formation and ulceration are rare. Vasospasm of arterioles due to cold exposure with resultant hypoxemia and localized perivascular mononuclear inflammation appears to be responsible for the disease. Frostbite due to extreme cold exposure is painful and histopathologically involves the epidermis, dermis, and subcutaneous fat. The pathogenic mechanism of cold panniculitis may be similar to that of subcutaneous fat necrosis, involving an increased propensity of fat to solidify in infants compared with that in older children and adults as a result of the higher percentage of saturated fatty acids in the subcutaneous fat of infants.

Factitial panniculitis results from subcutaneous injection by self or proxy of a foreign substance, the most common types of which include organic materials such as milk or feces; drugs such as the opiates or pentazocine; oily materials such as mineral oil or paraffin; and the synthetic polymer povidone. Indurated plaques, ulcers, or nodules that liquefy and drain may be noted clinically. The histopathologic picture is variable, depending on the injected substance, but may include the presence of birefringent crystals, oil cysts surrounded by fibrosis and inflammation, and an acute inflammatory reaction with fat necrosis. Vessels are characteristically spared.

Lipodystrophy.

Several rare conditions are associated with loss of fatty tissue in a partial or generalized distribution.

Partial lipodystrophy occurs more commonly in females than in males and generally

begins during the 1st decade of life. There is gradual symmetric loss of subcutaneous tissue. Although the sites of loss are heterogeneous, loss of fat may occur primarily on the trunk and extremities, sparing the face; on the extremities, sparing both the face and trunk; or on the extremities and buttocks. The most common variant involves loss of fat from the face and the upper half of the body, resulting in a cadaverous facies and marked disproportion between the upper and lower halves of the body (*Weir-Mitchell type*). In some cases, there is a concurrent hypertrophy of the subcutaneous fat of the lower part of the body (*Laignel-Lavastine* and *Viard types*); others have hemilipodystrophy involving one half of the face or body. Loss of adipose tissue is not preceded by an inflammatory phase, and histopathologic examination reveals only absence of subcutaneous fat. Some patients have had hypocomplementemia (i.e., low C3) and associated renal disease, particularly progressive membranous mesangiocapillary glomerulonephritis, disordered glucose metabolism, or abnormal serum lipid profiles. The cause of the disorder is not understood, and there is no effective treatment, although dietary restrictions of fats and carbohydrates may be prudent. *Generalized lipodystrophy* may be congenital (*Berardinelli-Seip syndrome*) or acquired (*Seip-Lawrence syndrome*).

Congenital generalized lipodystrophy is a progressive multisystem disorder inherited as an autosomal recessive trait. The earliest manifestation is generalized loss of subcutaneous and visceral fat; it may be evident at birth or may occur during infancy. Associated cutaneous changes include prominent superficial veins, hirsutism, abundant curly scalp hair, and acanthosis nigricans. Patients have an anabolic syndrome with a voracious appetite; accelerated skeletal growth, resulting in tall stature; skeletal sclerosis; enlarged joints, especially of the hands and feet; accelerated muscle growth, resulting in a protuberant abdomen; and hypertrophic cardiomyopathy. Precocious enlargement of the genitals and mental deficiency and hemiplegia are seen commonly. Insulin resistance is present from birth. Hyperlipidemia, hyperinsulinism, and insulin-resistant nonketotic diabetes mellitus develop gradually and are reflected by increasing hepatomegaly caused by fatty infiltration and cirrhosis. Serum levels of growth hormone may be normal, but its secretion in response to stimuli may be disturbed. Hypothalamic releasing factors that are not ordinarily found in plasma have been identified in affected patients and suggest a lack of hypothalamic regulation. The underlying problem may be an insulin receptor or postreceptor defect. The acquired form is preceded by an undefined illness or an infection. Pathogenesis appears to involve autoimmune destruction of adipose tissue that results secondarily in an anabolic syndrome with insulin-resistant diabetes. When fat loss becomes generalized, the disease resembles the congenital form, although the anabolic features tend to be less striking. Pimozide, a selective dopamine blocker, or fenfluramine, a serotonergic agonist, may be helpful to some patients. Control of the diabetes with insulin is difficult to achieve, does not affect the course of the lipodystrophy, and is considered contraindicated by some authorities. Dietary fat regulation of energy consumption is the most important and efficacious intervention.

Localized lipoatrophy is an idiopathic condition that presents as annular atrophy at the ankles, a bandlike semicircular depression 2–4?cm in diameter on the thighs or, rarely, on the abdomen and upper groin as a centrifugally spreading, bluish, depressed plaque with an erythematous margin. It occurs predominantly in Japanese children.

Insulin lipoatrophy usually occurs approximately 6 mo–2 yr after initiation of relatively high doses of insulin. A dimple or well-circumscribed depression at the site of injection is typically seen, although loss of fat may extend beyond the site of injection, leading to an extensive, depressed plaque. Biopsy reveals a marked decrease or absence of subcutaneous tissue, without inflammation or fibrosis. In some patients, hypertrophy occurs clinically. In these cases, the mid-dermal collagen is replaced by hypertrophic fat cells on histopathologic sections. The mechanism of insulin lipoatrophy may be cross reaction of insulin antibodies with fat cells; the incidence of this condition has decreased since the implementation of widespread use of highly purified insulins. Lesions may also be prevented by frequent alteration of injection sites.

Chapter 651 - Disorders of the Sweat Glands

Eccrine glands are found over nearly the entire skin surface and provide the primary means, through evaporation of the water in sweat, for cooling the body. These glands have no anatomic relationship to hair follicles and secrete a relatively large amount of odorless aqueous sweat. In contrast, apocrine glands are limited in distribution to the axillae, anogenital skin, mammary glands, ceruminous glands of the ear, Moll glands in the eyelid, and selected areas of the face and scalp. The apocrine gland duct enters the pilosebaceous follicle at the level of the infundibulum and secretes a small amount of a complex, viscous fluid that, on alteration by microorganisms, produces a distinctive body odor. Some disorders of these two sweat glands are similar pathogenetically, whereas others are unique to a given gland.

Anhidrosis.

Neuropathic anhidrosis results from a disturbance in the neural pathway from the control center in the brain to the peripheral efferent nerve fibers that activate sweating. Disorders in this category, which are characterized by generalized anhidrosis, include tumors of the hypothalamus and damage to the floor of the third ventricle. Pontine or medullary lesions may produce anhidrosis of the ipsilateral face or neck and ipsilateral or contralateral anhidrosis of the rest of the body. Peripheral or segmental neuropathies, caused by leprosy, amyloidosis, diabetes mellitus, alcoholic neuritis, or syringomyelia, may be associated with anhidrosis of the innervated skin. Various autonomic disorders are also associated with altered eccrine sweat gland function.

At the *level of the sweat gland,* drugs such as the anticholinergics atropine and scopolamine may paralyze the sweat glands. Acute intoxication with barbiturates or diazepam has produced necrosis of sweat glands, resulting in anhidrosis with or without erythema and bullae. Eccrine glands are largely absent throughout the skin or are present in a localized area among patients with anhidrotic ectodermal dysplasia or localized congenital absence of sweat glands, respectively. Infiltrative or destructive disorders that may produce atrophy of sweat glands by pressure or scarring include scleroderma, acrodermatitis chronica atrophicans, radiodermatitis, burns, Sjögren disease, multiple myeloma, and lymphoma. Obstruction of sweat glands may occur in miliaria and in a number of inflammatory and hyperkeratotic disorders such as the ichthyoses, psoriasis, lichen planus, pemphigus, porokeratosis, atopic dermatitis, and seborrheic dermatitis. Occlusion of the sweat pore may also occur with the topical agents aluminum and zirconium salts, formaldehyde, or glutaraldehyde.

Diverse *disorders that are associated with anhidrosis by unknown mechanisms* include dehydration; toxic overdose with lead, arsenic, thallium, fluorine, or morphine; uremia; cirrhosis; endocrine disorders such as Addison disease, diabetes mellitus, diabetes insipidus, or hyperthyroidism; and inherited conditions such as Fabry disease, Franceschetti-Jadassohn syndrome, which combines features of incontinentia pigmenti and anhidrotic ectodermal dysplasia, and familial anhidrosis with neurolabyrinthitis.

Whereas anhidrosis may be complete, in many cases, what appears clinically to be anhidrosis is actually *hypohidrosis* caused by anhidrosis of many but not all eccrine glands. Compensatory, localized *hyperhidrosis* of the remaining functional sweat glands may occur, particularly in diabetes mellitus and miliaria. The primary complication of anhidrosis is hyperthermia, seen primarily in anhidrotic ectodermal dysplasia or in otherwise normal preterm or full-term *neonates* who have immature eccrine glands.

Hyperhidrosis.

The numerous disorders that may be associated with increased production of eccrine sweat may also be classified into those with neural mechanisms involving an abnormality in the pathway from the neural regulatory centers to the sweat gland and those that are non-neurally mediated by direct effects on the sweat glands (Box 651–1). Excessive sweating of the palms and soles in response to emotional stimuli (volar hyperhidrosis) may respond to 10% glutaraldehyde soaks, 20% aluminum chloride in anhydrous ethanol applied under occlusion for several hours, iontophoretic therapy with anticholinergics, or in severe, refractory cases, cervicothoracic or lumbar sympathectomy. Axillary hyperhidrosis does not respond to topical glutaraldehyde or salts of aluminum, zirconium, or zinc. Aluminum chloride (Drysol) applied to the axillae at bedtime under occlusion, aided, if necessary, by oral administration of an anticholinergic agent such as glycopyrrolate, may produce a prompt and significant reduction in sweating. Local injection of botulism toxin may also be effective. Cervicothoracic sympathectomy or selective surgical removal of the most highly

sudoriferous eccrine glands in the axillae may be effective in refractory cases.

Miliaria.

This results from retention of sweat in occluded eccrine sweat ducts as a result of a keratinous plug in the sweat duct. Retrograde pressure may result in rupture of the duct and leakage of sweat into the epidermis and/or the dermis. The eruption is most often induced by hot, humid weather, but it may also be caused by high fever. Infants who are dressed too warmly may develop this eruption indoors, even during the winter.

In *miliaria crystallina,* asymptomatic, noninflammatory, pinpoint clear vesicles may suddenly erupt in profusion over large areas of the body surface, leaving brawny desquamation on healing (Fig. 651–1). The clarity of the fluid, superficiality of the vesicles, and absence of inflammation permit differentiation from other blistering disorders. This type of miliaria occurs most frequently in newborn infants because of the relative immaturity and delayed patency of the sweat duct and the tendency for infants to be nursed in relatively warm, humid conditions. It may also occur in older patients with hyperpyrexia. Histopathologically, an intracorneal or subcorneal vesicle is seen in communication with the sweat duct.

Miliaria rubra is a less superficial eruption characterized by erythematous, minute papulovesicles that may impart a prickling sensation. The lesions are usually localized to sites of occlusion or to flexural areas, such as the neck, groin, and axillae, where friction may have a role in their pathogenesis. Involved skin may become macerated and eroded. This lesion may be confused with or superimposed on other diaper area eruptions, including candidosis and folliculitis; lesions of miliaria rubra, however, are extrafollicular. Histopathologically, one sees focal areas of spongiosis and spongiotic vesicle formation in close proximity to sweat ducts that generally contain a keratinous plug. The keratinous plug does not form, however, until the later stages of the disease and therefore does not appear to be the primary cause of sweat duct obstruction. The initial obstruction is postulated to be due to swelling of the ductal epidermal cells, perhaps from imbibition of water. Miliaria rubra is generally reversible. Supplemental vitamin C may help restore normal sweating in refractory cases. Prophylactic use of antibacterial agents may prevent development of miliaria rubra. Repeated attacks of miliaria rubra may lead to *miliaria profunda,* which is

Figure 651-1 Superficial clear vesicles of miliaria crystallina in a patient with hyperpyrexia and lymphoma.

due to rupture of the sweat duct deeper in the skin at the level of the dermoepidermal junction. Severe, extensive miliaria rubra or miliaria profunda may result in disturbance of heat regulation. Lesions of miliaria rubra may become infected, particularly in malnourished or debilitated infants, leading to development of periporitis staphylogenes, which involves extension of the process from the sweat duct into the sweat gland.

All forms of miliaria respond dramatically to cooling the patient by regulation of environmental temperatures and by removal of excessive clothing; administration of antipyretics is also beneficial to patients with fever. Topical agents are usually ineffective and may exacerbate the eruption.

Bromhidrosis.

The excessive odor that characterizes bromhidrosis may result from alteration of either apocrine or eccrine sweat. Apocrine bromhidrosis develops after puberty as a result of the formation of short-chain fatty acids and ammonia by the action of anaerobic diphtheroids on axillary apocrine sweat. Treatments that may be helpful include cleansing with germicidal soaps; topical application of aluminum, zirconium, or zinc salts or gentamicin cream, all of which have antibacterial action; and axillary shaving. Eccrine bromhidrosis is caused by microbiologic degradation of stratum corneum that has become softened by excessive eccrine sweat. The soles of the feet and the intertriginous areas are the primary affected sites. Hyperhidrosis, warm weather, obesity, intertrigo, and diabetes mellitus are predisposing factors. In addition to local measures, oral anticholinergic drugs such as propantheline (Pro-Banthine) may decrease eccrine sweating but do not alter apocrine gland secretion. Topical aluminum chloride preparations such as Drysol are particularly useful for plantar eccrine bromhidrosis.

Hidradenitis Suppurativa.

This is a chronic, inflammatory, suppurative disorder of the apocrine glands in the axillae, the anogenital area, and occasionally the scalp, posterior aspect of the ears, female breasts, and periumbilical area. Onset of clinical manifestations, sometimes preceded by pruritus or discomfort, usually occurs during puberty or early adulthood. Solitary or multiple painful erythematous nodules, deep abscesses, and contracted scars are sharply confined to areas of skin containing apocrine glands. When the disease is severe and chronic, sinus tracts, ulcers, and thick, linear fibrotic bands develop. Hidradenitis suppurativa tends to persist for many years, punctuated by relapses and partial remissions. Complications include cellulitis, ulceration, and burrowing abscesses that may perforate adjacent structures, forming fistulas to the urethra, bladder, rectum, or peritoneum. Episodic inflammatory arthritis develops in some patients. A minority of patients have the follicular occlusion triad, which includes acne and perifolliculitis capitis. Early lesions are often mistaken for infected epidermal cysts, furuncles, scrofuloderma, actinomycosis, cat-scratch disease, granuloma inguinale, or lymphogranuloma venereum. Sharp localization to areas of the body that bear apocrine glands, however, should suggest hidradenitis. When involvement is limited to the anogenital region, the condition may be difficult to distinguish from Crohn disease and may coexist with it.

Histopathologically, early lesions are characterized by a keratinous plug in the apocrine duct or hair follicle orifice and by cystic distention of the follicle. The process generally but not necessarily extends into the apocrine gland. Later changes include inflammation within and around apocrine glands and the presence of groups of cocci within apocrine glands and in the adjacent dermis. Skin appendages may become obliterated by scarring. The disease is probably initiated by plugging of apocrine gland ducts with keratinous debris. Bacterial infection, particularly with *Staphylococcus aureus, Streptococcus milleri, Escherichia coli,* and possibly anaerobic streptococci, appears to be important in the progressive dilatation below the obstruction, leading to rupture of the duct, inflammation, sinus tract formation, and destructive scarring. Pathogenesis of hidradenitis

suppurativa is controversial, but it appears to be an androgen-dependent condition.

Patients should be counseled to avoid tight-fitting clothes, because occlusion may exacerbate the condition. *Treatment* with topical antibiotic agents such as chlorhexidine, erythromycin, or clindamycin or with topical retinoids may be effective in early, indolent disease. Systemic antibiotics, chosen on the basis of bacterial culture (usually staphylococcal and streptococcal pathogens) and sensitivity tests, should be administered in the acute phase. Empirical therapy may be initiated with tetracycline, doxycycline, or minocycline if the patient is 8 yr or older; clindamycin and cephalosporins also are effective. Some patients require long-term treatment with tetracycline or erythromycin. Intralesional triamcinolone acetonide (5–10?mg/mL) is often helpful in early disease. The addition of prednisone, 40–60?mg/day for 7–10 days, tapering gradually as inflammation subsides, to the regimen of patients who respond poorly to antibiotics may decrease fibrosis and scarring. Oral contraceptive agents, which contain a high estrogen-to-progesterone ratio and low androgenicity of the progesterone, or oral retinoids may be helpful in some patients. Warm compresses encourage spontaneous rupture of abscesses; those that are “pointing” should be incised and drained. Ultimately, surgical measures may be required for control or cure.

Fox-Fordyce Disease.

This disease is most common in females and presents during puberty or the 3rd decade of life with pruritus in the axillae and, occasionally, in the anogenital region and around the breasts. Pruritus is exacerbated by emotional stress and stimuli that induce apocrine sweating. Skin-colored to slightly hyperpigmented dome-shaped follicular papules develop in the pruritic areas. Histopathologically, one sees keratinous plugging of the distal apocrine duct, rupture of the intraepidermal portion of the apocrine duct, paraductal microvesicle formation, and paraductal acanthosis. The condition generally remits during pregnancy, particularly in the third trimester. Oral contraceptive pills and topical corticosteroids or retinoic acid may help some patients.

Chapter 652 - Disorders of Hair

Disorders of hair in infants and children may be due to intrinsic disturbances of hair growth, underlying biochemical or metabolic defects, inflammatory dermatoses, or structural anomalies of the hair shaft. Excessive and abnormal hair growth is referred to as hypertrichosis or hirsutism. Hypertrichosis is excessive hair growth at inappropriate locations; hirsutism is an androgen-dependent male pattern of hair growth in women. Hypotrichosis is deficient hair growth, and hair loss, partial or complete, is called alopecia. Alopecia may be classified as nonscarring or scarring; the latter type is rare in children and, if present, is most often due to prolonged or untreated inflammatory conditions such as pyoderma or tinea capitis.

Hypertrichosis

Hypertrichosis is rare in children and may be localized or generalized and permanent or transient. Hypertrichosis has many causes, some of which are listed in Box 652–1
.

Box 652-1. Causes of and Conditions Associated with Hypertrichosis

INTRINSIC FACTORS

Racial and familial forms such as hairy ears, hairy elbows, intraphalangeal hair, or generaslized hirsutism

EXTRINSIC FACTORS

CONGENITAL AND GENETIC DISORDERS

Hypertrichosis lanuginosa, mucopolysaccharidosis, leprechaunism, congenital generalized lipodystrophy, de Lange syndrome, trisomy 18, Rubinstein-Taybi syndrome, Bloom syndrome, congenital hemihypertrophy, gingival fibromatosis with hypertrichosis, Winchester syndrome, lipoatrophic diabetes (Lawrence-Seip syndrome), fetal hydantoin syndrome, fetal alcohol syndrome, congenital erythropoietic or variegate porphyria (sun-exposed areas), porphyria cutanea tarda (sun-exposed areas), Cowden syndrome, Seckel syndrome, Gorlin syndrome, partial trisomy 3?q, Ambra syndrome

HYPOTRICHOSIS AND ALOPECIA

Some of the disorders associated with hypotrichosis and alopecia are listed in Box 652–2 . True alopecia is rarely congenital; it is more often related to an inflammatory dermatosis, mechanical factors, drug ingestion, infection, endocrinopathy, nutritional disturbance, or disturbance of the hair cycle. Any inflammatory condition of the scalp, such as atopic dermatitis or seborrheic dermatitis, if severe enough, may result in partial alopecia; hair growth returns to normal if the underlying condition is treated successfully, unless the hair follicle has been permanently damaged.

Telogen Effluvium.

Telogen effluvium presents with sudden loss of large amounts of hair, often with brushing, combing, and washing of hair. Diffuse loss of scalp hair occurs from premature conversion of growing, or anagen, hairs, which normally constitute 80–90% of hairs, to resting, or telogen, hairs. Hair loss is noted 6 wk to 3 mo after the precipitating cause, which may include childbirth; a febrile episode; surgery; acute blood loss, including blood donation; sudden severe weight loss;

discontinuation of high-dose corticosteroids or oral contraceptives; and psychiatric stress. Telogen effluvium also accounts for the loss of hair by infants during the first few months of life; friction from bed sheets, particularly in infants with pruritic, atopic skin, may exacerbate the problem. There is no inflammatory reaction; the hair follicles remain intact, and telogen bulbs can be demonstrated microscopically on shed hairs. Because more than 50% of the scalp hair is rarely involved, alopecia is usually not severe. Parents should be reassured that normal hair growth will return within approximately 6 mo.

Toxic Alopecia (Anagen Effluvium).

Anagen effluvium is an acute, severe, diffuse inhibition of growth of anagen follicles, resulting

bullosa, ectodermal dysplasias, ichthyoses, loose anagen hair

Diffuse alopecia of endocrine origin: hypopituitarism, hypothyroidism, hypoparathyroidism, hyperthyroidism, diabetes mellitus

Alopecia of nutritional origin: marasmus, kwashiorkor, iron deficiency, zinc deficiency (acrodermatitis enteropathica), gluten-sensitive enteropathy, essential fatty acid deficiency, biotinidase deficiency

Disturbances of the hair cycle: telogen effluvium

Toxic alopecia: anagen effluvium

Autoimmune alopecia: alopecia areata

Traumatic alopecia: traction alopecia, trichotillomania

Cicatricial alopecia: lupus erythematosus, lichen planus pilaris, pseudopelade, scleroderma, dermatomyositis, infection (kerion, favus, tuberculosis, syphilis, folliculitis, leishmaniasis, herpes zoster, varicella), acne keloidalis, follicular mucinosis, cicatricial pemphigoid, lichen sclerosus et atrophicus, sarcoidosis

Hair shaft abnormalities: monilethrix, pili annulati, pili torti, trichorrhexis invaginata, trichorrhexis nodosa, woolly hair syndrome, Menkes disease, trichothiodystrophy, trichodento-osseous syndrome, trichorhinophalangeal syndrome, uncombable hair syndrome (spun glass hair, pili trianguli et canaliculi)

in loss of greater than 80–90% of scalp hair. Hairs become dystrophic, and the hair shaft breaks at the narrowed segment. Loss is diffuse, rapid (1–3 wk after

treatment), and temporary, as regrowth occurs after the offending agent is discontinued. Causes of anagen effluvium include radiation; cancer chemotherapeutic agents such as antimetabolites, alkylating agents, and mitotic inhibitors; thallium; thiouracil; heparin; the coumarins; boric acid; and hypervitaminosis A.

Traction Alopecia (Marginal or Traumatic Alopecia).

Traction alopecia is due to trauma to hair follicles by tight braids or ponytails, headbands, rubber bands, curlers, and rollers (Fig. 652–1*A*). Broken hairs and inflammatory follicular papules in circumscribed patches at the scalp margins are characteristic and may be subtended by regional lymphadenopathy. Children and parents must be encouraged to avoid devices that cause trauma to the hair and, if necessary, to alter the hair style. Otherwise, scarring of hair follicles may occur.

Trichotillomania.

Compulsive pulling, twisting, and breaking of hair produces irregular areas of incomplete hair loss, most often on the crown and in the occipital and parietal areas of the scalp (see Fig. 652–1*B*). Occasionally, eyebrows, eyelashes, and body hair are traumatized. Some plaques of alopecia may have a linear outline. The hairs remaining within the areas of loss are of various lengths and are typically blunt tipped because of breakage. The scalp appears normal, although chronic folliculitis may also occur. Trichophagy, resulting in trichobezoars, may complicate this disorder. The lifetime occurrence is 3% in girls and 1% in boys.

The *diagnosis* of trichotillomania is often difficult and may require biopsy confirmation. The *Diagnostic and Statistical Manual of Mental Disorders* diagnostic criteria include visible hair loss attributable to pulling; mounting tension preceding hair pulling; gratification or release of tension after hair pulling; and absence of hair pulling attributable to hallucinations, delusions, or an inflammatory skin condition. Histologic changes include coexistent normal and damaged follicles, perifollicular hemorrhage, atrophy of some follicles, and catagen transformation of hair. In late stages, perifollicular fibrosis may occur. Long-term repeated trauma may result in irreversible damage and permanent alopecia. Tinea capitis and alopecia areata must be considered in the differential diagnosis.

Trichotillomania is closely related to, and may be an expression of, obsessive-compulsive disorder in some children; in others, it is a benign habit disorder. *Treatment* of concurrent thumb sucking may be effective in the latter children. When trichotillomania occurs secondary to obsessive-compulsive disorder, clomipramine, fluoxetine, or trazodone may be helpful, particularly when combined with behavioral interventions.

Alopecia Areata.

Alopecia areata is characterized by rapid and complete loss of hair in round or oval patches on the scalp (see Fig. 652–1*C*) and on other body sites. In *alopecia totalis*, all the scalp hair is lost; *alopecia universalis* involves all body and scalp hair. The lifetime incidence of alopecia areata is 1% of the population; approximately 60% of patients are younger than 20 yr of age.

CLINICAL MANIFESTATIONS.

Peripheral spread and confluence of plaques of alopecia areata often result in bizarre patterns. At the margin of active patches, the hairs can often be extracted with gentle traction and, on examination, demonstrate an attenuated or catagen bulb at the termination of a tapered, poorly pigmented shaft (i.e., exclamation hair). The skin within the plaques of hair loss appears normal. A perifollicular infiltrate of inflammatory round cells is found in biopsy specimens from active areas. In the chronic stages, the number of telogen hairs is increased, the diameter of hair fibers is reduced, and trichodystrophies such as trichorrhexis nodosa and trichomalacia may be found. Alopecia areata is associated with atopy; nail changes such as pits, ridges, opacification, serration of the free nail edge, dystrophy, and a red lunula; cataracts or lens opacification; and autoimmune diseases such as Hashimoto thyroiditis, Addison disease, pernicious anemia, ulcerative colitis, myasthenia gravis, collagen vascular diseases, and vitiligo. An increased incidence of alopecia areata has been reported in patients with Down syndrome (5–10%).

ETIOLOGY.

The cause of alopecia areata is unknown. Emotional factors and stress have been suggested as triggering factors, but supportive evidence is tenuous. About 10–20% of patients have a family history of alopecia areata; the estimated risk for first-degree relatives is 6%. Inheritance is thought to be autosomal dominant with variable penetrance. The infrequent but striking association with autoimmune diseases has suggested an autoimmune pathogenesis. Some patients have serum antibodies to thyroglobulin, parietal cells, and adrenal gland, and autoantibodies to hair follicle antigens has been demonstrated. Interleukin 1 alpha (IL-1a) and IL-1ß) are important inhibitors of hair growth in vitro, and genes of the IL-1 cluster are candidate genes for alopecia areata.

DIFFERENTIAL DIAGNOSIS AND PROGNOSIS.

Tinea capitis, seborrheic dermatitis, trichotillomania, traumatic alopecia, and lupus erythematosus should be considered. The course is unpredictable, but spontaneous resolution within 6–12 mo is usual, particularly when relatively small, stable patches of alopecia are present. Recurrences, however, are common. In general, onset at a young age, extensive or prolonged hair loss, numerous episodes, and associated atrophy are poor prognostic signs. Alopecia universalis, totalis, and *ophiasis*, a type of alopecia areata in which hair loss is circumferential, are also less likely to resolve.

TREATMENT.

This is difficult to evaluate because the course is erratic and unpredictable. The use of high-potency topical

Figure 652-1 *A*, Marginal alopecia caused by traction. *B*, Partial alopecia with bizarre pattern typical of trichotillomania. *C*, Multiple areas of alopecia characteristic of alopecia areata. The scalp is normal.

fluorinated corticosteroids with occlusion at night is effective in some patients. Intradermal injections of steroid may also stimulate hair growth locally, but this mode of treatment is impractical in young children or in those with extensive hair loss. Systemic corticosteroid therapy has, on occasion, been associated with good results; however, the permanence of cure is questionable, and the side effects are a serious deterrent. Additional therapies that are sometimes effective include short-contact anthralin, topical minoxidil, and contact sensitization with squaric acid dibutylester or diphencyprone. Psoralen and ultraviolet A phototherapy may also be effective but has limited applicability in children. In general, parents and patients can be reassured that spontaneous remission usually occurs. New hair growth may initially be of finer caliber and lighter color, but replacement by normal terminal hair can be expected.

Structural Defects of Hair.

Structural defects of the hair shaft may be congenital, reflect known biochemical aberrations, or relate to damaging grooming practices. All the defects can be demonstrated by microscopic examination of affected hairs, particularly by scanning and transmission electron microscopy.

Trichorrhexis Nodosa.

This is the most common of all hair shaft abnormalities. The hair is dry, brittle, and lusterless, with irregularly spaced grayish-white nodes on the hair shaft. Microscopically, the nodes have the appearance of two interlocking brushes. The defect results from a fracture of the hair shaft at the nodal points caused by disruption of the cells in the hair cortex. Trichorrhexis nodosa has been noted as an isolated congenital defect in some families, has been observed in some infants with Menkes syndrome or argininosuccinic aciduria, and may occur in Netherton syndrome or in association with ectodermal dysplasia and other hair shaft abnormalities such as pili annulati.

ACQUIRED TRICHORRHEXIS NODOSA.

This, the most common cause of hair breakage, occurs in two forms. *Proximal defects* are found most frequently in black children, whose complaint is not of alopecia but of failure of their hair to grow. The hair is short, and longitudinal splits, knots, and whitish nodules can be demonstrated in hair mounts. Easy breakage is demonstrated by gentle traction on the hair shafts. A history of other affected family members may be obtained. The problem may be caused by a combination of genetic predisposition and the cumulative mechanical trauma of rough combing and brushing, hair-straightening procedures, and “permanents.” Patients must be cautioned to avoid damaging grooming techniques. A soft natural-bristle brush and a wide-toothed comb should be used. The condition is self-limited, with resolution in 2–4 yr if patients avoid damaging practices. *Distal trichorrhexis nodosa* is seen more frequently in white and Asian children. The distal portion of the hair shaft is thinned, ragged, and faded; white specks, sometimes mistaken for nits, may be noted along the shaft. Hair mounts reveal the paintbrush defect and the sites of excessive fragility and breakage. Localized areas of the moustache or beard may also be affected. Avoidance of traumatic grooming, regular trimming of affected ends, and the use of cream rinses to lessen tangling ameliorate this condition.

Pili Torti.

This is the second most common hair shaft abnormality. At age 3 mo–2 yr, patients present with spangled, brittle, coarse hair of different lengths over the entire scalp or with circumscribed alopecia. There is a structural defect in which the hair shaft is grooved and flattened at irregular intervals and is twisted on its axis to various degrees. Minor twists that occur in

normal hair should not be misconstrued as pili torti. Curvature of the hair follicle apparently leads to the flattening and rotation of the hair shaft. Most cases of classic, isolated pili torti of early onset have autosomal dominant inheritance. Autosomal recessive forms have been described, however, and many cases are sporadic. Keratosis pilaris, nail dystrophy, and corneal opacity develop in some patients. Syndromes in which the hair shaft abnormalities of pili torti are seen in association with other cutaneous and systemic abnormalities include Menkes kinky hair, Bazex syndrome, Björnstad syndrome (pili torti with deafness), Crandall and Rapp-Hodgkin ectodermal dysplasia syndrome, and trichothiodystrophy. It has also occurred in children treated with retinoids.

Monilethrix.

This rare defect of the hair shaft is inherited as an autosomal dominant trait with variable age of onset, severity, and course. The hair appears dry, lusterless, and brittle, and it fractures spontaneously or with mild trauma. Eyebrows, lashes, body and pubic hair, and scalp hair may be affected. Monilethrix may be present at birth, but the hair is usually normal at birth and is replaced over the first few months of life by abnormal hairs; the condition sometimes is first apparent in childhood. Follicular papules may appear on the nape of the neck and the occiput and, occasionally, over the entire scalp. Short, fragile beaded hairs that emerge from the horny follicular plugs give a distinctive appearance. Keratosis pilaris and koilonychia of fingernails and toenails may also be present. Microscopically, a distinctive, regular beading pattern of the hair shaft is evident, characterized by elliptic nodes that are separated by narrower internodes. Not all hairs have nodes, and both normal and beaded hairs may break. Patients should be advised to handle the hair gently to minimize breakage. Treatment is generally ineffective, although topical minoxidil and oral etretinate have helped some patients. Spontaneous improvement may occur at puberty, during pregnancy, and with use of oral contraceptive pills.

Trichothiodystrophy.

Hair in trichothiodystrophy is sparse, short, brittle, and uneven; the scalp hair, eyebrows, or eyelashes may be affected. Microscopically, the hair is flattened, folded, and variable in diameter; has longitudinal grooving; and has nodal swellings that resemble those of trichorrhexis nodosa. Under a polarizing microscope, distinctive alternating dark and light bands are seen. The abnormal hair has a cystine content that is less than 50% of normal because of a major reduction and altered composition of constituent high-sulfur matrix proteins. Trichothiodystrophy may occur as an isolated finding or in association with various syndrome complexes that include intellectual impairment, short stature, ichthyosis, nail dystrophy, dental caries, cataracts, decreased fertility, neurologic abnormalities, bony abnormalities, and immunodeficiency. Some patients are photosensitive and have impaired DNA repair mechanisms, similar to that seen in group D xeroderma pigmentosum; the incidence of skin cancers, however, is not increased. Patients with trichothiodystrophy tend to resemble one another, with a receding chin, protruding ears, raspy voice, and sociable, outgoing personality. *Trichoschisis*, a fracture perpendicular to the hair shaft, is characteristic of the many syndromes that are associated with trichothiodystrophy. Perpendicular breakage of the hair shaft has also been described in association with other hair abnormalities, particularly monilethrix.

Trichorrhexis Invaginata (Bamboo Hair).

Short, sparse, fragile hair without apparent growth is characteristic of this condition, which is found primarily in association with Netherton syndrome (see Chapter 648). It has also been reported in other ichthyosiform dermatoses. The distal portion of the hair is invaginated into the cuplike proximal portion, forming a fragile nodal swelling. The abnormality is thought to result from a transient defect in keratinization of the inner root sheath and/or a partial defect in the conversion of sulfhydryl groups to disulfide bonds in the cortex. The abnormality may be identified in body and scalp hair and seems to abate as the child matures.

Menkes Kinky Hair Syndrome (Trichopoliodystrophy).

Males with this sex-linked recessive trait are born to an unaffected mother after a normal pregnancy. Neonatal problems include hypothermia, hypotonia, poor feeding, seizures, and failure to thrive. Hair is normal to sparse at birth but is replaced by short, fine, brittle, light-colored hair that may have features of trichorrhexis nodosa, pili torti, or monilethrix. The skin is hypopigmented and thin cheeks typically appear plump, and the nasal bridge is depressed. Heterozygotes may have loss of skin pigmentation. Progressive psychomotor retardation is noted in early infancy. Mutations in the ATP7A gene, encoding a copper transporting ATPase protein cause Menkes kinky hair syndrome. The disorder has been localized by linkage analysis to chromosome Xq13.3 and is due to a maldistribution of copper in the body. Copper uptake across the brush border of the small intestine is increased, but copper transport from these cells into the plasma is defective, resulting in low total body copper stores. Variable treatment success has been achieved with subcutaneous or intramuscular injection of copper salts.

Pili Annulati.

Pili annulati is characterized by alternate light and dark bands of the hair shaft. When one is viewing the hair under the light microscope, the region that appeared bright in reflected light instead appears dark in the transmitted light as a result of focal aggregates of abnormal air-filled cavities within the hair shaft. The hair is not fragile. The defect may be autosomal dominant or sporadic. *Pseudopili annulati* is a variant of normal blond hair; an optical effect caused by the refraction and reflection of light from the partially twisted and flattened shaft creates the impression of banding.

Woolly Hair Disease.

This disorder presents at birth with peculiarly tight, curly, abnormal hair in a nonblack person. It becomes worse in childhood and ameliorates in adulthood. An autosomal dominant form, evident at birth or in infancy, consists of excessively curly, fragile hair. An autosomal recessive type includes scalp hair that is brittle, has a bleached appearance, and is markedly reduced in diameter; body hair is short and pale. Woolly hair nevus, a sporadic form, involves only a circumscribed portion of the scalp hair. The affected hair is fine, tightly curled, and light colored, and it grows poorly. It may be associated with a pigmented or epidermal nevus in another site of the body or with ocular defects. Microscopically, affected hairs are oval and show twisting 180 degrees on their axis.

Uncombable Hair Syndrome (Spun Glass Hair).

The hair of patients with this syndrome appears disorderly, is often silvery blond, and may break because of repeated, futile efforts to control it. The condition is probably autosomal dominant in inheritance, is usually first noticed in the first 3 yr of life, and may spontaneously improve in childhood. Eyebrows and eyelashes are normal. A longitudinal depression along the hair shaft is a constant feature, and most hair follicles and shafts are triangular (pili trianguli et canaliculi). The shape of the hair varies along its length, however, preventing the hairs from lying flat.

Chapter 653 - Disorders of the Nails

Nail abnormalities in children may be manifestations of generalized skin disease, skin disease localized to the periungual region, systemic disease, drugs, trauma, or localized bacterial and fungal infections. Nail anomalies are also common in certain congenital disorders (Box 653–1).

Anonychia is absence of the nail plate, usually a result of a congenital disorder or trauma. It may be an isolated finding or may be associated with malformations of the digits. *Koilonychia* is flattening and concavity of the nail plate with loss of normal contour, producing a spoon-shaped nail. Koilonychia occurs as an autosomal dominant trait or in association with hypochromic anemia, Plummer-Vinson syndrome, and hemochromatosis. The nail plate is relatively thin during the first 1–2 yr of life and consequently may be spoon-shaped in otherwise normal children.

Leukonychia is a white opacity of the nail plate that may involve the entire plate or may be punctate or striate. The nail plate itself remains smooth and undamaged. Leukonychia can be traumatic or associated with infections such as leprosy and tuberculosis, dermatoses such as lichen planus and Darier disease, malignancies such as Hodgkin disease, anemia, and arsenic poisoning (Mees lines). Leukonychia of all nail surfaces is an uncommon hereditary autosomal dominant trait that may be associated with congenital epidermal cysts, renal calculi, and deafness. Paired parallel white bands that do not change position with growth of the nail and thus reflect a change in the nail bed are associated with hypoalbuminemia and are called Muehrcke lines. When the proximal portion of the nail is white and the distal 20–50% of the nail is red, pink, or brown, the condition is called half-and-half nails or Lindsay nails; this is seen most commonly in patients with renal disease but may occur as a normal variant. White nails of cirrhosis, or Terry nails, are characterized by a white ground-glass appearance of the entire or the proximal end of the nail and a normal pink distal 1–2?mm of the nail; this is associated with hypoalbuminemia.

Onycholysis indicates separation of the nail plate from the distal nail bed. Common causes are trauma, chronic exposure to moisture, hyperhidrosis, cosmetics, psoriasis, fungal infection (distal onycholysis), atopic or contact dermatitis, porphyria, drugs (bleomycin, vincristine, retinoid agents, indomethacin, Thorazine), and drug-induced phototoxicity from tetracyclines or chloramphenicol. *Beau lines* are transverse grooves in the nail plate that represent a temporary disruption of formation of the nail plate. The lines first appear a few weeks after the event that caused the disruption in nail growth. A single transverse ridge appears at the proximal nail fold in most 4–6 wk old infants and works its way distally as the nail

grows; this line may reflect metabolic changes after delivery. At other ages, Beau lines are usually indicative of periodic trauma or episodic shutdown of

Box 653-1. Congenital Disease with Nail Defects

Large nails: Pachyonychia congenita, Rubinstein-Taybi syndrome, hemihypertrophy

Small or absent nails: Ectodermal dysplasias, nail-patella, dyskeratosis congenita, focal dermal hypoplasia, cartilage-hair hypoplasia, Ellis–van Creveld, Larsen, epidermolysis bullosa, incontinentia pigmenti, Rothmund-Thomson, Turner, popliteal web, trisomy 13, trisomy 18, Apert, Gorlin-Pindborg, long arm 21 deletion, otopalatodigital, fetal alcohol, fetal hydantoin, elfin facies, anonychia, acrodermatitis enteropathica

Other: Congenital malalignment of the great toenails, familial dystropic shedding of the nails

the nail matrix secondary to a systemic disease such as measles, mumps, pneumonia, or zinc deficiency.

Nail changes may be particularly associated with various other diseases. Nail changes of *psoriasis* most characteristically include pitting, onycholysis, yellow-brown discoloration, and thickening. Nail changes in *lichen planus* include violaceous papules in the proximal nail fold and nail bed, leukonychia, longitudinal ridging, thinning of the entire nail plate, and *pterygium* formation, which is abnormal adherence of the cuticle to the nail plate or, if the plate is destroyed focally, to the nail bed. *Reiter disease* may include painless erythematous induration of the base of the nail fold; subungual parakeratotic scaling; and thickening, opacification, or ridging of the nail plate. *Dermatitis* that involves the nail folds may produce dystrophy, roughening, and coarse pitting of the nails. Nail changes are more common in atopic dermatitis than in other forms of dermatitis that affect the hands. *Darier disease* is characterized by red or white streaks that extend longitudinally and cross the lunula. Where the streak meets the distal end of the nail, a V-shaped notch may be present. Total leukonychia may also occur. Transverse rows of fine pits are characteristic of *alopecia areata*. In severe cases, the entire nail surface may be rough. Patients with *acrodermatitis enteropathica* may have transverse grooves (Beau lines) and nail dystrophy as a result of periungual dermatitis.

Twenty-nail dystrophy is characterized by longitudinal ridging, pitting fragility, thinning, distal notching, and opalescent discoloration of all the nails. Patients have no associated skin or systemic diseases and no other ectodermal defects. Its occasional association with alopecia areata has led some authorities to suggest that 20-nail dystrophy may reflect an abnormal immunologic response to the nail matrix, whereas histopathologic studies have suggested that it may be a manifestation of lichen planus or spongiotic (eczematous) inflammation of the nail matrix. It also can be a feature of vitiligo or psoriasis. The disorder must be differentiated from fungal infections, psoriasis, nail changes of alopecia areata, and nail dystrophy secondary to eczema. Eczema and fungal infections rarely produce changes of all the nails simultaneously. The disorder is self-limited and eventually remits by adulthood.

Congenital nail dysplasia, an autosomal dominant disorder, manifests with onset at birth and longitudinal streaks and thinning of the nail plate. There is platonychia, koilonychia, which may overgrow the lateral folds and involve all nails of the toes and fingers.

Black pigmentation of an entire nail plate or linear bands of pigmentation (melanonychia striata) are common in black (90%) and Asian (10–20%) individuals but are unusual in whites (<1%). Most often, the pigment is melanin, which is produced by melanocytes of a junctional nevus in the nail matrix and nail bed and is of no consequence. Extension or alteration in the pigment should be evaluated by biopsy because of the possibility of malignant change. Bluish-black to greenish nails may be caused by pseudomonas infection, particularly in association with onycholysis or chronic paronychia. The coloration is due to subungual debris and pyocyanin pigment from the bacterial organisms.

Splinter hemorrhages most often result from minor trauma but may also be associated with subacute bacterial endocarditis, vasculitis, severe rheumatoid arthritis, peptic ulcer disease, hypertension, chronic glomerulonephritis, cirrhosis, scurvy, trichinosis, malignant neoplasms, and psoriasis.

Clubbing of the nails (hippocratic nails) is characterized by swelling of the distal digit, an increase in the angle between the nail plate and the proximal nail fold (Lovibond angle) to greater than 180 degrees, and a spongy feeling when one pushes down and away from the interphalangeal joint because of an increase in fibrovascular tissue between the matrix and the phalanx. The pathogenesis is not known, but altered prostaglandin metabolism has been described. Nail clubbing is seen in association with

diseases of numerous organ systems, including pulmonary, cardiovascular, gastrointestinal, and hepatic systems, and in healthy individuals as an idiopathic finding.

Habit tic deformity consists of a depression down the center of the nail with numerous horizontal ridges extending across the nail from it. One or both thumbs are

usually involved as a result of chronic rubbing and picking at the nail with an adjacent finger.

Fungal infection of the nails has been classified into four types. *White superficial onychomycosis* presents with diffuse or speckled white discoloration of the surface of the toenails. It is caused primarily by *Trichophyton mentagrophytes*, which invades the nail plate. The organism may be scraped off the nail plate with a blade, but treatment is best accomplished by the addition of a topical azole antifungal agent. *Distal subungual onychomycosis* presents with foci of onycholysis under the distal nail plate or along the lateral nail groove, followed by development of hyperkeratosis and yellow-brown discoloration. The process extends proximally, resulting in nail plate thickening, crumbling, and separation from the nail bed. *Trichophyton rubrum* and occasionally *T. mentagrophytes* are most common on toenails; fingernail disease is almost exclusively due to *T. rubrum*, which may be associated with superficial scaling of the plantar surface of the feet and often of one hand. These dermatophytes are found most readily at the most proximal area of the nail bed or adjacent ventral portion of the nail plates that are involved. Topical therapies alone are ineffective in most cases, but nail evulsion in combination with topical antifungal agents may be effective. Because of their long half-life in the nail, terbinafine or itraconazole may be effective when given as pulse therapy (1 wk of each mo for 3–4 mo). Either agent is superior to griseofulvin or ketoconazole. The risks, most concerning of which is hepatic toxicity, and costs of oral therapy must be weighed carefully against the benefits of treatment for a condition that generally causes only cosmetic problems.

Proximal white subungual onychomycosis occurs when the organism, generally *T. rubrum*, enters the nail through the proximal nail fold, producing yellow-white portions of the undersurface of the nail plate. The surface of the nail is unaffected. This occurs almost exclusively in immunocompromised patients and is a well-recognized manifestation of AIDS.

Candidal onychomycosis involves the entire nail plate in patients with chronic mucocutaneous candidiasis. It is also commonly seen in patients with AIDS. The organism, generally *Candida albicans*, enters distally or along the lateral nail folds, rapidly involves the entire thickness of the nail plate, and produces thickening, crumbling, and deformity of the plate. Topical azole antifungal agents may be sufficient for treatment of candidal onychomycosis in an immunocompetent host, but oral antifungal agents are necessary for treatment of those with immune deficiencies.

Paronychial inflammation may be acute or chronic and generally involves one or two nail folds on the fingers. Acute paronychia presents with erythema, warmth, edema, and tenderness of the proximal nail fold, most commonly as a result of pathogenic staphylococci or streptococci. Warm soaks and oral antibiotics such as clindamycin or amoxicillin plus clavulanic acid are generally effective; incision and drainage may be necessary in some cases. Development of chronic paronychia is favored by prolonged immersion in water, such as occurs in finger or thumb sucking; exposure to irritating solutions; nail fold trauma; or diseases including Raynaud phenomenon, collagen vascular diseases, or diabetes. Swelling of the proximal nail fold is followed by separation of the nail fold from the underlying nail plate and suppuration. Foreign material, embedded in the dermis of the nail fold, becomes a nidus for inflammation and infection with *Candida* species and mixed bacterial flora. A combination of attention to predisposing factors, meticulous drying of the hands, including use of 4% thymol solution, and long-term antifungal, antibacterial, and topical anti-inflammatory agents may be required for successful treatment of chronic paronychia. The primary chancre of syphilis also may present on the finger as a relatively nontender paronychia.

Ingrown nails occur when the lateral edge of the nail, including spicules that have separated from the nail plate, penetrates the soft tissue of the lateral nail fold. Erythema, edema, and pain, most often involving the lateral great toes, are noted acutely; recurrent episodes may lead to formation of granulation tissue. Predisposing factors include (1) compression of the side of the toe from poorly fitting shoes, particularly if the great toes are abnormally long and the lateral nail folds are prominent, and (2) improper cutting of the nail in a curvilinear manner rather than straight across. Management includes proper fitting of shoes; allowing the nail to grow out beyond the free edge before cutting it straight across; warm water soaks; oral antibiotics if cellulitis affects the lateral nail fold; and, in severe, recurrent cases, application of silver nitrate to granulation tissue, nail avulsion, or excision of the lateral aspect of the nail followed by matricectomy.

Tumors in the paronychial area include pyogenic granulomas, mucous cysts, subungual exostoses, and junctional nevi. Periungual fibromas that appear during late childhood should suggest a diagnosis of tuberous sclerosis.

Nail-patella syndrome is an autosomal dominant disorder in which the nails are 30–50% their normal size and often have triangular or pyramidal lunulae. The thumbnails are always involved, although in some cases only the ulnar half of the nail may be affected or may be missing. The nails from the index finger to the little finger are progressively less damaged. The patella is also smaller than usual, and this anomaly may lead to knee instability. Bony spines arising from the posterior aspect of the iliac bones, overextension of joints, skin laxity, hyperhidrosis, and renal anomalies may also be present. Nail patella syndrome is caused by mutations in the transcription factor LMX1B gene.

Pachyonychia congenita (see Chapter 648).

Yellow nail syndrome presents with thickened, excessively curved, slow-growing yellow nails without lunulae. All nails are affected in most cases. Associated systemic disease includes bronchiectasis, recurrent bronchitis, chylothorax, and focal edema of the limbs and face. Deficient lymphatic drainage, due to hypoplastic lymphatic vessels, is believed to lead to the manifestations of this syndrome.

Chapter 654 - Disorders of the Mucous Membranes

The mucous membranes may be involved in developmental disorders, infections, acute and chronic skin diseases, genodermatoses, and benign and malignant tumors. Some of the more common and distinctive diseases specific to mucous membranes are presented in this chapter.

Cheilitis.

Inflammation of the lips (cheilitis) and angles of the mouth (angular cheilitis or perlèche) are most commonly due to dryness, chapping, and lip licking; excessive salivation and drooling, particularly in children with neurologic deficits, may also cause chronic irritation. Lesions of oral thrush may occasionally extend to the angles of the mouth. Protection can be provided by frequent applications of a bland ointment such as petrolatum. Candidosis should be treated with an appropriate antifungal agent, and contact dermatitis of the perioral skin should be treated with a mild topical corticosteroid preparation and an emollient.

Fordyce Spots.

These are asymptomatic, minute, yellow-white papules on the vermilion border of the lips and buccal mucosa. These ectopic sebaceous glands may be found in otherwise normal individuals and require no therapy.

Mucocele.

Mucus retention cysts are painless, bluish, fluctuant, tense, 2–10?mm papules on the lips, tongue, palate, or buccal mucosa. Traumatic severance of the duct of a minor salivary gland leads to submucosal retention of mucus secretion. Those on the floor of the mouth are known as *ranulas* when the submaxillary or sublingual salivary ducts are involved. Fluctuations in size are usual, and the lesions may disappear temporarily after traumatic rupture. Recurrence is prevented by excising the mucocele.

Aphthous Stomatitis (Canker Sores).

Solitary or multiple painful ulcerations occur on the labial, buccal, or lingual mucosa

and on the sublingual, palatal, or gingival mucosa. Lesions may present initially as erythematous, indurated papules that erode rapidly to form sharply circumscribed, necrotic ulcers with a gray fibrinous exudate and an erythematous halo. Minor aphthous ulcers are 2–10?mm in diameter and heal spontaneously in 7–10 days. Major aphthous ulcers are greater than 10?mm in diameter and take 10–30 days to heal. A third type of aphthous ulceration is herpetiform in appearance, presenting with a few to numerous grouped 1–2?mm lesions that tend to coalesce into plaques that heal over 7–10 days. Approximately one third of patients with recurrent lesions have a family history of the disorder. (See Chapter 296 for differential diagnosis.)

The *etiology* of aphthous stomatitis is probably multifactorial; the condition probably represents an oral manifestation of a number of conditions. Altered local regulation of the cell-mediated immune system, after activation and accumulation of cytotoxic T cells, may contribute to the localized mucosal breakdown. Predisposing factors include trauma, emotional stress, low serum iron or ferritin levels, deficiency of vitamin B_{12} or folate, malabsorption in association with celiac or Crohn disease, menstruation accompanied by a decrease in progestogens during the luteal phase, food hypersensitivity, and allergic or toxic drug reactions. It is a common misconception that aphthous stomatitis is a manifestation of herpes simplex virus infection. Recurrent herpes infections remain localized to the lips and rarely cross the mucocutaneous junction; involvement of the oral mucosa occurs only in primary infections.

Treatment of aphthous stomatitis is palliative. Use of 0.2% aqueous chlorhexidine gluconate mouthwash helps to maintain oral hygiene. Relief of pain, particularly before eating, may be achieved by use of a topical anesthetic such as viscous lidocaine (Xylocaine) or an oral rinse with a solution of elixir of diphenhydramine, viscous lidocaine, and 0.5% dyclonine hydrochloride. A topical corticosteroid in a mucosal adhering agent (0.1% triamcinolone in Orabase) may help to reduce inflammation, and topical tetracycline mouthwash may also hasten healing. In severe, debilitating cases, systemic therapy with corticosteroids, colchicine, or dapsone may be helpful.

Cowden Syndrome (Multiple Hamartoma Syndrome).

This is an autosomal dominant condition that usually presents during the 2nd or 3rd decade with smooth, pink or whitish papules on the palatal, gingival, buccal, and labial mucosae. Mutations in the tumor suppressor gene PTEN cause Cowden syndrome. These benign fibromas may coalesce into a cobblestone appearance. Numerous flesh-colored papules also develop on the face, particularly around the mouth, nose, and ears; these papules most commonly are trichilemmomas, a benign neoplasm of the hair follicle. Associated findings may include acral keratotic papules, thyroid goiter, gastrointestinal polyps, fibrocystic breast nodules, and carcinoma of the breast or thyroid.

Epstein Pearls (Gingival Cysts of the Newborn).

These are white keratin-containing cysts on the palatal or alveolar mucosa of approximately 80% of neonates. They cause no symptoms and are generally shed within a few weeks.

Geographic Tongue (Benign Migratory Glossitis).

This consists of single or multiple sharply demarcated, irregular, smooth red plaques on the dorsum of the tongue caused by transient atrophy of the filiform papillae and the surface epithelium, often with elevated gray margins composed of intervening filiform papillae that are increased in thickness. Symptoms of mild burning or irritation may occasionally be bothersome. Onset is rapid, and the pattern may change over hours to days. Geographic tongue is associated with scrotal tongue in nearly 50% of patients. Some patients have atopy; some feel that the condition is exacerbated by stress or by hot or spicy foods; and some have anemia, diabetes mellitus, Reiter disease, seborrheic dermatitis, or pustular psoriasis. Geographic tongue may be an oral manifestation of pustular psoriasis, with which it shares histologic features. No therapy other than reassurance is necessary.

Scrotal (Fissured) Tongue.

Approximately 1% of infants and 2.5% of children have many folds with deep grooves on the dorsal tongue surface. These impart a pebbled or wrinkled appearance. Some cases are congenital, caused by incomplete fusion of the two halves of the tongue; others develop in association with infection, trauma, malnutrition, or low vitamin A levels. Many patients with fissured tongue also have geographic tongue. Food particles and debris may become trapped in the fissures, resulting in irritation, inflammation, and halitosis. Careful cleansing with a mouth rinse and soft-bristled toothbrush is recommended.

Black Hairy Tongue.

This is a dark coating on the dorsum of the tongue caused by hyperplasia and elongation of the filiform papillae; overgrowth of chromogenic bacteria and fungi and entrapped pigmented residues that adsorb to microbial plaque and desquamating keratin may contribute to the dark coloration. Changes often begin posteriorly and extend anteriorly on the dorsum of the tongue. The condition is most common in adults but may also present during adolescence. Poor oral hygiene and bacterial overgrowth, treatment with systemic antibiotics such as tetracycline (which promotes the growth of *Candida* species), and smoking are predisposing factors. Improved oral hygiene and brushing with a soft-bristled toothbrush may be all that are necessary for treatment. The filiform hyperplasia may also be decreased with topical keratolytic agents such as trichloroacetic acid, urea, or podophyllin.

Oral Hairy Leukoplakia.

This occurs in approximately 25% of patients with AIDS but is rare in the pediatric population. It presents as a mostly asymptomatic white thickening and accentuation of the normal vertical folds of the lateral margins of the tongue. The mucosa is white and irregularly thickened but remains soft. Spread may occur occasionally to the ventral tongue surface, the floor of the mouth, the tonsillar pillars, and the pharynx. The condition appears to be due to Epstein-Barr virus, which is present in the upper layer of the affected epithelium. The plaques have no malignant potential. The disorder occurs predominantly in HIV-infected patients but may also be found in

individuals who are immunosuppressed for other

reasons, such as organ transplantation or leukemia and chemotherapy. The condition is generally asymptomatic and does not require therapy. Resolution of the plaques may be hastened, however, by use of antiviral agents such as acyclovir or local application of 0.1% vitamin A acid twice daily.

Vincent Gingivitis (Acute Necrotizing Ulcerative Gingivitis, Fusospirochetal Gingivitis, Trench Mouth).

This disorder presents with punched-out ulceration, necrosis, and bleeding of interdental papillae. A grayish-white pseudomembrane may cover the ulcerations. Lesions may spread to involve the buccal mucosa, lips, tongue, tonsils, and pharynx and may be associated with dental pain, a bad taste, low-grade fever, and lymphadenopathy. It presents most commonly during the 2nd or 3rd decade, particularly in the context of poor dental hygiene, scurvy, or pellagra. A synergistic association between fusospirochetal organisms *(Fusobacterium nucleatum)* and *Borrelia vincenti* has been proposed to contribute to the pathogenesis.

Noma is a severe form of fusospirillary gangrenous stomatitis that presents primarily in malnourished children 2–5 yr of age who have had a preceding illness such as measles, scarlet fever, tuberculosis, malignancy, or immunodeficiency. It presents as a painful red, indurated papule on the alveolar margin, followed by ulceration and mutilating gangrenous destruction of tissue in the oronasal region. The process may also involve the scalp, neck, shoulders, perineum, and vulva. *Noma neonatorum* presents in the 1st mo of life with gangrenous lesions of the lips, nose, mouth, and anal regions. Affected infants are usually small for gestational age, malnourished, premature, and frequently ill, particularly with *Pseudomonas aeruginosa* sepsis. Care consists of nutritional support, conservative debridement of necrotic soft tissues, empirical broad-spectrum antibiotics such as penicillin and metronidazole, and in the case of noma neonatorum, antipseudomonal antibiotics.

Chapter 655 - Cutaneous Bacterial Infections

Skin complaints or findings are noted in 20–30% of children who attend general pediatric clinics. Bacterial skin infection is the single most common diagnosis among children with skin problems, accounting for 17% of all clinic visits. The most common bacterial skin infection of children is impetigo, which makes up approximately 10% of all skin problems.

IMPETIGO

See Chapters 166 and 168 .

Clinical Manifestations

NONBULLOUS IMPETIGO.

There are two classic forms of impetigo: nonbullous and bullous. Nonbullous impetigo accounts for more than 70% of cases. Lesions typically begin on the skin of the face or on extremities that have been traumatized. The most common lesions that precede nonbullous impetigo include insect bites, abrasions, lacerations, chickenpox, scabies pediculosis, and burns. A tiny vesicle or pustule forms initially (Fig. 655–1*A*) and rapidly develops into a honey-colored crusted plaque that is generally less than 2?cm in diameter (see Fig. 655–1*B*). The infection may be spread to other parts of the body by the fingers, clothing, and towels. Lesions are associated with little to no pain or surrounding erythema, and constitutional symptoms are generally absent. Pruritus occurs occasionally, regional adenopathy is found in up to 90% of cases, and leukocytosis is present in approximately 50% of patients. Without treatment, most cases resolve spontaneously without scarring within approximately 2 wk. The differential diagnosis of nonbullous impetigo includes viral (herpes simplex, varicella-zoster), fungal (tinea corporis, kerion), and parasitic infections (scabies, pediculosis capitis), all of which may become impetiginized.

Staphylococcus aureus is the predominant organism of nonbullous impetigo in the United States; group A ß-hemolytic streptococci (GABHS) are implicated in the development of some lesions. Staphylococci generally spread from the nose to normal skin and then infect the skin. In contrast, the skin becomes colonized with GABHS an average of 10 days before development of impetigo. GABHS then colonize the nasopharynx an average of 2–3 wk after the appearance of lesions of impetigo. The skin serves as the source for acquisition of GABHS in the respiratory tract and the probable primary source for spread of impetigo. Lesions of nonbullous impetigo that grow staphylococci in culture cannot be distinguished clinically from those that grow pure cultures of GABHS. Whereas *S. aureus* can be cultured from lesions of impetigo in children of all ages, GABHS is most commonly cultured from children of preschool age and is unusual before 2 yr of age, except in highly endemic areas. The staphylococcal types that cause nonbullous impetigo are variable but are not generally from phage group 2, the group that is associated with scalded skin and toxic shock syndromes. Several serotypes of GABHS, termed “impetigo strains,” are found most frequently in lesions of nonbullous impetigo and are different from those that cause pharyngitis.

BULLOUS IMPETIGO.

This is mainly an infection of infants and young children. Bullous impetigo is always caused by coagulase-positive *S. aureus;* approximately 80% are from phage group 2, among which 60% are type 71, and most of the remainder are types 3A, 3B, 3C, and 55. Flaccid, transparent bullae develop most commonly on skin of the face, buttocks, trunk, perineum, and extremities; neonatal bullous impetigo can begin in the diaper area. Rupture of bullae occurs easily, leaving a narrow rim of scale at the edge of a shallow, moist erosion. Surrounding erythema and regional adenopathy are generally absent. Unlike those of nonbullous impetigo, lesions of bullous impetigo are a manifestation of localized staphylococcal scalded skin syndrome and develop on intact skin.

Diagnosis.

Cultures of fluid from an intact blister or moist plaque should yield the causative agent; if the patient appears ill, blood cultures should also be obtained. On histopathologic examination, lesions of bullous impetigo show vesicle formation in the subcorneal or granular region, neutrophils and occasionally acantholytic cells within the blister, spongiosis, edema of the papillary dermis, and a mixed infiltrate of lymphocytes and neutrophils around blood vessels of the superficial plexus. Unless staphylococci can be cultured from the bullae or, less commonly, can be seen on Gram stain, it may be impossible to differentiate bullous impetigo from pemphigus foliaceous or subcorneal pustular dermatosis histopathologically. Nonbullous impetigo has histopathologic findings similar to those of the bullous variant, except that blister formation is slight.

Figure 655-1 *A*, Multiple crusted and oozing lesions of streptococcal impetigo. *B*, Multiple tense and flaccid blisters of bullous impetigo on the trunk and arm of an infant.

The *differential diagnosis* of bullous impetigo in neonates includes epidermolysis bullosa, bullous mastocytosis, herpetic infection, and early scalded skin syndrome. In older children, allergic contact dermatitis, burns, erythema multiforme, chronic bullous dermatosis of childhood, pemphigus, and bullous pemphigoid must be considered, particularly if the lesions do not respond to therapy.

Complications.

Potential but very rare complications of either nonbullous or bullous impetigo include osteomyelitis, septic arthritis, pneumonia, and septicemia; positive blood culture results are rare in otherwise healthy children with localized lesions. Cellulitis has been reported in approximately 10% of patients with nonbullous impetigo but rarely follows the bullous form. Lymphangitis, suppurative lymphadenitis, guttate psoriasis, and scarlet fever occasionally follow streptococcal disease. There is no correlation between number of lesions and clinical involvement of the lymphatics or development of cellulitis in association with streptococcal impetigo.

Infection with nephritogenic strains of GABHS may result in acute poststreptococcal glomerulonephritis (Chapter 503.1). The clinical character of impetigo lesions is not predictive of the development of poststreptococcal glomerulonephritis. The most commonly affected age group is school-aged children 3–7 yr old. The latent period from onset of impetigo to development of poststreptococcal glomerulonephritis averages 18–21 days, which is longer than the 10-day latency period after pharyngitis. Poststreptococcal glomerulonephritis occurs epidemically after either pharyngeal or skin infection. Impetigo-associated epidemics have been caused by M groups 2, 49, 53, 55, 56, 57, and 60. Strains of GABHS that are associated with endemic impetigo in the United States have little or no nephritogenic potential. Acute rheumatic fever does not occur as a result of impetigo.

Treatment.

Topical or systemic antibiotic treatment is superior to placebo or cleansing with 3% hexachlorophene soap. Furthermore, cleansing with 3% hexachlorophene soap adds little to no benefit over systemic antibiotics alone. Mupirocin is an ointment that is bactericidal by reversible inhibition of bacterial isoleucyl-transfer RNA synthetase. Applied topically three times daily for 7–10 days, it is equal to or greater in effectiveness, with fewer side effects, than oral erythromycin ethylsuccinate, 30–50?mg/kg/24?hr for 7–10 days. Rare instances of bacterial resistance to mupirocin have been reported, but most patients were treated irregularly or prophylactically for more than 2 wk. Topical fusidic acid may also be effective.

Systemic therapy with a ß-lactamase–resistant oral antibiotic should be prescribed for patients with widespread involvement; when lesions are near the mouth, where topical medication may be licked off; or in cases of evidence of deep involvement, including cellulitis, furunculosis, abscess formation, or suppurative lymphadenitis. In areas without a high prevalence of *S. aureus* resistance to erythromycin, erythromycin ethylsuccinate (40?mg/kg/24?hr divided three to four times daily for 7 days) or erythromycin estolate (30?mg/kg/24?hr divided three to four times daily) is the preferred oral therapy. If erythromycin resistance is widespread in the community, alternative oral antibiotics that have been shown to be effective in children for treatment of impetigo include dicloxacillin; amoxicillin plus clavulanic acid, clindamycin, and a cephalosporin such as cephalexin, cefaclor, cefadroxil, cefprozil, or cefpodoxime. The choice among these various agents may be guided primarily by issues of cost, local availability, and compliance. The macrolides clarithromycin or azithromycin may be advantageous primarily in instances of intolerance to erythromycin but will not provide cure rates superior to those of erythromycin. No evidence suggests that a 10-day course of therapy is superior to a 7-day one. If a satisfactory clinical response is not achieved within 7 days, however, a culture should be taken by swabbing beneath the lifted edge of a crusted lesion. If a resistant organism is detected, an appropriate antibiotic should be given for an additional 7 days.

SUBCUTANEOUS TISSUE INFECTIONS

The principal determination for soft tissue infections is whether it is non-necrotizing or necrotizing; the former responds to antibiotic therapy alone, whereas the latter requires prompt surgical removal of all devitalized tissue in addition to antimicrobial therapy. Necrotizing soft tissue infections are potentially life-threatening conditions that are characterized by rapidly advancing local tissue destruction and systemic toxicity. Tissue necrosis distinguishes them from cellulitis; in cellulitis, an inflammatory infectious process involves subcutaneous tissue but does not destroy it. Necrotizing soft tissue infections characteristically present with a paucity of early cutaneous signs relative to the rapidity and degree of destruction of the subcutaneous tissues.

Cellulitis.

Cellulitis is characterized by infection and inflammation of loose connective tissue, with limited involvement of the dermis and relative sparing of the epidermis. A break in the skin due to previous trauma, surgery, or an underlying skin lesion predisposes to cellulitis. Cellulitis is also more common in individuals with lymphatic stasis, diabetes mellitus, or immunosuppression.

ETIOLOGY.

Streptococcus pyogenes and *S. aureus* are the most common etiologic agents. Occasionally, *Streptococcus pneumoniae*, group G or C streptococci, and in neonates, group B streptococci or rarely *Escherichia coli* are the causal organism. In patients who are immunocompromised or have diabetes mellitus, a number of other bacterial or fungal agents may be

---

involved, notably *Pseudomonas aeruginosa; Aeromonas hydrophila* and occasionally other Enterobacteriaceae; *Legionella* spp; the Mucorales, particularly *Rhizopus* spp, *Mucor* spp, and *Absidia* spp; and *Cryptococcus neoformans*. Children with relapsed nephrotic syndrome may develop cellulitis due to *E. coli*. In children age 3 mo to 3–5 yr, *Haemophilus influenzae* type b was once an important cause of facial cellulitis, but its incidence has declined significantly since institution of immunization against this organism.

CLINICAL MANIFESTATIONS.

Cellulitis presents clinically as an area of edema, warmth, erythema, and tenderness. The lateral margins tend to be indistinct because the process is deep in the skin, primarily involving the subcutaneous tissues in addition to the dermis. Application of pressure may produce pitting. Although distinction cannot be made with certainty in any particular patient, cellulitis as a result of *S. aureus* tends to be more localized

and may suppurate, whereas infections due to *S. pyogenes* tend to spread more rapidly and may be associated with lymphangitis. Regional adenopathy and constitutional signs and symptoms of fever, chills, and malaise are common. Complications of cellulitis include subcutaneous abscess, bacteremia, osteomyelitis, septic arthritis, thrombophlebitis, endocarditis, and necrotizing fasciitis. Lymphangitis or glomerulonephritis also can follow infection with *S. pyogenes*.

DIAGNOSIS.

Aspirates from the site of inflammation, skin biopsy, and blood cultures allow identification of the causal organism in approximately 25% of cases of cellulitis. Yield of the causative organism is approximately one third when the site of origin of the cellulitis is apparent, such as an abrasion or ulcer. An aspirate taken from the point of maximum inflammation yields the causal organism more often than does a leading-edge aspirate. Lack of success in isolating an organism stems primarily from the low number of organisms present within the lesion.

TREATMENT.

Empirical therapy for cellulitis should be directed by the history of the illness, the location and character of the cellulitis, and the age and immune status of the patient. Cellulitis in a neonate should prompt a full sepsis work-up, followed by initiation of empirical therapy intravenously with a ß-lactamase–stable antistaphylococcal antibiotic such as methicillin and an aminoglycoside such as gentamicin or a cephalosporin such as cefotaxime. Treatment of cellulitis in an infant or child younger than about 5 yr should provide coverage for *S. pyogenes and S. aureus* as well as *H. influenzae* type b and *S. pneumoniae.* The evaluation should include a blood culture, and if the infant is younger than 1 year, if signs of systemic toxicity are present, or if an adequate examination cannot be carried out, a lumbar puncture should also be performed. In most cases of cellulitis on an extremity, regardless of age, *S. aureus* and *S. pyogenes* are the cause and bacteremia is unlikely in an otherwise well-appearing child. Blood cultures should be obtained if sepsis is suspected. If fever, lymphadenopathy, and other constitutional signs are absent (e.g., white blood cell count < 15,000), treatment of cellulitis on an extremity may be initiated orally on an outpatient basis with a penicillinase-resistant penicillin such as dicloxacillin or cloxacillin or a first-generation cephalosporin such as cephalexin. If improvement is not noted or the disease progresses significantly within the first 24–48?hr of therapy, parenteral therapy is necessary. If fever, lymphadenopathy, or constitutional signs are present, therapy should be initiated parenterally. Oxacillin or nafcillin is effective in most cases, although if systemic toxicity is significant, consideration should be given to the addition of penicillin or clindamycin. Once the erythema, warmth, edema, and fever have decreased significantly, a 10-day course of treatment may be completed on an outpatient basis. Immobilization and elevation of an affected limb, particularly early in the course of therapy, may help to reduce swelling and pain.

Necrotizing Fasciitis.

Necrotizing fasciitis is a subcutaneous tissue infection that involves the deep layer of superficial fascia but largely spares adjacent epidermis, deep fascia, and muscle.

ETIOLOGY.

Relatively few organisms possess sufficient virulence to cause necrotizing fasciitis when acting alone. The most fulminant infections, associated with toxic shock syndrome and a high case-fatality rate, are caused by *S. pyogenes* (also see Chapter 168). Streptococcal necrotizing fasciitis in the absence of toxic shock-like syndrome may occur and is seldom fatal but may be associated with substantial morbidity. Necrotizing fasciitis can occasionally be caused by *S. aureus, Clostridium perfringens, Clostridium septicum, P. aeruginosa, Vibrio* spp, particularly *V. vulnificus,* and fungi of the order Mucorales, particularly *Rhizopus* spp, *Mucor* spp, and *Absidia* spp. Necrotizing fasciitis has also been reported on rare occasions to result from non–group A streptococci such as group B, C, F, or G streptococci, *S. pneumoniae,* or *H. influenzae* type b. Necrotizing fasciitis may be a polymicrobial infection. In most of these cases, a mixture of anaerobic bacteria and aerobic or facultative bacteria appear to act together to cause tissue necrosis. The most common aerobic or facultative bacteria are several species of hemolytic or nonhemolytic non–group A streptococci, *S. aureus, E. coli, Enterobacter* spp, and various other Enterobacteriaceae, and *Pseudomonas* spp. The anaerobes present are similar to those found in subcutaneous abscesses: *Bacteroides* spp, *Peptostreptococcus* spp, *Peptococcus* spp, *Prevotella* spp, *Porphyromonas* spp, *Clostridium* spp, and *Fusobacterium* spp. Infections due to any one organism or combination of organisms cannot be distinguished clinically from one another, although development of crepitance signals the presence of *Clostridium* spp or gram-negative bacilli such as *E. coli, Klebsiella, Proteus,* and *Aeromonas.*

EPIDEMIOLOGY.

Necrotizing fasciitis may occur anywhere on the body; the most common locations, however, are the extremities, abdomen, and perineal region. Common predisposing conditions in neonates are omphalitis and balanitis after circumcision. The incidence of necrotizing fasciitis is highest in hosts with systemic or local tissue immunocompromise, such as those with diabetes mellitus, neoplasia, or peripheral vascular disease, and those recently having undergone surgery, those who abuse intravenous drugs, or those on immunosuppressive treatment, particularly with corticosteroids. The infection also can occur in healthy individuals after minor puncture wounds, abrasions, or lacerations; blunt trauma; surgical procedures, particularly of the abdomen, gastrointestinal or genitourinary tracts, or the perineum; or hypodermic needle injection. Since the mid-1980s, there has been a resurgence of fulminant necrotizing soft tissue infections due to *S. pyogenes*, which may occur in previously healthy individuals with little or no apparent compromise of immunologic or skin integrity. Necrotizing fasciitis due to *S. pyogenes* may occur after superinfection of varicella lesions. These children have tended to display onset, recrudescence, or persistence of high fever and signs of toxicity after the 3rd to 4th day of varicella.

CLINICAL MANIFESTATIONS.

Necrotizing fasciitis begins with acute onset of local swelling, erythema, tenderness, and heat. Fever is usually present, and pain, tenderness, and constitutional signs are out of proportion to cutaneous signs, especially with involvement of fascia and

muscle. Lymphangitis and lymphadenitis are usually absent. The infection advances along the superficial fascial plane, and initially there are few cutaneous signs to herald the serious nature and extent of subcutaneous tissue necrosis that is occurring. Skin changes may appear over 24–48?hr as nutrient vessels are thrombosed and cutaneous ischemia develops. Early clinical findings include ill-defined cutaneous erythema and edema, which extend beyond the area of erythema. Additional signs include formation of bullae filled initially with straw-colored and later bluish to hemorrhagic fluid, and darkening of affected tissues from red to purple to blue. Skin anesthesia and finally frank tissue gangrene and

---

slough develop owing to the ischemia and necrosis. Vesiculation or bulla formation, ecchymoses, crepitus, anesthesia, and necrosis are ominous and indicative of advanced disease. Children with varicella lesions initially may show no cutaneous signs of superinfection with invasive *S. pyogenes* such as erythema or swelling. Significant systemic toxicity may accompany necrotizing fasciitis, including shock, organ failure, and death. Advance of the infection in this setting can be rapid, progressing to death within hours. In general, patients with involvement of the superficial or deep fascia and muscle tend to be more acutely and systemically ill and have more rapidly advancing disease than those with infection confined solely to subcutaneous tissues above the fascia. In an extremity, a *compartment syndrome* may develop and is manifest as tight edema, pain on motion, and loss of distal sensation and pulses. This is a surgical emergency.

DIAGNOSIS.

Definitive diagnosis is made by surgical exploration, which should be undertaken as soon as the diagnosis is suspected. Necrotic fascia and subcutaneous tissue are gray and offer little resistance to blunt probing. Although MRI aids in delineating the extent and tissue planes of involvement, this procedure should not delay surgical intervention. Frozen section incisional biopsy specimen obtained early in the course of the infection can aid management by decreasing the time to diagnosis and helping establish margins of involvement. Gram stain of tissue can be particularly useful if chains of gram-positive cocci, indicative of infection with *S. pyogenes,* are seen.

TREATMENT.

Early supportive care, surgical debridement, and parenteral antibiotic administration are mandatory. All devitalized tissue should be removed to freely bleeding edges, and repeat exploration is generally indicated within 24–36?hr to confirm that no necrotic tissue remains. This may need to be repeated on several occasions until devitalized tissue has ceased to form. Daily, meticulous wound care is also paramount.

Antibiotic therapy should be initiated parenterally as soon as possible with broad-spectrum agents against all potential pathogens. Most experts recommend initial empirical therapy with penicillin, ampicillin, or nafcillin; clindamycin; and an aminoglycoside for coverage against *S. pyogenes* and the broad spectrum of potential anaerobic and gram-negative pathogens. Clindamycin is often added to inhibit protein synthesis of new bacterial necrotizing toxins.

PROGNOSIS.

The combined case fatality rate among children and adults with necrotizing fasciitis and toxic shock-like syndrome due to *S. pyogenes* has been approximately 60%. Death is less common in children, however, and in cases not complicated by toxic shock-like syndrome.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME (RITTER DISEASE)

Clinical Manifestations.

Staphylococcal scalded skin syndrome occurs predominantly in infants and children younger than 5 yr of age and includes a range of disease from localized bullous impetigo to generalized cutaneous involvement with systemic illness. Onset of the rash may be preceded by malaise, fever, irritability, and exquisite tenderness of the skin. Scarlatiniform erythema develops diffusely and is accentuated in flexural and periorificial areas. The conjunctivas are inflamed and occasionally become purulent. The brightly erythematous skin may rapidly acquire a wrinkled appearance, and in severe cases sterile, flaccid blisters, and erosions develop diffusely. Circumoral erythema is characteristically prominent, as is radial crusting and fissuring around the eyes, mouth, and nose. At this stage, areas of epidermis may separate in response to gentle shear force (Nikolsky sign). As large sheets of epidermis peel away, moist, glistening, denuded areas become apparent, initially in the flexures and subsequently over much of the body surface (Fig. 655–2). This may lead to secondary cutaneous infection, sepsis, and fluid and electrolyte disturbances. The desquamative phase begins after 2–5 days of cutaneous erythema; healing occurs without scarring in 10–14 days. Patients may have pharyngitis, conjunctivitis, and superficial erosions of the lips, but intraoral mucosal surfaces are spared. Although some patients appear ill, many are reasonably comfortable except for the marked skin tenderness.

A presumed abortive form of the disease presents with diffuse, scarlatiniform, tender erythroderma, which is accentuated in the flexural areas but does not progress to blister formation. In these patients, Nikolsky sign may be absent. Although the exanthem is similar to that of streptococcal scarlet fever, strawberry tongue and palatal petechiae are absent. Staphylococcal scalded skin syndrome may be mistaken for a number of other blistering and exfoliating disorders, including bullous impetigo, epidermolysis bullosa, epidermolytic hyperkeratosis, pemphigus, drug eruption, erythema multiforme, and drug-induced toxic epidermal necrolysis. Toxic epidermal necrolysis can often be distinguished by a history of drug ingestion, the presence of Nikolsky sign only at sites of erythema, absence of perioral crusting, full-thickness epidermal necrosis, and a blister cleavage plane in the lowermost epidermis.

Etiology and Pathogenesis.

Staphylococcal scalded skin syndrome is caused predominantly by phage group 2 staphylococci, particularly strains 71 and 55, which are present at localized sites of infection. Foci of infection include the nasopharynx and, less commonly, the

umbilicus, urinary tract, a superficial abrasion, conjunctivae, and blood. The clinical manifestations of staphylococcal scalded skin syndrome are mediated by hematogenous spread, in the absence of specific antitoxin antibody of staphylococcal epidermolytic or exfoliative toxins A or B. The toxins have reproduced the disease in both animal models and human volunteers. Decreased renal clearance of the toxins may account for the fact that the disease is most common in infants and young children. Epidermolytic toxin A is heat stable and is encoded by bacterial chromosomal genes; epidermolytic toxin B is heat labile and is encoded on a 37.5-kb plasmid. Histopathologically, the site of blister cleavage is subcorneal through the granular layer. The epidermolytic toxins appear to produce the granular layer split by binding to desmoglein I within desmosomes. Evidence suggests that the toxins are members of the trypsin-like serine protease family and may exert their action through proteolysis.

Figure 655-2 Infant with staphylococcal scalded skin syndrome.

Diagnosis.

Intact bullae are consistently sterile, unlike those of bullous impetigo, but cultures should be obtained from all suspected sites of localized infection and from the blood to identify the source for elaboration of the epidermolytic toxins. The subcorneal, granular layer split can be identified on skin biopsy; absence of an inflammatory infiltrate is characteristic. In cases that demand a rapid diagnosis, the exfoliated corneal layer can be seen on a frozen biopsy specimen of the desquamating epidermis. Scattered acantholytic cells, which are evident in the cleftlike bullae, can also be seen in a Tzanck preparation.

Treatment.

Systemic therapy, either orally, in cases of localized involvement, or parenterally, with a semisynthetic penicillinase-resistant penicillin, should be prescribed because the staphylococci are usually penicillin resistant. Clindamycin may be added to inhibit bacterial protein (toxin) synthesis. The skin should be gently moistened and cleansed with Burow solution, Dakin solution, or isotonic saline. Application of an emollient provides lubrication and decreases discomfort. Topical antibiotics are unnecessary. Recovery is usually rapid, but complications such as excessive fluid loss, electrolyte imbalance, faulty temperature regulation, pneumonia, septicemia, and cellulitis may cause increased morbidity.

ECTHYMA (see Chapters 168 and 188)

This resembles nonbullous impetigo in onset and appearance but gradually evolves into a deeper, more chronic infection. The initial lesion is a vesicle or vesiculopustule with an erythematous base that erodes through the epidermis into the dermis to form an ulcer with elevated margins. The ulcer becomes obscured by a dry, heaped-up, tightly adherent crust that contributes to the persistence of the infection and scar formation. Lesions may be spread by autoinoculation, may be as large as 4?cm, and occur most frequently on the legs. Predisposing factors include pruritic lesions, such as insect bites, scabies, or pediculosis, which are subject to frequent scratching; poor hygiene; and malnutrition. Complications include lymphangitis, cellulitis, and rarely poststreptococcal glomerulonephritis. The causative agent is usually GABHS; *S. aureus* is also cultured from most lesions but is probably a secondary pathogen. Crusts should be softened with warm compresses and removed with an antibacterial soap. Systemic antibiotic therapy, as for impetigo, is indicated; almost all lesions are responsive to treatment with penicillin.

Ecthyma gangrenosa is a necrotic ulcer covered with a gray-black eschar. It is usually a sign of *P. aeruginosa* sepsis and usually occurs in immunosuppressed patients. Ecthyma gangrenosum occurs in up to 6% of patients with systemic *P. aeruginosa* infection but can also occur as a primary cutaneous infection by inoculation. The lesion begins as a red or purpuric macule that vesiculates and then ulcerates; there is a surrounding rim of pink to violaceous skin. The punched-out ulcer develops raised edges with a dense, black, depressed, crusted center. Lesions may be single or multiple; patients with bacteremia commonly have lesions in apocrine areas. Clinically similar lesions may also develop as a result of infection with other agents such as *S. aureus, A. hydrophila, Enterobacter* species, *Proteus* species, *Pseudomonas cepacia, Serratia marcescens, Aspergillus* species, Mucorales, *E. coli*, and *Candida* species. There is bacterial invasion of the adventitia and media of dermal veins but not arteries; the intima and lumina are spared. Blood cultures and skin biopsy for culture should be obtained, and empirical broad-spectrum, systemic therapy that includes coverage for *Pseudomonas* should be initiated as soon as possible.

BLASTOMYCOSIS-LIKE PYODERMA (PYODERMA VEGETANS)

This is an exuberant cutaneous reaction to bacterial infection, primarily in children who are malnourished and immunosuppressed. The organisms isolated most commonly from lesions are *S. aureus* and GABHS, but several other organisms have been associated with these lesions, including *P. aeruginosa, Proteus mirabilis*, diphtheroids, *Bacillus* species and *C. perfringens*. Hyperplastic, crusted plaques on the extremities are characteristic, sometimes forming from the coalescence of many pinpoint, purulent, crusted abscesses. Ulceration and sinus tract formation may develop, and additional lesions may appear at sites distant from the site of inoculation. Regional lymphadenopathy is common, but fever is not. Histopathologic examination reveals pseudoepitheliomatous hyperplasia and abscesses composed of neutrophils and/or eosinophils; giant cells are usually lacking. The differential diagnosis includes deep fungal infection, particularly blastomycosis and tuberculous and atypical mycobacterial infection. Underlying immunodeficiency should be ruled out, and the selection of antibiotics should be guided by susceptibility testing because the response to antibiotics is often poor.

BLISTERING DISTAL DACTYLITIS

This is a superficial blistering infection of the volar fat pad on the distal portion of the finger or thumb. More than one finger may be involved, as may the volar surfaces of the proximal phalanges, palms, and toes. Blisters are filled with a watery purulent fluid that contains polymorphonuclear leukocytes and chains of gram-positive cocci. Patients usually have no preceding history of trauma, and systemic symptoms are generally absent. Poststreptococcal glomerulonephritis has not occurred after

blistering distal dactylitis. The infection is caused most commonly by GABHS but has also occurred as a result of infection with group B ß-hemolytic streptococci and *S. aureus*. If left untreated, blisters may continue to enlarge and extend to the paronychial area. The infection responds to incision and drainage and a 10-day course of systemic penicillin or erythromycin therapy.

PERIANAL DERMATITIS

This presents most commonly in boys (70% of cases) between the ages of 6 mo and 10 yr as perianal dermatitis (90% of cases) and pruritus (80% of cases). The incidence of perianal dermatitis is not known precisely but ranges from 1/2,000 to 1/218 patient visits. The rash is superficial, erythematous, well marginated, nonindurated, and confluent from the anus outward. Acutely (<6 wk), the rash tends to be bright red, moist, and tender to touch. At this stage, a white pseudomembrane may be present. As the rash becomes more chronic, the perianal eruption may consist of painful fissures, a dried mucoid discharge, or psoriasiform plaques with yellow peripheral crust. In girls, the perianal rash may be associated with vulvovaginitis; the penis may be involved in boys. Approximately 50% of patients have rectal pain, most commonly described as burning inside the anus during defecation, and 33% have blood-streaked stools. Fecal retention is a frequent behavioral response to the infection. Patients may also have presented with guttate psoriasis. Although local induration or edema may occur, constitutional symptoms of fever, headache, and malaise are absent, suggesting that subcutaneous involvement, as in cellulitis, is absent. Familial spread of perianal dermatitis is common, particularly when family members bathe together or use the same water.

The *differential diagnosis* of perianal dermatitis includes psoriasis, seborrheic dermatitis, candidosis, pinworm infestation, sexual abuse, and inflammatory bowel disease. Differentiation from these other conditions can be accomplished by culturing a moderate to heavy growth of GABHS on 5% sheep blood agar. Perianal dermatitis may also be caused by *S. aureus*. Children with asymptomatic perianal colonization have light growth of GABHS on blood agar. Direct antigen studies for GABHS are also very sensitive (89%), but results may be falsely negative early in

the course of the disease. Acute and convalescent sera for antistreptolysin O or anti-DNase B are not helpful in making the diagnosis. The index case and family members should be cultured initially, and follow-up cultures to document bacteriologic cure after a course of treatment are also recommended.

Treatment with a single 10-day course of oral penicillin produces resolution of the dermatitis and symptoms in most patients; however, recurrence rates of 40–50% have been reported, emphasizing the need for close follow-up, including repeat culture. Erythromycin estolate and ethylsuccinate are excellent alternative treatments for those who are allergic to penicillin, who have not responded to a course of penicillin, or who are infected with *S. aureus*. Clindamycin has also been used successfully to treat recurrent perianal dermatitis. Mupirocin has been used in conjunction with oral antibiotics to treat recurrences but has not been evaluated as a single-drug therapy.

ERYSIPELAS (see Chapter 168)

FOLLICULITIS

This superficial infection of the hair follicle is most often caused by *S. aureus* (Bockhart impetigo); coagulase-negative staphylococci are the cause occasionally. The lesions are typically small, discrete, dome-shaped pustules with an erythematous base, located at the ostium of the pilosebaceous canals. Hair growth is unimpaired, and the lesions heal without scarring. Favored sites include the scalp, buttocks, and extremities. Poor hygiene, maceration, and drainage from wounds and abscesses can be provocative factors. Folliculitis can also occur as a result of tar therapy or occlusive wraps; the moist environment encourages bacterial proliferation. In HIV-infected patients, *S. aureus* may produce confluent erythematous patches with satellite pustules in intertriginous areas and violaceous plaques composed of superficial follicular pustules in the scalp, axillas, or groin. *Candida* may cause satellite follicular papules and pustules surrounding erythematous patches of intertrigo, and *Malassezia furfur* produces pruritic 2–3?mm erythematous, perifollicular papules and pustules on the back, chest, and extremities, particularly in patients with diabetes mellitus or on corticosteroids or antibiotics. Diagnosis is made by examining potassium hydroxide-treated scrapings from lesions. Detection of *Malassezia* may require a skin biopsy, demonstrating clusters of yeast and short, branching hyphae ("spaghetti and meatballs") in widened follicular ostia mixed with keratinous debris. *Malassezia* may be cultured on Sabouraud's dextrose agar supplemented with gentamicin, vancomycin, and olive oil.

The causative organism of folliculitis can be identified by Gram stain and culture of purulent material from the follicular orifice. *Treatment* for folliculitis includes topical antibiotic cleansers such as chlorhexidine or hexachlorophene. Topical antibiotic therapy is usually all that is required for mild cases, but more severe cases may require use of penicillinase-resistant systemic antibiotics such as dicloxacillin or cephalexin. In chronic recurrent folliculitis, daily application of a benzoyl peroxide lotion or gel may facilitate resolution.

Folliculitis caused by gram-negative organisms occurs primarily in patients with acne vulgaris treated long term with broad-spectrum systemic antibiotics. A superficial pustular form, caused by *Klebsiella, Enterobacter, E. coli*, or *P. aeruginosa*, occurs around the nose and spreads to the cheeks and chin. A deeper, nodular form of folliculitis on the face and trunk is caused by *Proteus*. Culture of infected follicles is necessary to establish the diagnosis. Treatment consists of incision and drainage of the deeper, larger cysts; topical neomycin or bacitracin; or selection of an oral antibiotic based on the sensitivity profile of the pathogenic organism. For severe, recalcitrant cases, 13-*cis*-retinoic acid, 1?mg/kg/24?hr, is helpful but should be administered only by experienced physicians because of side effects.

Sycosis barbae is a deeper, more severe recurrent inflammatory form of folliculitis caused by *S. aureus* that involves the entire depth of the follicle. Erythematous follicular papules and pustules develop on the chin, upper lip, and angle of the jaw, primarily in young black males. Papules may coalesce into plaques, and healing may occur with scarring. Affected individuals frequently are found to be *S. aureus* carriers. Treatment with warm saline compresses and topical antibiotics such as

mupirocin generally clears the infection. More extensive, recalcitrant cases may require therapy with ß-lactamase–resistant systemic antibiotics and elimination of *S. aureus* from sites of carriage.

Hot tub folliculitis is attributable to *P. aeruginosa*, predominantly serotype O-11. The lesions are pruritic papules and pustules or deeply erythematous to violaceous nodules that develop 8–48?hr after exposure and are most dense in areas covered by a bathing suit. Patients occasionally develop fever, malaise, and lymphadenopathy. The organism is readily cultured from pus. The eruption usually resolves spontaneously within 1–2 wk, often leaving postinflammatory hyperpigmentation, but topical agents with antipseudomonal activity, such as potassium permanganate and gentamicin cream, are sometimes necessary. Consideration should be given to use of systemic antibiotics (e.g., ciprofloxacin) in adolescent patients with constitutional symptoms. Immunocompromised children are susceptible to complications of pseudomonas folliculitis (e.g., cellulitis) and should avoid hot tubs.

FURUNCLES AND CARBUNCLES

These follicular lesions may originate from a preceding folliculitis or may arise initially as a deep-seated, tender, erythematous, perifollicular nodule. Although lesions are initially indurated, central necrosis and suppuration follow, leading to rupture and discharge of a central core of necrotic tissue and destruction of the follicle. Healing occurs with scar formation. Sites of predilection are the hair-bearing areas on the face, neck, axillae, buttocks, and groin. Pain may be intense if the lesion is situated in an area where the skin is relatively fixed, such as in the external auditory canal or over the nasal cartilages. Patients with furuncles usually have no constitutional symptoms; however, bacteremia may occasionally ensue. Rarely, lesions on the upper lip or cheek may lead to cavernous sinus thrombosis. Infection of a group of contiguous follicles, with multiple drainage points, accompanied by inflammatory changes in surrounding connective tissue is a carbuncle. Carbuncles may be accompanied by fever, leukocytosis, and bacteremia.

Etiology.

The causative agent is usually *S. aureus*, which penetrates abraded perifollicular skin. Conditions predisposing to furuncle formation include obesity, hyperhidrosis, maceration, friction, and pre-existing dermatitis. Furunculosis is also more common in individuals with low serum iron levels, diabetes, malnutrition, HIV infection, or other immunodeficiency states. Recurrent furunculosis is frequently associated with carriage of *S. aureus* in the nares, axillae, or perineum or close contact with someone such as a family member who is a carrier. Other bacteria or fungi may occasionally cause furuncles or carbuncles; therefore, Gram stain and culture of the pus are indicated.

Treatment.

This includes regular bathing with antimicrobial soaps and wearing of loose-fitting clothing, which minimizes predisposing factors for furuncle formation. Frequent application of a hot, moist compress may facilitate drainage of lesions. Large lesions may be drained by a small incision. Carbuncles and large or numerous furuncles should be treated with systemic penicillinase-resistant antibiotics such as cloxacillin orally or oxacillin parenterally. Penicillin-allergic patients can be treated with a cephalosporin, clindamycin, or erythromycin. Treatment of recurrent cases has been successful by colonization of the individual with a less virulent strain of *S. aureus* such as 502A.

The carriage state may be eliminated temporarily by application of mupirocin ointment for 5 days to the anterior nares. Attention to personal hygiene, use of an antibacterial soap, low-dose oral antistaphylococcal penicillin or clindamycin, and frequent handwashing may also be beneficial.

PITTED KERATOLYSIS

Pitted keratolysis occurs most frequently in humid tropical and subtropical climates, particularly in individuals whose feet are moist for prolonged periods, for example, as a result of hyperhidrosis, prolonged wearing of boots, or immersion in water. The lesions consist of 1–7?mm irregularly shaped superficial erosions of the horny layer on the soles, particularly at weight-bearing sites. Brownish discoloration of involved areas may be apparent. The condition is usually asymptomatic but frequently is malodorous. A rare, painful variant is manifested as thinned, erythematous to violaceous plaques in addition to the typical pitted lesions. The most likely etiologic agent is a species of *Corynebacterium*. *Actinomycetes*, *Dermatophilus*, and micrococci have also been isolated from lesions. Avoidance of moisture and maceration produces slow, spontaneous resolution of the infection. Therapeutic regimens that have been effective include topical application of 2% buffered glutaraldehyde, 20% formaldehyde solution (formalin) in Aquaphor, erythromycin, clindamycin, and the imidazoles.

ERYTHRASMA

This is a benign chronic superficial infection caused by *Corynebacterium minutissimum*. Predisposing factors include heat, humidity, obesity, skin maceration, and poor hygiene. Approximately 20% of patients have involvement of the toe webs. Other frequently affected sites are moist intertriginous areas such as the groin and axillas; the inframammary and perianal regions are involved occasionally. Sharply demarcated, irregularly bordered, brownish-red, slightly scaly patches are characteristic of the disease. Mild pruritus is the only constant symptom. *C. minutissimum* is a complex of related organisms that produce porphyrins that fluoresce brilliant coral-red under ultraviolet light. The diagnosis is readily made, and erythrasma is differentiated from dermatophyte infection and from tinea versicolor by Wood lamp examination. Bathing within 20?hr of Wood lamp examination, however, may remove the water-soluble porphyrins. Staining of skin scrapings with methylene blue or Gram stain reveals the pleomorphic, filamentous coccobacillary forms.

Most cases represent colonization, are asymptomatic, and require no therapy. Effective *treatment* can be achieved with topical erythromycin, clindamycin, miconazole, or Whitfield ointment or a 10–14 day course of oral erythromycin. Recurrence may be inhibited by frequent use of an antibacterial soap or an

astringent such as 10–20% aluminum chloride in anhydrous ethyl alcohol.

ERYSIPELOID

This rare cutaneous infection is caused by inoculation of *Erysipelothrix rhusiopathiae* from contaminated animals, birds, fish, or their products. The localized cutaneous form is most common, characterized by well-demarcated diamond-shaped erythematous to violaceous patches at sites of inoculation. Local symptoms are generally not severe, constitutional symptoms are rare, and the lesions resolve spontaneously after weeks but can recur at the same site or develop elsewhere weeks to months later. The diffuse cutaneous form presents with lesions at several areas of the body in addition to the site of inoculation; it is also self-limited. The systemic form, caused by hematogenous spread, is accompanied by constitutional symptoms and may include endocarditis, septic arthritis, cerebral infarct and abscess, meningitis, and pulmonary effusion. Diagnosis is confirmed by skin biopsy, which reveals the gram-positive organisms, and culture. The treatment of choice is parenteral erythromycin or penicillin.

TUBERCULOSIS OF THE SKIN (see Chapters 197 and 199)

Cutaneous tuberculosis infection occurs worldwide, particularly in association with HIV infection, malnutrition, and poor hygiene. Primary cutaneous tuberculosis is rare in the United States but occurs with the greatest frequency in infants and children; the overall incidence of cutaneous tuberculosis among those with all forms of tuberculosis in the United States is approximately 1–2%. All forms of cutaneous disease are caused by *Mycobacterium tuberculosis*, by *Mycobacterium bovis*, and occasionally by the bacillus Calmette-Guérin (BCG), an attenuated form of *M. bovis*; the manifestations caused by a given organism are indistinguishable from one another. After invasion of the skin, mycobacteria either multiply intracellularly within macrophages, leading to progressive disease, or are controlled by the host immune reaction.

A primary lesion, a *tuberculous chancre*, results when *M. tuberculosis* or *M. bovis* gains access to the skin or mucous membranes through trauma. Sites of predilection are the face, lower extremities, and genitals. The initial lesion develops 2–4 wk after introduction of the organism into the damaged tissue. A red-brown papule gradually enlarges to form a shallow, firm, sharply demarcated ulcer; satellite abscesses may be present. Some lesions acquire a crust resembling impetigo, and others become heaped up and verrucous at the margins. The primary lesion occurs in one third of cases as a painless ulcer on the conjunctiva, gingiva, or palate and occasionally as a painless acute paronychia. Painless regional adenopathy appears approximately 3–8 wk after inoculation and may be accompanied by lymphangitis, lymphadenitis, or perforation of the skin surface, forming scrofuloderma. Erythema nodosum develops in approximately 10% of cases. Untreated lesions heal with scarring within approximately 12 mo but may reactivate, may form lupus vulgaris, or rarely may progress to the acute miliary form.

M. tuberculosis or *M. bovis* can be cultured from the skin lesion and local lymph nodes, but acid-fast staining of histologic sections, particularly of a well-controlled infection, often does not reveal the organism. Clinically, the differential diagnosis is broad, including a syphilitic chancre; deep fungal or atypical mycobacterial infection; leprosy; tularemia; cat-scratch disease; sporotrichosis; nocardiosis; leishmaniasis; reaction to foreign substances such as zirconium, beryllium, silk or nylon sutures, talc, or starch; papular acne rosacea; and lupus miliaris disseminatum faciei. Spontaneous healing with scarring coincides with acquisition of immunity, at which time the skin lesions and infected nodes may become calcified. Antituberculous therapy is indicated (see Chapter 197).

Direct cutaneous inoculation of the tubercle bacillus into a previously infected individual with a moderate to high degree of immunity initially produces a small papule with surrounding inflammation. *Tuberculosis verrucosa cutis* (warty tuberculosis) forms when the papule becomes hyperkeratotic and warty, and several adjacent papules coalesce or a single papule expands peripherally to form a brownish-red to violaceous, exudative, crusted verrucous plaque. Irregular extension of the margins of the plaque produces a serpiginous border. Children have the lesion most commonly on the lower extremities after trauma and contact with infected material such as sputum or soil. Regional lymph nodes are involved only rarely. Spontaneous healing with atrophic scarring takes place slowly, over months to years; healing is also gradual with antituberculous therapy.

Lupus vulgaris is a rare, chronic, progressive form of cutaneous tuberculosis that develops in individuals with a moderate to high degree of tuberculin sensitivity induced by previous infection.

The incidence is greater in cool, moist climates, particularly in females. Lupus vulgaris develops as a result of direct extension from underlying joints or lymph nodes; through lymphatic or hematogenous spread; or rarely, by cutaneous inoculation with BCG vaccine. It most commonly follows cervical adenitis or pulmonary tuberculosis. Approximately 33% of cases are preceded by scrofuloderma, and 90% of cases present on the head and neck, most commonly on the nose or cheek; involvement of the trunk is uncommon. A typical solitary lesion consists of a brownish-red, soft papule that has an apple-jelly color when examined by diascopy. Expansion of the papule peripherally, or occasionally the coalescence of several papules, forms an irregular lesion of variable size and form. One or several lesions may develop, including nodules or plaques that are flat and serpiginous, hypertrophic and verrucous, or edematous in appearance. Spontaneous healing occurs centrally, and lesions characteristically reappear within the area of atrophy. Chronicity is characteristic, and persistence and progression of plaques over many years is common. Lymphadenitis is present in 40% of those with lupus vulgaris, and 10–20% have infection of the lungs, bones, or joints. Vegetative masses and ulceration involving the nasal, buccal, or conjunctival mucosa; the palate; the gingiva; or the oropharynx may cause extensive deformities. Squamous cell carcinoma, with a relatively high metastatic potential, may develop, usually after several years of the disease. After a temporary impairment in immunity, particularly after measles infection (i.e., *lupus exanthematicus*), multiple lesions may form at distant sites as a result of hematogenous spread from a latent focus of infection. The histopathology reveals a tuberculoid granuloma without caseation; organisms are extremely difficult to demonstrate. The differential diagnosis includes sarcoidosis, leprosy, atypical mycobacterial infection, blastomycosis, chromoblastomycosis, actinomycosis, leishmaniasis, tertiary syphilis, leprosy, hypertrophic lichen planus, psoriasis, lupus erythematosus, lymphocytoma, and Bower disease. Small lesions

can be excised; antituberculous drug therapy usually halts further spread and induces involution.

Scrofuloderma results from enlargement, cold abscess formation, and breakdown of a lymph node, most frequently in a cervical chain, with extension to the overlying skin. Linear or serpiginous ulcers and dissecting fistulas and subcutaneous tracts studded with soft nodules may develop. Spontaneous healing may take years, eventuating in cordlike keloid scars; lupus vulgaris may also develop. Scrofuloderma of a cervical lymph node often originates in the larynx and was linked in the past to ingestion of milk containing *M. bovis*. Lesions may also originate from an underlying infected joint, tendon, bone, or epididymis. The differential diagnosis includes syphilitic gumma, deep fungal infections, actinomycosis, and hidradenitis suppurativa. The course is indolent, and constitutional symptoms are typically absent. Antituberculous therapy is usually effective.

Orificial tuberculosis presents on the mucous membranes and periorificial skin after autoinoculation of mycobacteria from sites of progressive infection; it is a sign of advanced internal disease and carries a poor prognosis. Lesions appear as yellowish or red, painful nodules that form punched-out ulcers with inflammation and edema of the surrounding mucosa. Treatment consists of identification of the source of infection and initiation of antituberculous therapy.

Miliary tuberculosis (hematogenous primary tuberculosis) rarely presents cutaneously, most commonly in infants and in individuals who are immunosuppressed after chemotherapy or infection with measles or HIV. The eruption consists of crops of symmetrically distributed, minute, erythematous to purpuric macules, papules, or vesicles. The lesions may ulcerate, drain, crust, and form sinus tracts or may form subcutaneous gummas, especially in malnourished children with impaired immunity. Constitutional signs and symptoms are common, and a leukemoid reaction or aplastic anemia may develop. Tubercle bacilli are readily identified in an active lesion. A fulminant course should be anticipated, and aggressive antituberculous therapy is indicated.

Single or multiple *metastatic tuberculous abscesses* (tuberculous gummas) may develop on the extremities and trunk by hematogenous spread from a primary focus of infection during a period of decreased immunity, particularly in malnourished and immunosuppressed children. The fluctuant, nontender, erythematous subcutaneous nodules may ulcerate and form fistulas.

Vaccination with BCG characteristically produces a papule approximately 2 wk after vaccination. The papule expands in size, typically ulcerates within 2–4 mo, and heals slowly with scarring. In approximately 1–2 per million vaccinations, a complication caused specifically by the BCG organism occurs, including regional lymphadenitis, lupus vulgaris, scrofuloderma, and subcutaneous abscess formation.

Tuberculids are skin reactions that exhibit tuberculoid features histologically but do not contain detectable mycobacteria. The lesions appear in a host who usually has moderate to strong tuberculin reactivity, has a history of previous tuberculosis of other organs, and usually shows a therapeutic response to antituberculous therapy. The cause of tuberculids is poorly understood. Most patients are in good health with no clear focus of disease at the time of the eruption. The most commonly observed tuberculid is the *papulonecrotic tuberculid*. Recurrent crops of symmetrically distributed, asymptomatic, firm, sterile, dusky-red papules appear on the extensor aspects of the limbs, the dorsum of the hands and feet, and the buttocks. The papules may undergo central ulceration and eventually heal, leaving sharply delineated, circular, depressed scars. The duration of the eruption is variable, but it usually disappears promptly after treatment of the primary infection. *Lichen scrofulosorum*, another form of tuberculid, is characterized by asymptomatic, grouped, pinhead-sized, often follicular pink or red papules that form discoid plaques, mainly on the trunk. Healing occurs without scarring.

Atypical mycobacterial infection may cause cutaneous lesions in children. *Mycobacterium marinum* is found in salt and freshwater and diseased fish; in the United States, it is most commonly acquired from tropical fish tanks and swimming pools. Traumatic abrasion of the skin serves as a portal of entry for the organism. Approximately 3 wk after inoculation, a single reddish papule develops and enlarges slowly to form a violaceous nodule or occasionally a warty plaque. The lesion occasionally breaks down to form a crusted ulcer or a suppurating abscess. Sporotrichoid erythematous nodules along lymphatics may also suppurate and drain. Lesions are most common on the elbows, knees, and feet of swimmers and the hands and fingers in aquarium-acquired infection. Systemic signs and symptoms are absent; regional lymph nodes occasionally become slightly enlarged but do not break down. Rarely, the infection becomes disseminated, particularly in an immunosuppressed host. A biopsy specimen of a fully developed lesion demonstrates a granulomatous infiltrate with tuberculoid architecture; intracellular organisms can usually be identified within the histiocytes with appropriate stains. The most effective antituberculous regimens include tetracycline, minocycline, and rifampin plus ethambutol. Application of heat to the affected site may be a useful adjunctive therapy. Spontaneous healing with scarring can be expected within several months to 2 yr (see Chapter 199).

Mycobacterium kansasii primarily causes pulmonary disease; skin disease is rare, often occurring in an immunocompromised host. Most commonly, sporotrichoid nodules develop after inoculation of traumatized skin. Lesions may develop into ulcerated, crusted, or verrucous plaques. The organism is relatively sensitive to antituberculous medications, which should be chosen on the basis of susceptibility testing.

M. scrofulaceum causes cervical lymphadenitis (scrofuloderma) in young children, typically in the submandibular region. Nodes enlarge over several weeks, ulcerate, and drain. The local reaction is nontender and circumscribed, constitutional symptoms are absent, and there generally is no evidence of lung or other organ involvement. Other atypical mycobacteria may cause a similar presentation, including *M. avium* complex, *M. kansasii*, and *M. fortuitum*. Treatment is accomplished by excision and antituberculous drugs (see Chapter 199).

Mycobacterium ulcerans causes a painless subcutaneous nodule after inoculation of abraded skin. Most infections occur in children in tropical rain forests. The nodule usually ulcerates, develops undermined edges, and may spread over large areas, most commonly on an extremity. Local necrosis of subcutaneous fat, producing a

septal panniculitis, is characteristic. Ulcers persist for months to years before healing spontaneously with scarring and sometimes with lymphedema. Constitutional symptoms and lymphadenopathy are absent. Diagnosis is made by culturing the organism at 32–33°C. Treatment of choice is early excision of the lesion. Local heat therapy and oral chemotherapy may benefit some patients.

M. avium complex, composed of more than 20 subtypes, most commonly causes chronic pulmonary infection. Cervical lymphadenitis and osteomyelitis occur occasionally, and papules or purulent leg ulcers occur rarely by primary inoculation. Skin lesions may be an early sign of disseminated infection; the lesions may take various forms, including erythematous papules, pustules, nodules, abscesses, ulcers, panniculitis, and sporotrichoid spread along lymphatics. For treatment, see Chapter 199].

M. fortuitum complex is composed of two organisms: *M. fortuitum* and *M. chelonei*. These organisms cause disease in an immunocompetent host principally by primary cutaneous inoculation after traumatic injury, injection, or surgery. A nodule, abscess, or cellulitis develops 4–6 wk after inoculation. In an immunocompromised host, numerous subcutaneous nodules may form, break down, and drain. Treatment is based on identification and susceptibility testing of the organism.

Chapter 656 - Cutaneous Fungal Infections

TINEA VERSICOLOR

This common, innocuous, chronic fungal infection of the stratum corneum is caused by the dimorphic yeast *Malassezia furfur*. The synonyms *Pityrosporum ovale* and *P. orbiculare* were used previously to identify the causal organism.

Etiology.

M. furfur is part of the indigenous flora, predominantly in the yeast form, and is found particularly in areas of skin that are rich in sebum production. Proliferation of filamentous forms occurs in the disease state. Predisposing factors include a warm, humid environment, excessive sweating, occlusion, high plasma cortisol levels, immunosuppression, malnourishment, and genetically determined susceptibility. The disease is most prevalent in adolescents and young adults.

Clinical Manifestations.

The lesions vary widely in color. In whites, they typically are reddish brown, whereas in blacks they may be either hypopigmented or hyperpigmented. The characteristic macules are covered with a fine scale; they often begin in a perifollicular location, enlarge, and merge to form confluent patches, most commonly on the neck, upper chest, back, and upper arms (Fig. 656–1*A*). Facial lesions are not unusual in adolescents, and lesions occasionally appear on the forearms, dorsum of the hands, and pubis. There may be little or no pruritus. Involved areas do not tan after sun exposure. A papulopustular perifollicular variant of the disorder may occur on the back, chest, and sometimes the extremities.

Diagnosis.

Examination with a Wood lamp discloses a yellowish-gold fluorescence. A potassium hydroxide (KOH) preparation of scrapings is diagnostic, demonstrating groups of thick-walled spores and myriad short, thick, angular hyphae, resembling spaghetti and meatballs (see Fig. 656–1*B*). Skin biopsy, including culture and special stains for fungi (e.g., periodic acid-Schiff), are often necessary to make the diagnosis in cases of primarily follicular involvement; organisms and keratinous debris can be seen within dilated follicular ostia.

Tinea versicolor must be distinguished from dermatophyte infections, seborrheic dermatitis, pityriasis alba, and secondary syphilis. Nonscaling pigmentary disorders,

such as postinflammatory pigmentary change, may be mimicked if a patient has

removed the scales by scrubbing. Disseminated candidiasis must be differentiated from *M. furfur* folliculitis.

Figure 656-1 *A*, Hyperpigmented, sharply demarcated macules of varying sizes on the upper trunk characteristic of tinea versicolor. *B*, KOH preparation of *Malassezia furfur* demonstrating short, thick hyphae and clusters of spores.

Treatment.

Many therapeutic agents can be used to treat this disease successfully; however, the causative agent, a normal human saprophyte, is not eradicated from the skin, and the disorder recurs in predisposed individuals. Appropriate topical therapy may include one of the following: a selenium sulfide suspension applied for 5–10?min each day for 2 wk; 25% sodium hyposulfite or thiosulfate lotion applied twice daily for 2–4 wk; lotions, ointments, or creams containing 3–6% salicylic acid twice daily for 2–4 wk; or miconazole, clotrimazole, ketoconazole, or terbinafine cream twice daily for 2–4 wk. Recurrent episodes continue to respond promptly to these agents. Oral therapy may be more convenient and may be achieved successfully with ketoconazole or fluconazole, 400?mg, repeated in 1 wk, or itraconazole, 200?mg/24?hr for 5–7 days.

DERMATOPHYTOSES

Dermatophytoses are caused by a group of closely related filamentous fungi with a propensity for invading the stratum corneum, hair, and nails. The three principal genera responsible for infections are *Trichophyton, Microsporum*, and *Epidermophyton*.

Etiology.

Trichophyton species cause lesions of all keratinized tissue, including skin, nails, and hair; *T. rubrum* is the most common dermatophyte pathogen overall. *Microsporum* species principally invade the hair, and the *Epidermophyton* species invade the intertriginous skin. Dermatophyte infections are designated by the word *tinea* followed by the Latin word for the anatomic site of involvement. The dermatophytes are also classified according to source and natural habitat. Fungi acquired from the soil are called *geophilic*; they infect humans sporadically, inciting an inflammatory reaction. Dermatophytes that are acquired from animals are *zoophilic*; transmission may be through direct contact or indirectly by infected animal hair or clothing. Infected animals frequently are asymptomatic. Dermatophytes acquired from humans are referred to as *anthropophilic*; these infestations range from chronic low-grade to acute inflammatory disease. *Epidermophyton* infections are transmitted only by humans, but various species of *Trichophyton* and *Microsporum* can be acquired from both human and nonhuman sources.

Epidemiology.

Host defense has an important influence on the severity of the infection. Disease tends to be more severe in individuals with diabetes mellitus, lymphoid malignancies, immunosuppression, and states with high plasma cortisol levels, such as Cushing syndrome. Some dermatophytes, most notably the zoophilic species, tend to elicit more severe, suppurative inflammation in humans. Some degree of resistance to reinfection is acquired by most infected persons and may be associated with a delayed hypersensitivity response. No relationship has been demonstrated, however, between antibody levels and resistance to infection. The frequency and severity of infection are also affected by the geographic locale, the genetic susceptibility of the host, and the virulence of the strain of dermatophyte. Additional local factors that predispose to infection include trauma to the skin, hydration of the skin with maceration, occlusion, and elevated temperature.

Occasionally, a secondary skin eruption referred to as a *dermatophytid* or *"id" reaction* appears in sensitized individuals and has been attributed to circulating fungal antigens derived from the primary infection. The eruption occurs most frequently on the fingers, hands, and arms and is characterized by grouped papules and vesicles and, occasionally, by sterile pustules. Symmetric urticarial lesions and a more generalized maculopapular eruption also can occur. Id reactions are most often associated with tinea pedis but also occur with tinea capitis; in the latter case, a generalized papulovesicular follicular eruption may occur.

Diagnosis.

The important diagnostic procedures for the various dermatophyte diseases include examination of infected hairs with a Wood lamp, microscopic examination of KOH preparations of infected material, and identification of the etiologic agent by culture. Hairs infected with common *Microsporum* species fluoresce a bright blue-green; most *Trichophyton*-infected hairs do not fluoresce.

Clinical Manifestations.

Tinea capitis is a dermatophyte infection of the scalp most often caused by *Trichophyton tonsurans*, occasionally

by *Microsporum canis*, and much less commonly by other *Microsporum* and *Trichophyton* species. It is particularly common in black and Hispanic children age 4–14 yr. In *Microsporum* and some *Trichophyton* infections, the spores are distributed in a sheathlike fashion around the hair shaft (ectothrix infection), whereas *T. tonsurans* produces an infection within the hair shaft (endothrix). Endothrix infections may continue past the anagen phase of hair growth into telogen and are more chronic than infections with ectothrix organisms that persist only during the anagen phase. *T. tonsurans* is an anthropophilic species acquired most often by

contact with infected hairs and epithelial cells that are on such surfaces as theater seats, hats, and combs. Dermatophyte spores may also be airborne within the immediate environment, and high carriage rates have been demonstrated in noninfected schoolmates and household members. *M. canis* is a zoophilic species that is acquired from cats and dogs.

The *clinical presentation* of tinea capitis varies with the infecting organism. The pattern produced by *Microsporum audouinii*, the most common cause of tinea capitis in the 1940s and 1950s, is characterized initially by a small papule at the base of a hair follicle. The infection spreads peripherally, forming an erythematous and scaly circular plaque *(ringworm)* within which the infected hairs become brittle and broken. Numerous confluent patches of alopecia develop, and patients may complain of severe pruritus. *M. audouinii* infection is no longer common in the United States. Endothrix infections such as those caused by *T. tonsurans* create a pattern known as “black-dot ringworm,” characterized initially by many small circular patches of alopecia in which hairs are broken off close to the hair follicle. Another clinical variant presents with diffuse scaling with minimal hair loss secondary to traction; it strongly resembles seborrheic dermatitis, psoriasis, or atopic dermatitis. *T. tonsurans* may also produce a chronic and more diffuse alopecia (Fig. 656–2*A*). A severe inflammatory response produces elevated, boggy granulomatous masses *(kerions)*, which are often studded with pustules (see Fig. 656–2*B*). Fever, pain, and regional adenopathy are common, and permanent scarring and alopecia may result. The zoophilic organism *M. canis* or the geophilic organism *Microsporum gypseum* also may cause kerion formation. *Favus*, a chronic form of tinea capitis that is rare in the United States, is caused by the fungus *Trichophyton schoenleinii*. Favus starts as yellowish-red papules at the opening of hair follicles. The papules expand and coalesce to form cup-shaped, yellowish, crusted patches that fluoresce dull green under a Wood lamp.

Tinea capitis can be confused with seborrheic dermatitis, psoriasis, alopecia areata, trichotillomania, and certain dystrophic hair disorders. When inflammation is pronounced, as in kerion, primary or secondary bacterial infection must also be considered. In adolescents, the patchy, moth-eaten type of

Figure 656-2 *A*, Patchy alopecia associated with tinea capitis. *B*, Elevated, boggy granuloma with multiple pustules (kerion) caused by inflammatory tinea capitis.

alopecia associated with secondary syphilis may resemble tinea capitis. After prolonged tinea capitis has produced scarring, discoid lupus erythematosus and lichen planopilaris must also be considered in the differential diagnosis.

Microscopic examination of a KOH preparation of infected hair from the active border of a lesion discloses tiny spores surrounding the hair shaft in *Microsporum* infections and chains of spores within the hair shaft in *T. tonsurans* infections. Fungal elements usually are not seen in scales. A specific etiologic *diagnosis* of tinea capitis may be obtained by planting broken off infected hairs on Sabouraud medium with reagents to inhibit growth of other organisms; such identification may require 2 wk or more.

Oral administration of griseofulvin microcrystalline (15–20?mg/kg/24?hr) is the recommended *treatment* for all forms of tinea capitis; it may be necessary for 8–12 wk and should be terminated only after fungal culture results are negative. Adverse reactions to griseofulvin are rare but include nausea, vomiting, headache, blood dyscrasias, phototoxicity, and hepatotoxicity. Oral itraconazole is useful in instances of griseofulvin resistance, intolerance, or allergy. Itraconazole is given for 4–6 wk at a dosage of 3–5?mg/kg/24?hr with food, typically 100?mg on alternate days in children weighing 10–20?kg; 100?mg daily for children weighing 20–30?kg; 100?mg alternating with 200?mg for children weighing 30–50?kg; and 200?mg/day for >50?kg. Capsules are preferable to the syrup, which may cause diarrhea. Terbinafine also appears to be effective at a dosage of 3–6?mg/kg/24?hr for 4–6 wk (<20?kg weight—62.5?mg/24?hr; 20–40?kg—125?mg/24?hr; adult dose—250?mg/24?hr) or possibly in pulse therapy, although it has limited activity against *M. canis*. Neither itraconazole nor terbinafine is approved by the Food and Drug Administration for treatment of dermatophyte infections in the pediatric population. Topical therapy alone is ineffective; it may be an important adjunct because it may decrease the shedding of spores. Asymptomatic dermatophyte carriage in family members is extremely common. One in three families have at least one member who is a carrier. Therefore, treatment of both patient and potential carriers with a sporicidal shampoo may hasten clinical resolution. For this purpose, vigorous shampooing with a 2.5% selenium sulfide or zinc pyrithione preparation is helpful. It is not necessary to shave the scalp.

Tinea corporis, infection of the glabrous skin, excluding the palms, soles, and groin, can be caused by most of the dermatophyte species, although *T. rubrum* and *T. mentagrophytes* are the most prevalent etiologic organisms. In children, infections with *M. canis* are also frequent. Tinea corporis can be acquired by direct contact with infected persons or by contact with infected scales or hairs deposited on environmental surfaces. *M. canis* infections are usually acquired from infected pets. Not infrequently, a single dermatophyte lesion is responsible for dissemination.

The most typical *clinical lesion* begins as a dry, mildly erythematous, elevated, scaly papule or plaque that spreads centrifugally as it clears centrally to form the characteristic annular lesion responsible for the designation ringworm (Fig. 656–3). At times, plaques with advancing borders may spread over large areas. Grouped pustules are another variant. Most lesions clear spontaneously within several months, but some may become chronic. Central clearing does not always occur, and differences in host response may result in wide variability in the clinical appearance, for example, granulomatous lesions called *Majocchi granuloma* due to penetration of organisms along the hair follicle to the level of the dermis, producing a fungal folliculitis and perifolliculitis, and the kerion-like lesions referred to as *tinea profunda*.

Many skin lesions, both infectious and noninfectious, must be differentiated from the lesions of tinea corporis. Those most frequently confused are granuloma annulare, nummular eczema, pityriasis rosea, psoriasis, seborrheic dermatitis, erythema chronicum migrans, and tinea versicolor. Microscopic examination of KOH wet mount preparations and cultures should always be obtained when fungal infection is considered. Tinea corporis usually does not fluoresce with a Wood lamp.

Tinea corporis usually responds to *treatment* with one of the topical antifungal agents

(e.g., miconazole, clotrimazole, econazole, ketoconazole, terbinafine, naftifine) twice daily for 2–4 wk. In unusually severe or extensive disease, a course of therapy with oral griseofulvin microcrystalline may be required for several weeks. Itraconazole has produced excellent results in many cases with a 1–2 wk course of oral therapy.

Tinea cruris, infection of the groin, occurs most often in adolescent males and is usually caused by the anthropophilic species, *Epidermophyton floccosum* or *Trichophyton rubrum*, but occasionally by the zoophilic species *T. mentagrophytes*.

The initial *clinical lesion* is a small, raised, scaly, erythematous patch on the inner aspect of the thigh; this spreads peripherally, often developing numerous tiny vesicles at the advancing margin. It eventually forms bilateral, irregular, sharply bordered patches with hyperpigmented, scaly centers. In some cases, particularly in infections with *T. mentagrophytes*, the inflammatory reaction is more intense and the infection may spread beyond

Figure 656-3 Circinate lesion of tinea corporis on the shoulder. Note the active papular border, scaling, and relative clearing centrally.

the crural region. The penis is usually not involved in the infection, an important distinction from candidosis. Pruritus may be severe initially but abates as the inflammatory reaction subsides. Bacterial superinfection may alter the clinical appearance, and erythrasma or candidosis may coexist. Tinea cruris is more prevalent in obese persons and in those who perspire excessively and wear tight-fitting clothing.

The *diagnosis* is confirmed by culture and by demonstrating septate hyphae on a KOH preparation of epidermal scrapings. Tinea cruris must be differentiated from intertrigo, allergic contact dermatitis, candidosis, and erythrasma. Bacterial superinfection must be precluded when there is a severe inflammatory reaction.

Patients should be advised to wear loose cotton underwear. Topical *treatment* with an imidazole is recommended for severe infection, especially because these agents are effective in mixed candidal-dermatophytic infections. Pure dermatophytic infection may also be treated with tolnaftate.

Tinea pedis (athlete's foot), infection of the toe webs and soles of the feet, is uncommon in young children but occurs with some frequency in preadolescent and adolescent males. The usual etiologic agents are *T. rubrum, T. mentagrophytes*, and *E. floccosum*.

Most commonly, the lateral toe webs (third to fourth and fourth to fifth interdigital spaces) and the subdigital crevice are fissured, with maceration and peeling of the surrounding skin. Severe tenderness, itching, and a persistent foul odor are characteristic. These lesions may become chronic. This type of infection may involve overgrowth by bacterial flora, including *Micrococcus sedantarius, Brevibacterium epidermidis*, and gram-negative organisms. Less commonly, a chronic diffuse hyperkeratosis of the sole of the foot occurs with only mild erythema. In many cases, two feet and one hand are involved. This type of infection is more refractory to treatment and tends to recur. An inflammatory vesicular type of reaction may occur with *T. mentagrophytes* infection; this type is most common in young children. These lesions involve any area of the foot, including the dorsal surface, and are usually circumscribed. The initial papules progress to vesicles and bullae that may become pustular (Fig. 656–4). A number of factors, such as occlusive footwear and warm, humid weather, predispose to infection. Tinea pedis may be transmitted in shower facilities and swimming pool areas.

Tinea pedis must be differentiated from simple maceration and peeling of the interdigital spaces, which is common in children.

Figure 656-4 Multiple inflammatory bullae of tinea pedis.

Infection with *Candida albicans* and various bacterial organisms (erythrasma) may cause confusion or may coexist with primary tinea pedis. Contact dermatitis, dyshidrotic eczema, atopic dermatitis, and juvenile plantar dermatitis also simulate tinea pedis. Fungal mycelia can be seen on microscopic examination of a KOH preparation or by culture; the fourth toe web provides a high yield of infected scales; a blister top can also be used.

Treatment for mild infections includes simple measures such as avoidance of occlusive footwear, careful drying between the toes after bathing, and the use of an absorbent antifungal powder such as zinc undecylenate. Topical therapy with an azole, such as clotrimazole, miconazole, ketoconazole, or econazole is curative in most cases; each of these agents is also effective against candidal infection. Tolnaftate can be used in uncomplicated dermatophyte infections. Several weeks of therapy may be necessary, and low-grade, chronic infections, particularly those caused by *T. rubrum*, may be refractory. In such patients, oral griseofulvin therapy may effect a cure, but recurrences are common.

Tinea unguium is a dermatophyte infection of the nail plate; it occurs most often in patients with tinea pedis, but it may occur as a primary infection. It can be caused by a number of dermatophytes, of which *T. rubrum* and *T. mentagrophytes* are the most common.

The most superficial form of tinea unguium (i.e., white superficial onychomycosis) is due to *T. mentagrophytes*; it is manifested by irregular single or numerous white patches on the surface of the nail unassociated with paronychial inflammation or deep infection. *T. rubrum* generally causes a more invasive, subungual infection that is initiated at the lateral distal margins of the nail and is often preceded by mild paronychia. The middle and ventral layers of the nail plate, and perhaps the nail bed, are the sites of infection. The nail initially develops a yellowish discoloration and slowly becomes thickened, brittle, and loosened from the nail bed. In advanced infection, the nail may turn dark brown to black and may crack or break off.

Tinea unguium must be differentiated from various dystrophic nail disorders. Changes due to trauma, psoriasis, lichen planus, and eczema all can be confused with tinea unguium. Nails infected with *C. albicans* have several distinguishing features, most prominently pronounced paronychial swelling. Thin shavings taken

from the infected nail, preferably from the deeper areas, should be examined microscopically with KOH and cultured. Repeated attempts may be required to demonstrate the fungus.

The long half-life of itraconazole in the nail has led to promising trials of intermittent short courses of therapy (e.g., double the normal dose for 1 wk of each month for 3–4 mo). Oral terbinafine also shows promise for the treatment of onychomycosis. Terbinafine once daily for 3–4 mo is more effective than itraconazole pulse therapy. Griseofulvin and application of topical fungistatic agents to the nail bed often are ineffective and are not recommended.

Tinea nigra palmaris is a rare but distinctive superficial fungal infection that occurs principally in children and adolescents. It is caused by the dimorphic fungus *Exophiala werneckii*, which imparts a gray-black color to the affected palm. The characteristic lesion is a well-defined hyperpigmented macule; scaling and erythema are rare, and the lesions are asymptomatic. Tinea nigra is often mistaken for a junctional nevus, melanoma, or staining of the skin by contactants. Treatment with Whitfield ointment, undecylenic acid ointment, miconazole, or tincture of iodine is most successful.

CANDIDAL INFECTIONS (CANDIDOSIS, CANDIDIASIS, AND MONILIASIS) (see Chapter 215)

The dimorphic yeasts of the genus *Candida* are ubiquitous in the environment, but *C. albicans* is the one that usually causes candidosis in children. This yeast is not part of the indigenous skin flora, but it is a frequent transient on skin and may colonize the human alimentary tract and the vagina as a saprophytic organism. Certain environmental conditions, notably elevated temperature and humidity, are associated with an increased frequency of isolation of *C. albicans* from the skin. Many bacterial species inhibit the growth of *C. albicans*, and alteration of normal flora by the use of antibiotics may promote overgrowth of the yeast.

Oral Candidosis (Thrush).

See Chapter 215 .

Vaginal Candidosis.

See Chapters 215 and 541 . *C. albicans* is an inhabitant of the vagina in 5–10% of women, and vaginal candidosis is not uncommon in adolescent girls. A number of factors can predispose to this infection, including antibiotic therapy, corticosteroid therapy, diabetes mellitus, pregnancy, and the use of oral contraceptives. The infection is manifested by cheesy white plaques on an erythematous vaginal mucosa and by a thick white-yellow discharge. The disease may be relatively mild or may produce pronounced inflammation and scaling of the external genitals and surrounding skin with progression to vesiculation and ulceration. Patients often complain of severe itching and burning in the vaginal area. Before treatment is initiated, the diagnosis should be confirmed by microscopic examination and/or culture. The infection may be eradicated by insertion of nystatin or imidazole vaginal tablets, suppositories, creams, or foam. If these products are ineffective, the addition of oral nystatin tablets, 1–2 tablets tid for 14 days, may eliminate or decrease the candidal population in the gastrointestinal tract.

Congenital Cutaneous Candidosis.

See Chapter 215 .

Candidal Diaper Dermatitis.

This is a ubiquitous problem in infants and, although relatively benign, is often frustrating because of its tendency to recur. Predisposed infants usually carry *C. albicans* in their intestinal tract, and the warm, moist, occluded skin of the diaper area provides an optimal environment for its growth. A seborrheic, atopic, or primary irritant contact dermatitis usually provides a portal of entry for the yeast.

The primary *clinical manifestation* consists of an intensely erythematous, confluent plaque with a scalloped border and a sharply demarcated edge. It is formed by the confluence of numerous papules and vesiculopustules; satellite pustules, those that stud the contiguous skin, are a hallmark of localized candidal infections. The perianal skin, inguinal folds, perineum, and lower abdomen are usually involved (Fig. 656–5). In males, the entire scrotum and penis may be involved with an erosive balanitis of the perimeatal skin; in females, the lesions may be found on the vaginal mucosa and labia. In some infants, the process is generalized, with erythematous lesions distant from the diaper area; in some cases, the generalized process may represent a fungal id (hypersensitivity) reaction.

Figure 656-5 Erythematous confluent plaque with satellite pustules caused by candidal infection.

The *differential diagnosis* includes other eruptions of the diaper area that may coexist with candidal infection. For this reason, it is important to establish a diagnosis by a KOH preparation or culture.

Treatment consists of applications of an anticandidal agent (nystatin, miconazole, clotrimazole, ketoconazole) with each diaper change or four times daily. Ointments are better tolerated than creams; lotions and creams may cause a burning sensation when applied to irritated skin, and powder may cake and cause erosion due to friction during movement. The combination of a corticosteroid and an antifungal agent is justified if inflammation is severe but may confuse the situation if the diagnosis is not firmly established. Corticosteroid should not be continued for more than a few days. Protection of the diaper area by an application of thick zinc oxide paste overlying the anticandidal preparation may be helpful; the paste is more easily removed with mineral oil than with soap and water. *Fungal id reactions* gradually abate with successful treatment of the diaper dermatitis or may be treated with a mild corticosteroid preparation. When recurrences of diaper candidosis are frequent, it may be helpful to prescribe a course of oral anticandidal therapy to decrease the yeast population in the gastrointestinal tract. Some infants seem to be receptive

hosts for *C. albicans* and may reacquire the organism from a colonized adult.

Intertriginous Candidosis.

This occurs most often in the axillae and groin, under the breasts, under pendulous abdominal fat folds, in the umbilicus, and in the gluteal cleft. Typical lesions are large, confluent areas of moist, denuded, erythematous skin with an irregular, macerated, scaly border. Satellite lesions are characteristic and consist of small vesicles or pustules on an erythematous base. With time, intertriginous candidal lesions may become lichenified, dry, scaly plaques. The lesions develop on skin subjected to irritation and maceration. Candidal superinfection is more likely to occur under conditions that lead to excessive perspiration, especially in obese children and in those with underlying disorders, such as diabetes mellitus. A similar condition, *interdigital candidosis*, commonly occurs in individuals whose hands are constantly immersed in water; fissures occur between the fingers and have red, denuded centers, with an overhanging white epithelial fringe. Similar lesions between the toes may be secondary to occlusive footwear. Treatment is the same as for other candidal infections.

Perianal Candidosis.

Perianal dermatitis develops at sites of skin irritation as a result of occlusion, constant moisture, poor hygiene, anal fissures, and pruritus due to pinworm infestation. It may become superinfected with *C. albicans*, especially in children who are receiving oral antibiotic or corticosteroid medication. The involved skin becomes erythematous, macerated, and excoriated, and the lesions are identical to those of candidal intertrigo or candidal diaper rash. Application of a topical antifungal agent in conjunction with improved hygiene is usually effective. Underlying disorders such as pinworm infection must also be treated (see Chapter 270).

Candidal Paronychia and Onychia.

See Chapter 653 .

Candidal Granuloma.

This is a rare response to an invasive candidal infection of skin. The lesions appear as crusted, verrucous plaques and hornlike projections on the scalp, face, and distal limbs. Affected patients may have single or numerous defects in immune mechanisms and are often refractory to topical therapy. A systemic anticandidal agent may be required for palliation or eradication of the infection.

Chapter 657 - Cutaneous Viral Infections

WART (VERRUCA)

Human papillomaviruses (HPV) cause a spectrum of disease from warts to squamous cell carcinoma of the skin and mucous membranes, including the larynx (see Chapter 243). The incidence of all types of warts is highest in children and adolescents. HPV is spread by direct contact and autoinoculation, but transmission by fomites can occur. The clinical manifestations of infection develop 1 mo or longer after inoculation and depend on the HPV type, of which more than 70 are recognized; the size of the inoculum; the immune status of the host; and the anatomic site.

Clinical Manifestations.

Cutaneous warts develop in 5–10% of children. *Common warts (verruca vulgaris)*, caused most commonly by HPV types 2 and 4, occur most frequently on the fingers, dorsum of the hands, paronychial areas, face, knees, and elbows. They are well-circumscribed papules with a roughened, keratotic, irregular surface. When the surface is pared away, many black dots representing thrombosed dermal capillary loops are often visible. Periungual warts are often painful and may spread beneath the nail plate, separating it from the nail bed. *Plantar warts*, although similar to the common wart, are caused by HPV type 1 and are usually flush with the surface of the sole because of the constant pressure from weight bearing; they may be painful. Similar lesions (palmar) can also occur on the palms. They are sharply demarcated, often with a ring of thick callus. The surface keratotic material must sometimes be removed before the boundaries of the wart can be appreciated. Several contiguous warts (HPV type 4) may fuse to form a large plaque, the so-called *mosaic wart. Flat warts (verruca plana)*, caused by HPV types 2, 3, and 10, are slightly elevated, minimally hyperkeratotic papules that usually remain less than 3?mm in diameter and vary in color from pink to brown. They may occur in profusion on the face, arms, dorsum of the hands, and knees. The distribution of several lesions along a line of cutaneous trauma is a helpful diagnostic feature. Lesions may be

disseminated in the beard area by shaving and from the hairline onto the scalp by combing the hair. *Epidermodysplasia verruciformis*, caused primarily by HPV types 5 and 8, presents with many diffuse verrucous papules. Approximately 25% of cases are familial, occurring by autosomal recessive or X-linked inheritance, and 3–10% of patients have HPV-associated squamous cell carcinoma on sun-exposed skin.

Genital HPV infection occurs in nearly 40% of sexually active adolescents, most commonly as a result of infection with HPV types 6 and 11. *Condylomata acuminata (mucous membrane warts)* are moist, fleshy, papillomatous lesions that occur on the perianal mucosa (Fig. 657–1), labia, vaginal introitus, and perineal raphe and on the shaft, corona, and glans penis. Occasionally they obstruct the urethral meatus or the vaginal introitus. Because they are located in intertriginous areas, they may become moist and friable. When untreated, condylomata proliferate and become confluent, at times forming large cauliflower-like masses. Lesions can also occur on the lips, gingivae, tongue, and conjunctivae. Genital warts in children may occur after inoculation during birth through an infected birth canal, as a consequence of sexual abuse, or from incidental spread from cutaneous warts. A significant proportion of genital warts in children contain HPV types that are usually isolated from cutaneous warts. HPV infection of the cervix is a major risk factor for development of carcinoma, particularly if the infection is due to HPV types 16, 18, 31–33, 35, 39, 42, or 51–54. *Laryngeal (respiratory) papillomas* contain the same HPV types as in anogenital papillomas. Transmission is believed to occur from mothers with genital HPV infection to neonates who aspirate infectious virus during birth.

Pathology.

The various types of warts differ in minor ways but share the basic changes of hyperplasia of the epidermal cells and vacuolation of the spinous keratinocytes, which may contain basophilic intranuclear inclusions (viral particles). Warts are confined to the epidermis and, contrary to the common misconception, do not have “roots.” Parakeratosis, papillomatosis, and eosinophilic cytoplasmic inclusions, thought to represent altered keratohyalin, are additional variable histologic changes. Individuals with impaired cell-mediated immunity are particularly susceptible to HPV infection. Antibodies occur in response to infection but appear to have little protective effect.

Differential Diagnosis.

Common warts are most often confused with molluscum contagiosum. Plantar and palmar warts may be difficult to distinguish from punctate keratoses, corns, and calluses.

Figure 657-1 Condylomata acuminata in the perianal area of a toddler.

In contrast to calluses, warts obliterate normal skin markings. Juvenile flat warts mimic lichen planus, lichen nitidus, angiofibromas, syringomas, milia, and acne. Condylomata acuminata may resemble condylomata lata of secondary syphilis.

Treatment.

Various therapeutic measures are effective in the treatment of warts. More than 50% of warts disappear spontaneously within 2 yr, but failure to treat incurs the risk of spread to other sites. Warts are epidermal lesions and do not produce scarring unless they are managed surgically or treated in an overly aggressive fashion.

Hyperkeratotic lesions (common, plantar, and palmar warts) are more responsive to therapy if the excess keratotic debris is gently pared with a scalpel until thrombosed capillaries are apparent; further paring induces bleeding. Treatment is most successful when done regularly and frequently (e.g., every 2 wk).

Common warts can be destroyed by applications of liquid nitrogen or cantharidin or by light electrodesiccation and curettage. Daily applications of 10–17% lactic acid and 10–17% salicylic acid in flexible collodion is a slow but painless method of removal that is effective in some patients. Recalcitrant warts may respond to 5% 5-*fluorouracil ointment* rubbed into lesions daily. Care must be taken to avoid contact with adjacent normal skin, which may cause undue irritation, erosion, or postinflammatory hyperpigmentation. Plantar and palmar warts may be treated with salicylic and lactic acids in collodion or 40% salicylic acid or urea plasters. After prolonged soaking in lukewarm water, keratotic debris can be removed by an emery board or pumice stone. Occlusive taping without medication for several weeks is also very effective. Condylomata respond best to weekly applications of 25% podophyllin in tincture of benzoin; the medication should be left on the warts for 4–6?hr and then removed by bathing. Condylomata localized to keratinized sites (e.g., buttocks) may not respond to podophyllin. Imiquimod (5% cream) applied three times weekly may be beneficial. Imiquimod is indicated for genital warts but is also helpful in other locations. A moist environment, and daily application may improve efficacy but increase the risk of irritation. Resistant lesions can usually be eradicated by weekly freezing with liquid nitrogen or by treatment with a carbon dioxide laser. Although intralesional injection of 1 million units of interferon-a or -ß three times weekly for 3–4 wk appears to be effective against condylomata, this is not recommended because of a low incidence of effectiveness, high toxicity rate, and high cost. With all types of therapy, care should be taken to protect the surrounding normal skin from irritation.

MOLLUSCUM CONTAGIOSUM

The poxvirus that causes molluscum contagiosum is a large double-stranded DNA virus that replicates in the cytoplasm of host epithelial cells. The three types cannot be differentiated on the basis of clinical appearance, location of lesions, or a patient's age or sex. Type 1 virus causes most infections. The disease is acquired by direct contact with an infected person or from fomites and is spread by autoinoculation. School-aged children who are otherwise well and individuals who are immunosuppressed are affected most commonly. The incubation period is estimated to be 2 wk or longer.

Clinical Manifestations.

Discrete, pearly, skin-colored, dome-shaped, smooth papules vary in size from 1–5?mm. They typically have a central umbilication from which a plug of cheesy material can be expressed (Fig. 657–2). The papules may occur anywhere on the body, but the face, eyelids, neck, axillas, and thighs are sites of predilection. They may be found in clusters on the genitals or in the groin of adolescents and may be associated with other venereal diseases in sexually active individuals. Lesions commonly involve the genital area in children but in most cases are not acquired by sexual transmission; search

Figure 657-2 Grouped papules of molluscum contagiosum on the face.

should be undertaken, however, for other signs of sexual abuse. Lesions on the eyelid margin can produce unilateral conjunctivitis; rarely, lesions may appear on the conjunctiva or cornea. Mild surrounding erythema or an eczematous dermatitis may accompany the papules. Lesions on patients with AIDS tend to be large and numerous, particularly on the face; exuberant lesions may also be found in children with leukemia and other immunodeficiencies. Children with atopic dermatitis are susceptible to widespread involvement in areas of dermatitis.

Differential Diagnosis.

This includes trichoepithelioma, basal cell carcinoma, ectopic sebaceous glands, syringoma, hidrocystoma, keratoacanthoma, and warty dyskeratoma. In individuals with AIDS, cryptococcosis may be indistinguishable clinically from molluscum contagiosum; rarely, coccidioidomycosis, histoplasmosis, or *Penicillium marneffei* infection masquerades with molluscum-like lesions in an immunocompromised host.

Pathology and Diagnosis.

The epidermis is hyperplastic and hypertrophied, extending into the underlying dermis and projecting above the skin surface. The molluscum papule consists of a lobulated adhesive mass of virus-infected epidermal cells. Eosinophilic viral inclusion bodies (Henderson-Patterson or molluscum bodies) become more prominent as the cells move upward from the basal layer to the stratum corneum. The central plug of material, which is composed of virus-laden cells, may be shelled out from a lesion (see Treatment) and examined under the microscope with 10% potassium hydroxide or Wright or Giemsa stain. The rounded, cup-shaped mass of homogeneous cells, often with identifiable lobules, is diagnostic. Specific antibody against molluscum contagiosum virus is detectable in most infected individuals but is of uncertain immunologic significance. Cell-mediated immunity is thought to be important in host defense.

Treatment.

Molluscum contagiosum is a self-limited disease; the average attack lasts 6–9 mo. However, lesions can persist for years, can spread to distant sites, and may be transmitted to others. Affected patients should be advised to avoid shared baths and towels until the infection is clear. Infection may spread rapidly and produce hundreds of lesions in children with atopic dermatitis or immunodeficiency. A brief 6–9?sec application of liquid nitrogen is very effective and, in most instances, is a common treatment. The papules can also be destroyed by expressing the plug with a needle, a sharp curette, or a comedo extractor. Cantharidin 0.9% is a popular therapy and may be applied to each lesion without occlusion and frequently causes enough inflammation to facilitate spontaneous extrusion of the plug. Treatment of a few lesions is occasionally followed by resolution of the others. Sometimes, however, treatment with cantharidin results in formation of a rosette of new lesions encircling

the site of treatment. Facial molluscum are more cosmetically upsetting to children and parents, and are more difficult to treat with destructive modalities such as liquid nitrogen or cantharidin. Tretinoin or imiquimod applied topically may be beneficial if not excessively irritating. Molluscum is an epidermal disease and should not be overtreated so that scarring results. A lesion-free period of 4 mo can be regarded as a cure.

Chapter 658 - Arthropod Bites and Infestations

ARTHROPOD BITES

Arthropod bites are a common affliction of children and occasionally pose a problem in diagnosis. A patient may be unaware of the source of the lesions or deny being bitten, making interpretation of the eruption difficult. In these cases, knowledge of the habits, life cycle, and clinical signs of the more common arthropod pests of humans may help lead to a correct diagnosis. The principal classes of arthropods that cause skin injury to humans are listed in Box 658–1 . Some of the important dermatoses caused by arthropod bites and infestations are covered in this chapter; others are discussed in chapters addressing infectious organisms (Part XVI).

Clinical Manifestations.

The type of reaction that occurs after an arthropod bite depends on the species of insect and the age group and reactivity of the human host. Arthropods may cause injury to a host by various mechanisms, including mechanical trauma, such as the lacerating bite of a tsetse fly; invasion of host tissues, as in myiasis; contact dermatitis, as seen with repeated exposure to cockroach antigens; granulomatous reaction to retained mouth parts; transmission of systemic disease; injection of irritant cytotoxic or pharmacologically active substances, such as hyaluronidase, proteases, peptidases, and phospholipases in sting venom; and induction of anaphylaxis. Most reactions to arthropod bites, however, depend on antibody

Box 658-1. Arthropods that Cause Human Skin Disease

Class Arachnida (four pairs of legs): mites, spiders, ticks

Class Chilopoda: centipedes

Class Diplopoda: millipedes

Class Insecta (three pairs of legs):

- Order Diptera: mosquitoes, flies
- Order Siphonaptera: fleas
- Order Hymenoptera: ants, bees, wasps
- Order Anoplura: lice
- Order Hemiptera: bedbugs, kissing bugs
- Order Coleoptera: beetles
- Order Lepidoptera: butterflies, moths

formation to antigenic substances in saliva or venom. The type of reaction is determined primarily by the degree of previous exposure to the same or a related species of arthropod. When someone is bitten for the first time, no reaction develops. An immediate petechial reaction is occasionally seen, however, in newborn babies after a mosquito bite. After repeated bites, sensitivity develops, producing a pruritic papule approximately 24?hr after the bite; this is the most common reaction seen in young children. With prolonged, repeated exposure, a wheal develops within minutes after a bite, followed 24?hr later by papule formation; this combination of reactions is seen commonly in older children. By adolescence or adulthood, only a wheal may form, unaccompanied by the delayed papular reaction. Thus, adults may be unaffected in the same household as affected children. Ultimately, as a person becomes insensitive to the bite, no reaction occurs at all. This stage of nonreactivity is maintained only as long as the individual continues to be bitten regularly. Individuals in whom papular urticaria develops are in the transitional phase between development of primarily a delayed papular reaction and development of an immediate urticarial reaction.

Arthropod bites may occur as solitary, numerous, or profuse lesions, depending on the feeding habits of the perpetrator. For example, fleas tend to sample their host several times within a small localized area, whereas mosquitoes tend to attack a host at more randomly scattered sites. *Delayed hypersensitivity reactions* to insect bites, the predominant lesions in the young and uninitiated, are characterized by firm, persistent papules that may become hyperpigmented and are often excoriated and crusted. Pruritus may be mild or severe, transient or persistent. A central punctum is usually visible but may disappear as the lesion ages or is scratched. The *immediate hypersensitivity reaction* is characterized by an erythematous, evanescent wheal. If edema is marked, the wheal may be surmounted by a tiny vesicle. Certain beetles produce bullous lesions through the action of cantharidin, and hemorrhagic nodules and ulcers may be caused by various insects, including beetles and spiders. Bites on the lower extremities are more likely to be severe or persistent or become bullous than those located elsewhere. Complications of arthropod bites include development of impetigo, folliculitis, cellulitis, lymphangitis, and severe anaphylactic hypersensitivity reactions, particularly after the bite of certain Hymenoptera. The histopathologic changes are variable, depending on the arthropod, the age of the lesion, and the reactivity of the host. Acute urticarial lesions tend to show central vesiculation in which eosinophils are numerous. Papules most commonly show dermal edema and a mixed, superficial and deep perivascular inflammatory infiltrate, often including a number of eosinophils. At times, however, the dermal cellular infiltrate is so dense that a lymphoma is suspected. Retained mouth parts may stimulate a foreign body type of granulomatous reaction.

Papular urticaria occurs principally in the 1st decade of life, during the warmer months of the year. The most common culprits are species of fleas, mites, bedbugs, gnats, mosquitoes, chiggers, and animal lice. Individuals with papular urticaria have predominantly transitional lesions in various stages of evolution between delayed-onset papules and immediate-onset wheals. The most characteristic lesion is an edematous red-brown papule; an individual lesion frequently starts as a wheal that in turn is replaced by a papule. A given bite may incite an id reaction at distant sites of quiescent bites in the form of erythematous macules, papules, or urticarial plaques. The disorder is characterized by a temporary arrest at a transitional phase; after a season or two, however, the reaction progresses from a transitional to a primarily immediate hypersensitivity urticarial reaction.

One of the most commonly encountered arthropod bites is that due to human, cat, or dog *fleas* (family Pulicidae). Eggs, which are generally laid in dusty areas and cracks between floorboards, give rise to larvae that then form cocoons. The cocoon stage can persist for up to 1 yr, and the animal emerges in response to vibrations from footsteps, accounting for the assaults that frequently befall the new owners of a recently reopened dwelling. Adult dog fleas can live without a blood meal for approximately 60 days. Attacks from fleas are more likely to occur when the fleas do not have access to their usual host; for example, cat or dog fleas are more voracious and problematic when one visits an area frequented by the pet than when the pet is encountered directly. Flea bites tend to be grouped in lines or irregular clusters. Fleas are often not seen on the body of a pet; diagnosis of flea bites, however, is aided by examination of debris from the animal's bedding material. The debris is collected by shaking the bedding into a plastic bag and examining the contents for fleas or their eggs, larvae, or feces.

Treatment.

This is directed at alleviation of pruritus by oral antihistamines, cool compresses, and soothing lotions such as calamine, to which 0.25% menthol and 0.5% phenol can be added. Topical corticosteroid creams are rarely effective, and topical antihistamines

are potent sensitizers and have no role in the treatment of insect bite reactions. A short course of systemic steroids may be helpful if many severe reactions occur, particularly around the eyes. Insect repellents containing diethyltoluamide (DEET) may afford moderate protection against mosquitoes, fleas, flies, chiggers, and ticks but are relatively ineffective against wasps, bees, and hornets. DEET must be applied to exposed skin and clothing to be effective. The most effective protection against mosquitoes, the human body louse, and other blood-feeding arthropods is use of DEET and permethrin-impregnated clothing; these measures are not effective, however, against the phlebotomine sandfly, which transmits leishmaniasis. Advocates of treatment with B-complex vitamins or thiamine hydrochloride maintain that these agents impart an offensive odor to sweat, warding off mosquitoes; this claim has not been substantiated by clinical trials.

An effort should be made to identify and eradicate the etiologic agent. Pets should be carefully inspected; crawl spaces, eaves, and other sites of the house or outbuildings frequented by animals and birds should be decontaminated; and baseboard crevices, mattresses, rugs, furniture, and animal sleeping quarters should be decontaminated. Agents that are effective for ridding the home of fleas include lindane, pyrethroids, and organic thiocyanates. Flea-infested pets may be treated with powders containing rotenone, pyrethroids, malathion, or methoxychlor.

INFESTATIONS

Scabies.

Scabies is caused by burrowing and release of toxic or antigenic substances by the female mite *Sarcoptes scabiei* var. *hominis*. The most important factor that determines spread

of scabies is the extent and duration of physical contact with an affected individual; the children and sexual partner of an affected individual are most at risk. Scabies is transmitted only rarely by fomites because the isolated mite dies within 2–3 days.

CLINICAL MANIFESTATIONS.

In an immunocompetent host, scabies is frequently heralded by intense pruritus, particularly at night. The first sign of the infestation often consists of 1–2?mm red papules, some of which are excoriated, crusted, or scaling. Threadlike burrows are the classic lesion of scabies but may not be seen in infants. In infants, bullae and pustules are relatively common; the eruption may also include wheals, papules, vesicles, and a superimposed eczematous dermatitis; and the palms, soles (Fig. 658–1*B*), face, and scalp are often affected. In older children and adolescents, the clinical pattern is similar to that in adults, in whom preferred sites are the interdigital spaces, wrist flexors, anterior axillary folds, ankles, buttocks, umbilicus and belt line, groin, genitals in men, and areolas in women (see Fig. 658–1*A*); the head, neck, palms, and soles are generally spared. Red-brown nodules, most often located in covered areas such as the axillae, groin, and genitals, predominate in the less common variant called nodular

Figure 658-1 *A*, Eczematous dermatitis, papules, and nodules of human scabies. *B*, Vesiculopustular lesions of scabies on the soles of an infant. *C*, Human scabies mite obtained from scraping.

scabies. Untreated, scabies may lead to eczematous dermatitis, impetigo, ecthyma, folliculitis, furunculosis, cellulitis, lymphangitis, and id reaction. Children have been reported to develop glomerulonephritis as a result of streptococcal impetiginization of scabies lesions. In some tropical areas, scabies is the predominant underlying cause of pyoderma. A latent period of approximately 1 mo follows an initial infestation; thus, itching may be absent and lesions may be relatively inapparent in contacts who are asymptomatic carriers. On reinfestation, however, reactions to mite antigens are noted within hours.

ETIOLOGY AND PATHOGENESIS.

An adult female mite measures approximately 0.4?mm in length, has four sets of legs, and has a hemispheric body marked by transverse corrugations, brown spines, and bristles on the dorsal surface. A male mite is approximately half her size and is similar in configuration. After impregnation on the skin surface, a gravid female exudes a keratolytic substance and burrows into the stratum corneum, often forming a shallow well within 30?min. She gradually extends this tract by 0.5–5?mm/24?hr along the boundary with the stratum granulosum. She deposits one to three oval eggs and numerous brown fecal pellets (scybala)

daily. When egg laying is completed, in 4–5 wk, she dies within the burrow. The eggs hatch in 3–5 days, releasing larvae that move to the skin surface to molt into nymphs. Maturity is achieved in about 2–3 wk. Mating occurs, and the gravid female invades the skin to complete the life cycle.

DIAGNOSIS.

This can often be made clinically but is confirmed by microscopic identification of mites (see Fig. 658–1*C*), ova, and scybala in epithelial debris. Scrapings are most often positive when obtained from burrows, eczematous lesions, or fresh papules. A reliable method is application of a drop of mineral oil on the selected lesion, scraping of it with a No. 15 blade, and transfer of the oil and scrapings to a glass slide.

The *differential diagnosis* depends on the types of lesions present. Burrows are virtually pathognomonic for human scabies. Papulovesicular lesions are confused with papular urticaria, canine scabies, chickenpox, viral exanthems, drug eruptions, dermatitis herpetiformis, and folliculitis. Eczematous lesions may mimic atopic dermatitis and seborrheic dermatitis, and the less common bullous disorders of childhood may be suspected in infants with predominantly bullous lesions. Nodular scabies is frequently misdiagnosed as urticaria pigmentosa and Langerhans cell

hystiocytosis. The histopathologic appearance of nodular scabies, consisting of a deep, dense, perivascular infiltrate of lymphocytes, histiocytes, plasma cells, and atypical mononuclear cells, may mimic malignant lymphoid neoplasms.

TREATMENT.

Application of permethrin 5% cream (Elimite) or 1% lindane cream or lotion to the entire body from the neck down, with particular attention to intensely involved areas, is standard therapy. Scabies is frequently found above the neck in infants, however, also necessitating treatment of the scalp. The medication is left on the skin for 8–12?hr; if necessary, it may be reapplied in 1 wk for another 8–12?hr period. Because lindane is potentially neurotoxic, the vulnerability of small infants to percutaneous absorption dictates caution in prescribing it for them. Signs of lindane toxicity include nausea, vomiting, weakness, tremors, irritability, disorientation, seizures, and respiratory compromise. Systemic absorption and toxicity of lindane can be minimized by not applying the medication to warm, moist skin; not repeating an application within 7 days; and not using the medication on children who are underweight or malnourished or have extensive areas of inflamed, denuded, or secondarily infected skin. Permethrin 5% cream is a slightly more effective scabicide than lindane but is more expensive. It is poorly absorbed, rapidly metabolized by tissue esterases, and therefore of very low toxicity. For infants younger than 2 mo, alternative therapy includes 6% sulfur in petrolatum applied for three consecutive 24-hr periods. Topical sulfur ointment is messy and malodorous, stains clothing, and commonly causes irritant dermatitis. No controlled studies of its efficacy and safety have been published in recent years. Permethrin 5% cream is a better alternative for infants. Crotamiton cream or lotion is not recommended because of lack of efficacy and toxicity data.

Transmission of mites is unlikely more than 24?hr after treatment. Pruritus, which is due to hypersensitivity to mite antigens, may persist for a number of days and may be alleviated by a topical corticosteroid preparation. If pruritus persists for more than 2 wk after treatment, the patient should be reexamined for mites. Nodules are extremely resistant to treatment and may take several months to resolve. The entire family should be treated, as should caretakers of the infested child. Clothing, bed linens, and towels should be thoroughly laundered.

NORWEGIAN SCABIES.

This variant of human scabies is highly contagious and occurs mainly in individuals who are mentally and physically debilitated, particularly those who are institutionalized and those with Down syndrome; in patients with poor cutaneous sensation, such as those with leprosy or syringomyelia; in patients who have severe systemic illness such as leukemia or diabetes; and in immunosuppressed patients such as those with HIV infection. Affected individuals are infested by myriad mites that inhabit the crusts and exfoliating scales of the skin and scalp. The nails may become thickened and dystrophic; the subungual debris is densely populated by mites. The infestation is often accompanied by generalized lymphadenopathy and eosinophilia. On microscopic examination, one sees massive orthokeratosis and parakeratosis with numerous interspersed mites, psoriasiform epidermal hyperplasia, foci of spongiosis, and neutrophilic abscesses. Norwegian scabies is thought to represent a deficient host immune response to the organism. Management is difficult, requiring scrupulous isolation measures, removal of the thick scales, and repeated but careful applications of antiscabietic preparations. Ivermectin has been used successfully as single-dose therapy in refractory cases, particularly in HIV-infected patients; the Food and Drug Administration (FDA) has not approved it for treatment of scabies nor for any application in children younger than 5 yr.

CANINE SCABIES.

This is caused by *S. scabiei* var. *canis,* the dog mite that is associated with mange. The eruption in humans, which is most frequently acquired by cuddling an infested puppy, consists of tiny papules, vesicles, wheals, and excoriated eczematous plaques. Burrows are not present because the mite infrequently inhabits human stratum corneum. The rash is pruritic and has a predilection for the arms, chest, and abdomen, the usual sites of contact with dogs. Onset is sudden and usually follows exposure by 1–10 days, possibly resulting from development of a hypersensitivity reaction to mite antigens. Recovery of mites or ova from scrapings of human skin is rare. The disease is self-limited because humans are not a suitable host; bathing and changing clothes are generally sufficient. Removal or treatment of the infested animal, however, is also necessary. Symptomatic therapy for itching is helpful. In rare cases in which mites are demonstrated in scrapings from an affected child, they can be eradicated by the same measures applicable to human scabies.

Other mites that occasionally bite humans include the *chigger* or harvest mite *(Eutrombicula alfreddugesi)*, which prefers to live on grass, shrubs, vines, and stems of grain. Larvae have hooked mouthparts, which allow the chigger to attach to the skin, but not to burrow, to obtain a blood meal, most commonly on the lower legs. *Avian mites* may affect those who come into close contact with chickens or pet gerbils. Humans may occasionally be assaulted by avian mites that have infested a nest outside a window, an attic, heating vents, or an air conditioner. The dermatitis is variable, including grouped papules, wheals, and vesicular lesions on the wrists, neck, breasts, umbilicus, and anterior axillary folds. A prolonged investigation is often undertaken before the cause and source of the dermatitis are discovered.

Pediculosis.

Three types of lice are obligate parasites of the human host: body or clothing lice *(Pediculus humanus corporis)*, head lice *(Pediculus humanus capitis)*, and pubic or crab lice *(Phthirus pubis)*. Only the body louse serves as a vector of human disease (typhus, trench fever, relapsing fever). Body and head lice have similar physical characteristics; they are about 2–4?mm in length. Pubic lice are only 1–2?mm in length and are greater in width than length, giving them a crablike appearance. Female lice live for approximately 1 mo and deposit 3–10 eggs daily on the human host; body lice, however, generally lay eggs in or near the seams of clothing. The ova or nits are glued to hairs or fibers of clothing but not directly on the body. Ova hatch in 1–2 wk and require another week to mature; once the eggs hatch, the nits remain attached to the hair as empty sacs of chitin. Freshly hatched larvae die unless a meal is obtained within approximately 24?hr and every few days thereafter. Both nymphs and adult lice feed on human blood, injecting their

salivary juices into the host and depositing their fecal matter on the skin. Symptoms of infestation do not appear immediately but develop as an individual becomes sensitized. *The hallmark of all types of pediculosis is pruritus.*

Pediculosis corporis is rare in children except under conditions of poor hygiene, especially in colder climates when the opportunity to change clothes on a regular basis is lacking. The parasite is transmitted mainly on contaminated clothing or bedding. The primary lesion is an intensely pruritic small red macule or papule with a central hemorrhagic punctum located on the shoulders, trunk, or buttocks. Additional lesions include excoriations, wheals, and eczematous, secondarily infected plaques. Massive infestation may be associated with constitutional symptoms of fever, malaise, and headache. Chronic infestation may lead to "vagabond's skin," which is manifested as lichenified, scaling, hyperpigmented plaques, most commonly on the trunk. Lice are found on the skin only transiently when they are feeding; at other times, they inhabit the seams of clothing. Nits are attached firmly to fibers in the cloth and may remain viable for up to 1 mo. Nits hatch when they encounter warmth from the host's body when the clothes are worn again. Therapy consists of improved hygiene and hot water laundering of all infested clothing and bedding; a uniform temperature of 65℃, wet or dry, for 15–30?min kills all eggs and lice. Alternatively, eggs hatch and nymphs starve if clothing is stored for 2 wk at 75–85℉. For people who are unable to change clothes, the clothes may be dusted while inside out with 10% lindane powder; the effect lasts for approximately 1 mo. Lindane lotion or permethrin cream applied for 8–12?hr can be used to eradicate any eggs and lice that happen to be on body hair.

Pediculosis capitis is an intensely pruritic infestation of lice in the scalp hair. Head-to-head contact as well as fomites are important modes of transmission. In summer months in many areas of the United States and in the tropics at all times of the year, shared combs, brushes, or towels have a more important role in louse transmission. Translucent 0.5-mm eggs are laid near the proximal portion of the hair shaft and become adherent to one side of the hair shaft. A nit cannot be moved along or knocked off the hair shaft with the fingers. Secondary pyoderma, after trauma due to scratching, may result in matting together of the hair and cervical and occipital lymphadenopathy. Hair loss does not result from pediculosis but may accompany the secondary pyoderma. Head lice are a major cause of numerous pyodermas of the scalp, particularly in tropical environments. Lice are not always visible, but nits are detectable on the hairs, most commonly in the occipital region and above the ears, rarely on beard or pubic hair. Dermatitis may also be noted on the neck and pinnae. An id reaction, consisting of erythematous patches and plaques, may develop, particularly on the trunk. For unknown reasons, head lice infrequently infest blacks.

Brushing and combing of the hair regularly helps to reduce the number of lice and eggs and helps to minimize the severity of the infestation. The *treatments* of choice are 0.5% malathion oris permethrin 1% cream rinse (Nix) applied for 10?min with a repeat application in 7–10 days. Alternative treatments include natural pyrethrin shampoos (RID; A-200 Pyrinate liquid, shampoo, or gel; R & C shampoo; Barc; Paratrol; Paranit; Triple X) and 1% lindane shampoo (Kwell) for 10?min with a repeat application in 7–10 days. Malathion 0.5% in isopropanol (Ovide lotion) is FDA approved for the treatment of head lice and should be applied to dry hair until hair and scalp are wet, and left on for 12 hours. Malathion may be useful in cases of pyrethrin or permethrin resistance. Malathion, like lindane shampoo, is not indicated for use in neonates and infants. The combination of permethrin plus oral trimethoprim-sulfamethoxazole is also highly effective and may be useful in hard to treat cases or recurrent infestations. All household members should be treated at the same time. Nits can be removed with a fine-toothed comb after a 1:1 vinegar:water rinse or, if tenacious, after application of a creme rinse containing 8% formic acid, which dissolves the chitin attaching the nits to the hair shafts. Clothing and bed linens should be laundered in very hot water or dry-cleaned; brushes and combs should be discarded or coated with a pediculicide for 15?min and then thoroughly cleaned in boiling water.

Pediculosis pubis is transmitted by skin-to-skin or sexual contact with an infested individual; the chance of acquiring the lice by one sexual exposure is approximately 95%. The infestation is usually encountered in adolescents, although small children may occasionally acquire pubic lice on the eyelashes. Patients experience moderate to severe pruritus and may develop a secondary pyoderma from scratching. Excoriations tend to be shallower and the incidence of secondary infection is lower than in pediculosis corporis. Maculae ceruleae are steel-gray spots, usually less than 1?cm in diameter, which may appear in the pubic area and on the chest, abdomen, and thighs. Oval translucent nits, which are firmly attached to the hair shafts, may be visible to the naked eye or may be readily identified by a hand lens or by microscopic examination (Fig. 658–2). Grittiness, as a result of adherent nits, may sometimes be detected when the fingers are run through infested hair. Adult lice are difficult to detect because of their lower level of activity and smaller, translucent body compared with head or body lice. Because pubic lice may occasionally wander or be transferred to other sites on fomites, terminal hair on the trunk, thighs, axillary region, beard area, and eyelashes should be examined for nits. The coexistence of other venereal diseases should be considered.

Treatment by a 10-min application of a pyrethrin preparation is usually effective. Re-treatment may be required in 7–10 days. The shampoo form of lindane, which requires a 10-min application time, is an alternative choice, but lindane cream and lotion are no longer recommended for treatment of pubic lice. Infestation of eyelashes is eradicated by petrolatum applied three to five times/24?hr for 8–10 days. A less safe but effective alternative is 0.25% physostigmine ophthalmic ointment applied twice daily for 3 days. Clothing, towels, and bed linens

Figure 658-2 Intact nit on a human hair.

---

may be contaminated with nit-bearing hairs and should be thoroughly laundered or dry-cleaned.

Seabather's Eruption.

Seabather's eruption is a severely pruritic dermatosis of inflammatory papules that develops within approximately 12?hr of bathing in salt water, primarily on body sites that were covered by a bathing suit. The eruption has been described primarily in waters of Florida and the Caribbean. Lesions, which may include pustules, vesicles,

and urticarial plaques, are more numerous in those individuals who keep their bathing suit on for an extended period after leaving the water. The eruption may be accompanied by systemic symptoms of fatigue, malaise, fever, chills, nausea, and headache; approximately 40% of children younger than 16 yr had fever in one large series. Duration of the pruritus and skin eruption is 1–2 wk. Histopathologically, lesions consist of a superficial and deep perivascular and interstitial infiltrate of lymphocytes, eosinophils, and neutrophils. The eruption appears to be due to an allergic hypersensitivity reaction to venom from larvae of the thimble jellyfish *(Linuche unguiculata)*. Treatment is largely symptomatic; potent topical corticosteroids have been shown to provide relief to some patients.

Chapter 659 - Acne

ACNE VULGARIS

Acne, particularly the comedonal form, occurs in approximately 80% of adolescents.

Pathogenesis.

Lesions of acne vulgaris develop in sebaceous follicles, which consist of a large, multilobular sebaceous gland that drains its products into the follicular canal. The initial lesion of acne is a *comedo*, which is a dilated epithelium-lined follicular sac filled with lamellated keratinous material, lipid, and bacteria. An open comedo, known as a blackhead, has a patulous pilosebaceous orifice that permits visualization of the plug. An open comedo less commonly becomes inflammatory than a closed comedo or whitehead, which has only a pinpoint opening. An inflammatory papule or nodule develops from a comedo that has ruptured and extruded its follicular contents into the subadjacent dermis, inducing a neutrophilic inflammatory response. If the inflammatory reaction is close to the surface, a papule or pustule develops; if the inflammatory infiltrate develops deeper in the dermis, a nodule forms. Suppuration and an occasional giant cell reaction to the keratin and hair are the cause of nodulocystic lesions; these are not true cysts but liquefied masses of inflammatory debris.

The primary pathogenetic alterations in acne are (1) abnormal keratinization of the follicular epithelium, resulting in impaction of keratinized cells within the follicular lumen, (2) increased sebaceous gland production of sebum, (3) proliferation of *Propionibacterium acnes* within the follicle, and (4) inflammation. At puberty, the sebaceous gland enlarges and sebum production increases in response to the increased activities of androgens of primarily adrenal origin. Comedonal acne, particularly of the central face, is frequently the first sign of pubertal maturation. The prevalence and severity of acne correlate with pubertal development and amount of sebum production. Initiation of acne in prepubertal children age 7–10 yr correlates significantly with the amount of wax esters in skin surface lipids and the concentration of serum androgenic steroid dehydroepiandrosterone sulfate (DHEA-S) secreted primarily by the adrenal glands. DHEA-S levels are not elevated, however, in the serum of many individuals with acne. DHEA-S may act locally, however, to stimulate sebum production by the sebaceous glands after being metabolized in hair follicle dermal papillae and sebaceous glands by 5a-reductase to more potent androgens such as 5a-dihydrotestosterone. Other sex steroid hormones such as testosterone and estradiol may also have a role in enhancing sebum production. A significant number of women with acne (25–50%), particularly those with relatively mild papulopustular acne, note that their acne flares approximately 1

wk before menstruation. The pathogenesis of this phenomenon is unknown.

Freshly formed sebum consists of a mixture of triglycerides, wax esters, squalene, and sterol esters. Normal follicular bacteria produce lipases that hydrolyze sebum triglycerides to free fatty acids; those of medium chain length (C8–C14) may be provocative factors in initiating an inflammatory reaction. Sebum also provides a favorable substrate for proliferation of bacteria. Sebaceous follicles are colonized by organisms of three types: an anaerobic diphtheroid, *P. acnes*; coagulase-negative *Staphylococcus epidermidis*; and a dimorphic yeast, *Pityrosporum ovale*. Each of these organisms possesses lipolytic enzymes; however, *P. acnes* appears to be largely responsible for the formation of free fatty acids. It is probable that bacterial proteases, hyaluronidases, and hydrolytic enzymes produce biologically active extracellular materials that increase the permeability of the follicular epithelium. Chemotactic factors released by the intrafollicular bacteria attract neutrophils and monocytes. Lysosomal enzymes from the neutrophils, released in the process of phagocytizing the bacteria, further disrupt the integrity of the follicular wall and intensify the inflammatory reaction.

Clinical Manifestations.

Acne vulgaris is characterized by four basic types of lesions: open and closed comedones, papules, pustules, and nodulocystic lesions. One or more types of lesions may predominate; in its mildest form, which is often seen early in adolescence, lesions are limited to comedones on the central area of the face. Lesions may also involve the chest, upper back, and deltoid areas. A predominance of lesions on the forehead, particularly closed comedones, is often attributable to prolonged use of greasy hair preparations (pomade acne). Marked involvement on the trunk is most often seen in males. Lesions often heal with temporary postinflammatory erythema and hyperpigmentation; pitted, atrophic, or hypertrophic scars may be interspersed, depending on the severity, depth, and chronicity of the process. Diagnosis of acne is rarely difficult, although flat warts, folliculitis, and other types of acne may be confused with acne vulgaris.

Treatment.

No evidence shows that early treatment, with the exception of isotretinoin, alters the course of acne. Acne can be

---

controlled and severe scarring prevented, however, by judicious maintenance therapy that is continued until the disease process has abated spontaneously. Therapy must be individualized and aimed at preventing microcomedo formation through reduction of follicular hyperkeratosis, sebum production, the *P. acnes* population in follicular orifices, and free fatty acid production. Initial control takes at least 4–8 wk (Box 659–1). It is also important to address the potentially severe emotional impact of acne on adolescents.

The pediatrician must be aware of the frequently poor correlation between acne severity and psychosocial impact, particularly in adolescents. As adolescents become preoccupied with their appearance, offering treatment even to the youngster whose acne is mild may enhance self-image.

DIET.

Little evidence shows that ingestion of particular foods can trigger acne flares. When a patient is convinced that certain dietary items exacerbate acne, it is prudent to omit those foods; however, it is unnecessary to impose unwarranted dietary restrictions.

CLIMATE.

Climate appears to influence acne in that improvement frequently occurs during summer and flares are more common during winter. Remission during summer may relate, in part, to the relative absence of stress. Emotional tension and fatigue seem to exacerbate acne in many individuals; the mechanism is unclear but has been proposed to relate to an increased adrenocortical response.

CLEANSING.

Cleansing with soap and water removes surface lipid and renders the skin less oily in appearance, but no evidence shows that surface lipid has a role in generating acne lesions. Only superficial drying and peeling are achieved by cleansing, and almost any mild soap or astringent is adequate. Repetitive cleansing can be harmful because it irritates and chaps the skin. Cleansing agents that contain abrasives and keratolytic agents, such as sulfur, resorcinol, and salicylic acid, may temporarily remove sebum from the skin surface. They exert a mild drying and peeling effect and suppress lesions to a limited degree. They do not, however, prevent microcomedones from forming. No evidence shows that preparations containing alcohol or hexachlorophene decrease acne because surface bacteria are not involved in the pathogenesis. Greasy cosmetic and hair preparations must be discontinued because they exacerbate pre-existing acne and cause further plugging of follicular pores. Manipulation and squeezing of facial lesions only ruptures intact lesions and provokes a localized inflammatory reaction.

Box 659-1. Typical Treatment Regimens for Acne

COMEDONAL ACNE

Topical tretinoin, adapalene, or tazarotene applied daily

Salicylic acid

Azelaic acid

MILD PAPULOPUSTULAR ACNE

Benzoyl peroxide

Topical gel preparations of benzoyl peroxide with either clindamycin or erythromycin

Oral doxycycline or minocycline 75–100?mg twice daily plus topical retinoid

SEVERE PAPULOPUSTULAR OR NODULAR ACNE

Oral doxycycline or minocycline plus topical retinoid

Isotretinoin 1?mg/kg a day

From Webster GF: Acne vulgaris. Br Med J 2002;325:475–8.

TOPICAL THERAPY.

The most effective topical preparations, particularly for comedones and papulopustular acne, include the benzoyl peroxide gels, retinoic acid, adapalene, and topical antibiotics. *Benzoyl peroxide* is an organic peroxide and oxidizing agent that dries and peels the skin, inhibits triglyceride hydrolysis and production of free fatty acids, is bacteriostatic for *P. acnes,* and causes follicular desquamation, disimpacting the follicle. Preparations are available in concentrations of 2.5%, 5%, and 10% prescription gels and 5% and 10% over-the-counter lotions. Benzoyl peroxide should be applied as a thin film, initially every other day, advancing over 2–3 wk to once-daily use as tolerated; the incidence of irritant or allergic contact dermatitis is 1%. Water-based gels are less irritating than alcohol-based ones, particularly for patients with atopic dermatitis or otherwise sensitive skin. Over-the-counter lotions are less effective than prescription gels.

Tretinoin (Retin-A), a derivative of retinoic acid, is the single most effective agent for treatment of comedonal acne. It affects keratinization in the sebaceous follicle by increasing turnover of epidermal cells and by decreasing the cohesiveness of the squamous cells; it thus aids in elimination of keratinous plugs. Erythema and peeling may be expected, particularly on initiation of therapy, and pustular flares from rupture of microcomedones are common. Flares may be minimized by starting treatment with benzoyl peroxide 2–3 wk before tretinoin. It may be applied once daily, 30?min after washing, in the form best tolerated (0.025% cream, 0.05% cream, 0.1% cream, 0.01% gel, 0.025% gel, and 0.05% liquid in increasing order of potency). Typically, 0.025% cream is prescribed initially; the strength of the formulation is increased sequentially until adequate control, without undue irritation, is achieved. Optimal results are not seen for 3–6 mo. Increased sensitivity to sunlight may occur, necessitating use of a sunscreen. Tazarotene an acetylinic retinoid (0.1% gel), is more effective in reducing noninflammatory lesions and equally effective in reducing inflammatory lesions as tretinoin (0.025%); it is equally effective as adapalene gel (0.1%). Erythema, burning, pruritus and peeling may be more common than with these other topical agents.

Adapalene (Differin gel), a derivative of naphthoic acid, is comedolytic and anti-inflammatory. A 0.1% gel may be more effective than 0.025% tretinoin gel and may have fewer side effects.

Topical antibiotics for use in patients with acne include clindamycin and erythromycin; they may be applied once or twice daily. Although not as effective as orally administered antibiotics or benzoyl peroxide, they serve as a useful therapeutic adjunct by inhibiting growth of *P. acnes*. The effectiveness of a topical antibiotic is enhanced by concurrent use of benzoyl peroxide or tretinoin. Use of topical erythromycin or clindamycin has occasionally resulted in the emergence of resistant bacteria. *Azelaic acid* (Azelex cream) has antimicrobial and keratolytic properties. A 20% cream is as effective as 0.05% tretinoin cream.

All topical preparations must be used for 4–8 wk before their effectiveness can be assessed. They may be used alone but frequently are more effective when used together. A popular and effective combination is use of benzoyl peroxide gel in the morning and tretinoin at night.

SYSTEMIC THERAPY.

Antibiotics, especially tetracycline and its derivatives, are indicated for treatment of patients who cannot tolerate or have not responded to topical medications, who have moderate to severe inflammatory papulopustular and nodulocystic acne, and who have a propensity for scarring. The tetracyclines act by inhibiting bacterial lipases, causing a reduction in the concentration of free fatty acids; suppressing the normal

follicular flora, mainly *P. acnes;* and inhibiting neutrophil chemotaxis and follicular inflammation.

Tetracycline, minocycline, and doxycycline have been shown to suppress granuloma formation, perhaps by inhibition of protein kinase C, an important membrane signal transducer. For most adolescent patients, therapy may be initiated with tetracycline, 1?g/24?hr, divided twice daily, for at least 6 wk, followed by a gradual decrease to the minimal effective dose. The drugs are best administered in combination with topical benzoyl peroxide or tretinoin but not topical antibiotics. Tetracycline absorption is inhibited by food, milk, iron supplements, aluminum hydroxide gel, and calcium-magnesium salts. It should be taken on an empty stomach 1?hr before or 2?hr after meals. Side effects of tetracycline include vaginal candidosis, particularly in those who take tetracycline concurrently with oral contraceptives; gastrointestinal irritation; phototoxic reactions, including onycholysis and brown discoloration of nails; esophageal ulceration; inhibition of fetal skeletal growth; and staining of growing teeth, precluding its use during pregnancy and in those younger than 9 yr. Oral antibiotics may decrease the effectiveness of oral contraceptive pills. Alternatives to tetracycline include erythromycin, minocycline, doxycycline, clindamycin, and occasionally trimethoprim-sulfamethoxazole. A possible complication of prolonged systemic antibiotic use is proliferation of gram-negative organisms, particularly *Enterobacter, Klebsiella, Escherichia coli, or Pseudomonas aeruginosa,* producing severe, refractory folliculitis.

Women who have acne and hormonal abnormalities, who are unresponsive to antibiotic therapy, or who are not candidates for isotretinoin therapy should be considered for a trial of *hormonal therapy*. An effective combination is an antiandrogen such as cyproterone acetate or spironolactone, given on days 5–15 of the menstrual cycle, and ethinyl estradiol, a synthetic estrogen used in oral contraceptives that is a potent inhibitor of sebum production, given on days 5–26. Two oral contraceptives are currently FDA approved for the treatment of acne. Topically applied antiandrogens without systemic side effects are currently under investigation.

Isotretinoin (13-*cis*-retinoic acid, Accutane) is indicated for moderate to severe nodulocystic acne that has not responded to conventional therapy or has recurred quickly after several successful courses of conventional therapy; for severe, scarring acne such as acne conglobata and acne fulminans; and for acne that is associated with severe psychologic disturbance. The recommended dosage is approximately 0.5–1.0?mg/kg/24?hr; younger male patients and those with primarily truncal lesions tend to require doses at the upper end of this range. Four months of therapy is required for most patients; a standard course in the United States lasts 16–20 wk. At the end of one course of isotretinoin, approximately 30% are cured, 35% need conventional topical and/or oral medications to maintain adequate control, and 25% have relapses and need an additional course of isotretinoin. Dosages below 0.5?mg/kg/24?hr, or a cumulative dose of less than 120?mg/kg, are associated with a significantly higher rate of treatment failure and relapse. If the disease process is not in remission 2 mo after the first course of isotretinoin, a second course should be considered. Isotretinoin reduces sebum excretion by 80% within 1 mo, converts sebaceous units to epithelial buds, decreases the population of *P. acnes*, decreases ductal cornification, and inhibits neutrophil chemotaxis and thus decreases the inflammatory response. Isotretinoin therapy does not alter gonadal or adrenal functions but induces a significant local decrease in 5a-dihydrotestosterone formation in the skin.

Isotretinoin use has many side effects. *It is highly teratogenic and is absolutely contraindicated in pregnancy;* pregnancy should be avoided for 1 mo after discontinuation of therapy. Two or three forms of birth control are required, as are monthly pregnancy tests. Concerns over cases of pregnancy despite warnings have prompted a manufacturer registration program, S.M.A.R.T. (System to Manage Accutane Related Teratogenicity) that requires physician enrollment and careful patient pregnancy screening in order to prescribe isotretinoin. Many patients also experience cheilitis, xerosis, periodic epistaxis, and blepharoconjunctivitis. Increased serum triglyceride and cholesterol levels are also common; it is important to rule out pre-existent liver disease and hyperlipidemia before initiating therapy and to check the triglyceride response 4 wk after commencing therapy. Less common but significant side effects include arthralgias, myalgias, depression, temporary thinning of the hair, paronychia, increased susceptibility to sunburn, formation of pyogenic granulomas, and colonization of the skin with *Staphylococcus aureus*, leading to impetigo, secondarily infected dermatitis, and scalp folliculitis. Rarely, hyperostotic lesions of the spine develop after more than one course of isotretinoin. Concomitant use of tetracycline and isotretinoin is contraindicated because either drug, but particularly when used together, can cause benign intracranial hypertension. Although no cause and effect relationship has been established, media attention to a possible link between isotretinoin and depression and/or suicide has mandated close attention to psychiatric well-being before and during isotretinoin prescription.

SURGICAL THERAPY.

Intralesional injection of low-dose (3?mg/mL) midpotency glucocorticoids (e.g., triamcinolone) with a 30-gauge needle on a tuberculin syringe may hasten the healing of individual, painful nodulocystic lesions. Dermabrasion to minimize scarring should be considered only after the active process is quiescent.

DRUG-INDUCED ACNE

Pubertal and postpubertal patients who are receiving systemic corticosteroid therapy or potent topical steroids are predisposed to steroid-induced acne. This monomorphous folliculitis occurs primarily on the face, neck, chest (Fig. 659–1 *A*), shoulders, upper back, arms, and, rarely, the scalp. Onset follows the initiation of steroid therapy by about 2 wk. The lesions are small erythematous papules or pustules that may erupt in profusion and are all in the same stage of development. Comedones may occur subsequently, but nodulocystic lesions and scarring are rare. Pruritus is occasional. The steroid appears to induce focal degeneration of the follicular epithelium, which incites a localized neutrophilic inflammatory response. Although steroid acne is relatively refractory if the medication is continued, the eruption may respond to use of tretinoin and a benzoyl peroxide gel. A prepubertal child with severe acne should be examined for endocrine disorders such as congenital adrenal hyperplasia. Studies of adrenal function are indicated in appropriate patients (see Chapter 571).

Other drugs that can induce acneiform lesions in susceptible individuals include

isoniazid, phenytoin, phenobarbital, trimethadione, lithium carbonate, androgens (anabolic steroids), and vitamin B_{12} .

HALOGEN ACNE

Administration of medications containing iodides or bromides or, rarely, ingestion of massive amounts of vitamin-mineral preparations or iodine-containing "health foods" such as kelp may induce halogen acne. The lesions are often very inflammatory. Discontinuation of the provocative agent and appropriate topical preparations usually achieve reasonable therapeutic results.

CHLORACNE

Chloracne is due to external contact with, inhalation of, or ingestion of halogenated aromatic hydrocarbons, including

polyhalogenated biphenyls, polyhalogenated naphthalenes (e.g., Halowax, which may be a component of wood preservatives and sealing compounds), and dioxins. Lesions are primarily comedonal; inflammatory lesions are infrequent but may include papules, pustules, nodules, and cysts. Healing occurs with atrophic or hypertrophic scarring. The face, postauricular regions, neck, axillae, genitals, and chest are involved most commonly. The nose is often spared. In cases of severe exposure, associated findings may include hepatitis, production of porphyrins, bulla formation on sun-exposed skin, hyperpigmentation, hypertrichosis, and palmar and plantar hyperhidrosis. Topical or oral retinoids may be effective; benzoyl peroxide and antibiotics are generally ineffective.

NEONATAL ACNE

Approximately 20% of normal neonates develop at least a few comedones within the 1st mo of life. Closed comedones predominate on the cheeks and forehead (see Fig. 659–1 *B*); open comedones and papulopustules occur occasionally. The cause of neonatal acne is unknown but has been attributed to placental transfer of maternal androgens, hyperactive neonatal adrenal glands, and a hypersensitive neonatal end-organ response to androgenic hormones. Placental transfer of maternally ingested lithium and hydantoin may also cause acne in the neonate. The hypertrophic sebaceous glands involute spontaneously over a few months, as does the acne. If desired, the lesions can be treated effectively with topical tretinoin and/or benzoyl peroxide.

INFANTILE ACNE

Infantile acne usually presents at 3–16 mo of life, more commonly in boys than girls. Acne lesions are more numerous, pleomorphic, severe, and persistent than in neonatal acne. Open and closed comedones predominate on the face; papules and pustules occur frequently, but only occasionally do nodulocystic lesions develop. Pitted scarring is seen in 10–15%. The course may be relatively brief, or the lesions may persist for many months, although the eruption generally resolves by age 3 yr. Use of topical benzoyl peroxide gel and tretinoin usually clears the eruption within a few weeks; oral erythromycin is necessary occasionally. A history of severe acne in one or both parents is often elicited, and the child is at risk for development of severe acne in adolescence. A child with

Figure 659-1 *A*, Monomorphous papular eruption of steroid acne. *B*, Acne in a male infant.

refractory acne warrants a search for an abnormal source of androgens such as a virilizing tumor or congenital adrenal hyperplasia.

TROPICAL ACNE

A severe form of acne occurs in tropical climates and is believed to be due to the intense heat and humidity; hydration of the pilosebaceous duct pore may accentuate blockage of the duct. Affected individuals tend to have an antecedent history of adolescent acne that is quiescent at the time of the eruption. Lesions occur mainly on the entire back, chest, buttocks, and thighs, with a predominance of suppurating papules and nodules. Secondary infection with *S. aureus* may be a complication. The eruption is refractory to acne therapy if the environmental factors are not eliminated.

ACNE CONGLOBATA

Acne conglobata is a chronic progressive inflammatory disease that occurs mainly in men, more commonly in whites than in blacks, but it may begin during adolescence. Patients usually have a history of pre-existing acne vulgaris. The principal lesion is the nodule, although one often finds a mixture of comedones with multiple pores, papules, pustules, nodules, cysts, abscesses, and subcutaneous dissection with formation of multichanneled sinus tracts. Severe scarring is characteristic. The face is relatively spared, but in addition to the back and chest, the buttocks, abdomen, arms, and thighs may be involved. Constitutional symptoms and anemia may accompany the inflammatory process. Coagulase-positive staphylococci and ß-hemolytic streptococci are frequently cultured from lesions but do not appear to be involved primarily in the pathogenesis. Acne conglobata occasionally occurs in association with hidradenitis suppurativa and dissecting cellulitis of the scalp (as the follicular occlusion triad) and may be complicated by erosive arthritis and ankylosing spondyloarthritis. Endocrinologic studies are not revealing. Routine acne therapy is generally ineffective. Systemic therapy with a corticosteroid or sulfone may be required to suppress the intense inflammatory activity. Isotretinoin is the most effective form of therapy for some patients but may produce a flare after its initiation. Consequently, corticosteroids are often started before isotretinoin.

ACNE FULMINANS (ACUTE FEBRILE ULCERATIVE ACNE)

Acne fulminans is characterized by abrupt onset of extensive inflammatory, tender ulcerative acneiform lesions on the back and chest of male teenagers. The distinctive feature is the tendency for large nodules to form exudative, necrotic, ulcerated, crusted plaques. Lesions often spare the face and heal with scarring. A preceding history of mild papulopustular or nodular acne is noted in most patients. Constitutional symptoms and signs are common, including fever, debilitation, arthralgias, myalgias, weight loss, and leukocytosis. Blood cultures are sterile. Lesions of erythema nodosum sometimes develop on the shins. Osteolytic bone lesions may develop in the clavicle, sternum, and epiphyseal growth plates; affected bones appear normal or have slight sclerosis or thickening on healing. Salicylates may be helpful for the myalgias, arthralgias, and fever. Corticosteroids (1.0?mg/kg of prednisone) are started first; then approximately 1 wk later, isotretinoin (0.5?mg/kg) is added and continued for as long as inflammatory lesions persist, generally 3–4 mo. Dapsone may be effective if isotretinoin cannot be used. The corticosteroids are tapered over approximately 6 wk. Antibiotics are not indicated unless there is evidence of secondary infection. Compared with acne conglobata, acne fulminans presents in younger patients, is more explosive in onset, more commonly has associated constitutional symptoms and ulcerated crusted lesions, and less commonly has multiheaded comedones or involves the face.

Chapter 660 - Tumors of the Skin

See also Chapters 497 and Chapters 641 .

Epidermal Inclusion Cyst (Epidermoid Cyst).

These are sharply circumscribed, dome-shaped, firm, freely movable, skin-colored nodules, often with a central dimple or punctum that is a plugged, dilated pore of a pilosebaceous follicle. Epidermoid cysts form most frequently on the face, neck, chest, or upper back and may periodically become inflamed and infected secondarily, particularly in association with acne vulgaris. The cyst wall may also rupture and induce an inflammatory reaction in the dermis. The wall of the cyst is derived from the follicular infundibulum; a mass of layered keratinized material that may have a cheesy consistency fills the cavity. Epidermoid cysts may arise from occlusion of pilosebaceous follicles, from implantation of epidermal cells into the dermis as a result of an injury that penetrates the epidermis, and from rests of epidermal cells. Multiple epidermoid cysts may be present in *Gardner syndrome* and the *nevoid basal cell carcinoma syndrome*. Excision of the cysts with removal of the entire sac and its contents is indicated, particularly if the cyst becomes recurrently infected. A fluctuant, infected cyst should first be incised, drained, and packed, and the patient should receive an antibiotic effective against *Staphylococcus aureus*. After the inflammation subsides, the cyst should be removed.

Milium.

This is a pearly white or yellowish, firm, 1–2?mm subepidermal keratin cyst. Milia in newborns is discussed in Chapter 647 . Secondary milia occur in association with subepidermal blistering diseases, chronic corticosteroid-induced atrophy, 5-fluorouracil therapy, or after dermabrasion. They are retention cysts caused by hyperproliferation of injured epithelium and are indistinguishable histopathologically from primary milia; those that develop after blistering usually arise from the eccrine sweat duct, but they may develop from the hair follicle, sebaceous duct, or epidermis. A milium body differs from an epidermoid cyst only in its small size.

Pilar Cyst (Trichilemmal Cyst).

This is clinically indistinguishable from an epidermoid cyst. It presents as a smooth, firm, mobile nodule, predominantly on the scalp. These cysts occasionally develop on the face, neck, or trunk. The cyst may become inflamed and may occasionally suppurate and ulcerate. The cyst wall is composed of epithelial cells with indistinct intercellular bridges. The peripheral cell layer of the wall shows a palisade

arrangement, which is not seen in an epidermoid cyst. No granular layer is present, the cyst cavity contains homogeneous eosinophilic keratinous material, and foci of calcification are seen in 25% of cases. The propensity to develop pilar cysts is inherited in an autosomal dominant manner; more than one cyst generally develops. Numerous pilar and epidermoid cysts, desmoid tumors, fibromas, lipomas, or osteomas may be associated with colonic polyposis or adenocarcinoma in Gardner syndrome. Pilar cysts shell out easily from the dermis.

Pilomatricoma.

This is a benign tumor that presents as a 3–30?mm, firm, solitary, deep dermal or subcutaneous tumor on the head, neck, or upper extremities. The overlying epidermis is usually normal; the tumor may occasionally be located more superficially, however, tinting the overlying skin blue-red. Pilomatricomas may enlarge rapidly as a result of inflammation or hemorrhage and occasionally perforate the epidermis. Patients with both pilomatricoma and myotonic dystrophy are more likely to have several tumors and to have familial occurrence; in general, however, pilomatricomas are not hereditary. Histopathologically, irregularly shaped islands of epithelial cells are embedded in a cellular stroma. Calcium deposits are found in 75% of tumors. Pilomatricomas are caused by mutations in beta-catenin.

Trichoepithelioma.

This is a smooth, round, firm, skin-colored 2–8?mm papule that is derived from immature hair follicles. Trichoepitheliomas generally occur singly on the face during childhood or early adulthood. Multiple trichoepitheliomas *(epithelioma adenoides cysticum)* are inherited autosomal dominantly, appear in childhood or at puberty, and gradually

increase in number on the nasofacial folds, nose, forehead, and upper lip and occasionally on the scalp, neck, and upper trunk. Microscopically, these benign tumors are characterized by horn cysts composed of a fully keratinized center surrounded by basophilic cells in an adenoid network. Surgical excision is the therapy.

Eruptive Vellus Hair Cysts.

These are asymptomatic, follicular, skin-colored, soft 1–3-mm papules on the chest. They may become crusted or umbilicated. Abnormal vellus hair follicles become occluded at the level of the infundibulum, resulting in retention of hairs within an epithelium-lined cystic dilatation of the proximal part of the follicle. Most cases are chronic, but spontaneous regression has been reported.

Steatocystoma Multiplex.

This condition usually presents in adolescence or early adulthood with numerous soft to firm cystic nodules that are adherent to the underlying skin and are a few millimeters to 3?cm in diameter. When punctured, the cysts may drain oily or cheesy material. Sites of predilection include the sternal region, axillae, arms, and scrotal skin. The multiply folded cyst wall is lined on the luminal side with a thick, homogeneous, eosinophilic horny layer and lacks a granular layer. Flattened sebaceous gland lobules are often visible in the cyst wall, and lanugo hairs may be present in the cystic cavity.

Syringoma.

These benign tumors are soft, small, skin-colored or yellowish-brown papules that develop on the face, particularly in the periorbital regions. Other sites of predilection include the axillae and umbilical and pubic areas. They often develop during puberty and are more frequent in females. Eruptive syringomas (eruptive hidradenoma) develop in crops over the anterior trunk during childhood or adolescence. A syringoma is derived from an intraepidermal sweat gland duct. They are of cosmetic significance only. Sparse lesions may be excised, but they are often too numerous to remove.

Infantile Digital Fibroma.

This is a firm, smooth, erythematous or skin-colored nodule on the dorsal or lateral surfaces of the distal phalanges of the fingers and toes. More than 80% of tumors present in infancy; they may be present at birth. Lesions may be solitary or multiple and may present as “kissing” tumors on opposing digits. Generally, they are asymptomatic, but flexion deformity of the digits may occur. Clinically, the lesions resemble a fibroma, leiomyoma, angiofibroma, acquired digital fibrokeratoma, accessory digit, or mucous cyst. The diagnosis is confirmed by finding numerous spindle-shaped fibroblasts that contain small, dense, round eosinophilic cytoplasmic inclusion bodies composed of collections of actin microfilaments. A viral cause has been postulated. Local recurrence after simple excision of this tumor has been reported in 75% of patients. Because the tumor does not metastasize and may regress spontaneously within 2–3 yr, a course of expectant observation is advised. If functional impairment or flexion deformity of the digit becomes apparent, prompt full excision of the tumor is indicated.

Dermatofibroma (Histiocytoma).

These benign dermal tumors may be pedunculated, nodular, or flat and are usually well circumscribed and firm but occasionally feel soft on palpation. The overlying skin is usually hyperpigmented, may be shiny or keratotic, and dimples when the tumor is pinched. Dermatofibromas range in size from 0.5–10?mm, arise most frequently on the limbs, and are usually asymptomatic but may occasionally be pruritic. They are composed of fibroblasts, young and mature collagen, capillaries, and histiocytes in varying proportions, forming a nodule in the dermis that has poorly defined edges. The cause of these tumors is unknown, but trauma such as an insect bite or folliculitis appears to induce reactive fibroplasia. The differential diagnosis includes epidermal inclusion cyst, juvenile xanthogranuloma, hypertrophic scar, and neurofibroma. Dermatofibromas may be excised or left intact according to a patient's preference; they usually persist indefinitely but occasionally involute spontaneously.

Juvenile Xanthogranuloma.

These are firm, dome-shaped, yellow, pink, or orange papules or nodules that vary in size from a few millimeters to approximately 4?cm in diameter. They usually present at birth or within the first several months of life; occasionally, they first appear in late childhood and, rarely, in adulthood. They are 10 times more common in white than in black individuals. Sites of predilection are the scalp, face, and upper trunk, where they may erupt in profusion or remain as solitary lesions. Nodular lesions may appear on the oral mucosa. Mature lesions are characterized histopathologically by a dermal infiltrate of lipid-laden histiocytes, admixed inflammatory cells, and Touton giant cells. The lesions may clinically resemble papulonodular urticaria pigmentosa, dermatofibromas, or xanthomas of hyperlipoproteinemia but can be distinguished from these entities histopathologically.

Affected infants are nearly always otherwise normal, and blood lipid values are not elevated. Café-au-lait macules are found on 20% of patients with juvenile xanthogranuloma. Xanthogranulomatous infiltrates occur occasionally in ocular tissues. This may result in glaucoma, hyphema, uveitis, heterochromia iridis, iritis, or sudden proptosis. Age younger than 2 years old, multiple lesions, and periocular location may heighten concerns for intraocular involvement. There appears to be an association among juvenile xanthogranuloma, neurofibromatosis, and childhood leukemia, most frequently juvenile chronic myelogenous leukemia. There is no need to remove these benign lesions because most of them regress spontaneously during the first few years. Residual pigmentation and atrophy, but not scarring, may result.

Lipoma.

These benign collections of fatty tissue appear on the trunk, neck, and proximal portions of the limbs. They are soft, compressible, lobulated, subcutaneous masses that are movable against the overlying skin. Multiple lesions may occur occasionally, as in Gardner syndrome. Atrophy, calcification, liquefaction, or xanthomatous change may sometimes complicate their course. A lipoma is composed of normal fat cells surrounded by a thin connective tissue capsule. They represent a cosmetic defect and may be surgically excised. Multiple lipomas, identical to those that occur singly, are inherited in an autosomal dominant fashion and often appear by the 3rd decade in patients with *familial multiple lipomatosis*. Lipomas may appear intra-abdominally, intramuscularly, and subcutaneously. *Congenital lipomatosis* presents during the first few months of life as large subcutaneous fatty masses on the chest, with extension into skeletal muscle. Congenital lipomatosis can also be a manifestation of Proteus syndrome. *Angiolipomas* usually present as numerous painful subcutaneous nodules on the arms and trunk.

Basal Cell Epithelioma (Basal Cell Carcinoma).

Basal cell carcinoma is rare in children in the absence of a predisposing condition, such as nevoid basal cell carcinoma syndrome, xeroderma pigmentosum, nevus sebaceus of Jadassohn, arsenic intake, or exposure to irradiation. The lesions are pink, pearly, telangiectatic, smooth papules that enlarge slowly and

may bleed or ulcerate. Sites of predilection are the face, scalp, and upper back. The differential diagnosis includes pyogenic granuloma, nevocellular nevus, epidermal inclusion cyst, closed comedo, dermatofibroma, and adnexal tumor. Depending on the site of occurrence and associated disease of the host, electrodesiccation and curettage or simple excision is usually curative. When the tumor is recurrent, larger than 2?cm in diameter, located on problematic anatomic areas such as the midface or ears, or is an aggressive histopathologic type, Mohs microscopically controlled surgery may be the most appropriate treatment.

Nevoid Basal Cell Carcinoma Syndrome (Basal Cell Nevus Syndrome, Gorlin Syndrome).

This autosomal dominant syndrome maps to a gene on chromosome 9q22.3. This tumor suppressor gene is part of the hedgehog signaling pathway and is important in determining embryonic patterning and cell fate in a number of structures in the developing embryo. Mutations in human patched gene produce dysregulation of several genes involved in organogenesis and carcinogenesis. Consequently, the syndrome includes a wide spectrum of defects involving the skin, eyes, central nervous and endocrine systems, and bones. The predominant features are early onset basal cell carcinomas and mandibular cysts. Approximately 20% of those in whom a basal cell carcinoma develops before age 19 yr have this syndrome. Basal cell carcinomas appear between puberty and age 35 yr, erupting in crops of tumors that vary in size, color, and number and may be difficult to distinguish from other types of skin lesions. Sites of predilection are the periorbital skin, nose, malar areas, and upper lip, but the lesions can develop on the trunk and limbs and are not restricted to sun-exposed areas. Ulceration, bleeding, crusting, and local invasion can occur. Small milia, epidermal cysts, pigmented lesions, hirsutism, and palmar and plantar pits are additional cutaneous findings.

The facies of patients with this syndrome are characterized by temporoparietal bossing, prominent supraorbital ridges, a broad nasal root, ocular hypertelorism or dystopia canthorum, and prognathism. Keratinized cysts (odontogenic keratocysts) in the maxilla and mandible occur in most patients. They range in size from a few millimeters to several centimeters, may result in maldevelopment of the teeth, and cause pain, swelling of the jaw, facial deformity, bone erosion, pathologic fractures, and suppurating sinus tracts. Osseous defects such as anomalous rib development, spina bifida, kyphoscoliosis, and brachymetacarpalism occur in two thirds of patients, and ocular abnormalities including cataracts, glaucoma, coloboma, strabismus, and blindness occur in approximately one fourth. Some males have hypogonadism, with absent or undescended testes. Kidney malformations have also been reported. Neurologic manifestations include calcification of the falx, seizures, mental retardation, partial agenesis of the corpus callosum, hydrocephalus, and nerve deafness. The incidence of medulloblastoma, ameloblastoma of the oral cavity, fibrosarcoma of the jaw, teratoma, cystadenoma, cardiac fibroma, and ovarian fibroma is increased.

Treatment of these patients requires participation of various specialists according to individual clinical problems. Basal cell carcinomas should not be treated with irradiation. Most of the basal cell carcinomas have a clinically benign course, and it is

often impossible to remove them all; those with an aggressive growth pattern and those on the central areas of the face, however, should be removed promptly. Oral retinoids are helpful in preventing the development of new tumors in some patients. Genetic counseling is also indicated.

Mucosal Neuroma Syndrome (Sippel Syndrome).

Mucosal neuroma syndrome, an autosomal dominant trait, is characterized by an asthenic or marfanoid habitus with scoliosis, pectus excavatum, pes cavus, and muscular hypotonia. Patients have thick, patulous lips and soft tissue prognathism simulating acromegaly. Multiple mucosal neuromas or neurofibromas appear as pink, pedunculated or sessile nodules on the anterior third of the tongue, at the commissures of the lips, and on the buccal mucosa and palpebral conjunctiva. Various ophthalmologic defects and intestinal ganglioneuromatosis with recurrent diarrhea are additional common findings. There is a high incidence of medullary thyroid carcinoma associated with high calcitonin levels, pheochromocytoma, and hyperparathyroidism. Periodic screening tests for the associated malignant tumors are mandatory.

Chapter 661 - Nutritional Dermatoses

Acrodermatitis Enteropathica.

This is a rare autosomal recessive disorder caused by an inability to absorb sufficient zinc from the diet. Initial signs and symptoms usually occur during the first few months of life, often after weaning from breast to cow's milk. The cutaneous eruption consists of vesiculobullous, eczematous, dry, scaly, or psoriasiform skin lesions symmetrically distributed in the perioral, acral, and perineal areas and on the cheeks, knees, and elbows (Fig. 661–1). The hair often has a peculiar reddish tint, and alopecia of some degree is characteristic. Ocular manifestations include photophobia, conjunctivitis, blepharitis, and corneal dystrophy detectable by slit-lamp examination. Associated manifestations include chronic diarrhea, stomatitis, glossitis, paronychia, nail dystrophy, growth retardation, irritability, delayed wound healing, intercurrent bacterial infections, and superinfection with *Candida albicans.* Lymphocyte function and free radical scavenging are impaired. Without treatment, the course is chronic and intermittent but often relentlessly progressive. When the disease is less severe, only growth retardation and delayed development may be apparent.

The *diagnosis* is established by the constellation of clinical findings and detection of a low plasma zinc concentration. Histopathologic changes in the skin are nonspecific and include parakeratosis and pallor of the upper epidermis. The variety of manifestations of the syndrome may be due to the fact that zinc has a role in numerous metabolic pathways, including those of copper, protein, essential fatty acids, and prostaglandins, and zinc is incorporated into many zinc metalloenzymes.

Figure 661-1 *A*, Psoriasiform facial lesions of zinc deficiency dermatitis. *B*, Similar lesions on the feet with secondary nail dystrophy.

Oral therapy with zinc compounds is the *treatment* of choice. Optimal doses range from 50?mg of zinc sulfate, acetate, or gluconate daily for infants up to 150?mg/24?hr for children; plasma zinc levels should be monitored, however, to individualize the dosage. Zinc therapy rapidly abolishes the manifestations of the disease. A syndrome resembling acrodermatitis enteropathica has been observed in patients with secondary zinc deficiency caused by long-term total parenteral nutrition without supplemental zinc or by chronic malabsorption syndromes. A rash similar to that of acrodermatitis enteropathica has also been reported in infants fed breast milk

that is low in zinc and in those with maple syrup urine disease, organic aciduria, methylmalonic acidemia, biotinidase deficiency, essential fatty acid deficiency, severe protein malnutrition (e.g., kwashiorkor), and cystic fibrosis.

Essential Fatty Acid Deficiency.

This causes a generalized, scaly dermatitis composed of thickened, erythematous, desquamating plaques. The eruption has been induced experimentally in animals fed a fat-free diet and has been observed in patients with chronic severe malabsorption such as in short-gut syndrome and in those sustained on a fat-free diet or fat-free parenteral alimentation. Linoleic (18:2 n-6) and arachidonic (20:4 n-6) acids are deficient, and an abnormal metabolite, 5,8,11-eicosatrienoic acid (20:3 n-9), is present in the plasma. Additional manifestations of essential fatty acid deficiency include alopecia, thrombocytopenia, and failure to thrive. The horny layer of the skin is cracked microscopically, the barrier function of the skin is disturbed, and transepidermal water loss is increased. Topical application of linoleic acid, which is present in sunflower seed and safflower oils, may ameliorate the clinical and biochemical skin manifestations. Appropriate nutrition should be provided.

Kwashiorkor.

Severe protein and essential amino acid deprivation in association with adequate caloric intake can lead to kwashiorkor, particularly at the time of weaning to a diet that consists primarily of corn, rice, or beans (see Chapter 42.2). Cutaneous erythema develops first and, in mild cases in white children, progresses to fine desquamation along natural skin lines and on the shins, outer thighs, and back. In dark-skinned children, characteristic early findings include circumoral pallor, cutaneous depigmentation, and development of purple patches. As the disease advances, well marginated, slightly raised, purplish, waxy plaques appear, particularly in the diaper area and at sites of pressure such as the elbows, knees, and ankles and on the trunk. In severe cases, erosions and linear fissures develop. Sun-exposed skin is relatively spared, as are the feet and dorsal aspects of the hands. Nails are thin and soft, and hair is sparse, thin, and depigmented, sometimes displaying a flag sign of alternating light and dark bands that reflect alternating periods of adequate and inadequate nutrition. The cutaneous manifestations may closely resemble those of acrodermatitis enteropathica. The serum zinc level is often deficient, and in some cases, skin lesions of kwashiorkor heal more rapidly when zinc is applied topically.

Cystic Fibrosis (see Chapter 402).

Five per cent to 10% of patients with cystic fibrosis develop protein-calorie malnutrition. Rash in infants with cystic fibrosis and malnutrition is rare but may appear by age 6 mo. The initial eruption consists of erythematous, scaling papules and progresses within 1–3 mo to extensive desquamating plaques. The rash is accentuated around the mouth and perineum and on the extremities (lower > upper). Alopecia may be present, but mucous membranes and nails are uninvolved.

Pellagra (see Chapter 44.5).

This presents with edema, erythema, and burning of sun-exposed skin on the face, neck, and dorsal aspects of the hands, forearms, and feet. Lesions of pellagra may also be provoked by burns, pressure, friction, and inflammation. The eruption on the face frequently follows a butterfly distribution, and the dermatitis encircling the neck has been termed “Casal's necklace.” Blisters and scales develop, and the skin increasingly becomes dry, rough, thickened, cracked, and hyperpigmented. Skin infections may be unusually severe. Pellagra develops in those with insufficient dietary intake or absorption of niacin and/or tryptophan. Administration of isoniazid, 6-mercaptopurine, or 5-fluorouracil may also produce pellagra. Nicotinamide supplementation and sun avoidance are the mainstays of therapy.

Scurvy (Vitamin C or Ascorbic Acid Deficiency) (see Chapter 44.9).

This presents initially with follicular hyperkeratosis and coiling of hair on the upper arms, back, buttocks, and lower extremities. Perifollicular erythema and hemorrhage, particularly on the legs and advancing to involve large areas of hemorrhage, swollen, erythematous gums, stomatitis, and subperiosteal hematomas are also seen. The best method for confirmation of a clinical diagnosis of scurvy is a trial of vitamin C supplementation.

Vitamin A Deficiency (see Chapter 44.1).

This deficiency presents initially with impairment of visual adaptation to the dark. Cutaneous changes include xerosis and hyperkeratosis and hyperplasia of the epidermis, particularly the lining of hair follicles and sebaceous glands. In severe cases, desquamation may be prominent.

Part 31 - Bone and Joint Disorders

Section 1 - *Orthopedic Problems*

Chapter 662 - Growth and Development

George H. Thompson

Musculoskeletal disorders in children and adolescents are common; many can be managed safely and effectively by the pediatrician provided that an accurate diagnosis is established. The differential diagnosis of pediatric musculoskeletal disorders involves all diagnostic categories: congenital, developmental, acquired, infectious, inflammatory, mechanical, traumatic, neuromuscular, neoplastic, and psychogenic.

One must have a basic understanding of the effects of in utero positioning, the mechanism in which normal musculoskeletal growth occurs, and the relationships among skeletal growth, neurologic maturation, and normal developmental milestones.

In Utero Positioning.

In the newborn, the imprint of the in utero position may be evident and confused with an abnormality. In utero positioning produces temporary joint and muscle contractures and affects the torsional alignment of the long bones, especially those of the lower extremities. Normal full-term newborns have 20–30 degree hip and knee

flexion contractures. These resolve by 4–6 mo of age. The newborn hip externally rotates in extension 80–90 degrees and has limited internal rotation to 0–10 degrees. The lower leg frequently has inward rotation (internal tibial torsion), and the feet are supinated from their medial borders being wrapped against the posterolateral aspect of the opposite thigh. The top leg in the in utero position may show more changes than the bottom leg. The face may also be distorted, whereas the spine and upper extremities are less affected by the in utero position. The effects of in utero positioning, therefore, are physiologic in origin but may produce parental concerns. The child may be 3–4 yr old before the effects of the in utero position completely resolve.

Growth and Development.

Each of the individual components of the skeletal system grow by different mechanisms. The long bones of the extremities (humerus, radius-ulna, femur, and tibia-fibula) have growth plates or physes at each end. Each contributes a varying proportion to the longitudinal growth of the individual bone as well as the extremity through a process termed *endochondral ossification*. The ends of each long bone are composed of the epiphyses. These are covered by articular cartilage and form the associated joints. Initially, the epiphyses are almost entirely cartilaginous and become progressively more ossified during growth. The articular cartilage also has growth potential, which contributes to the growth of the epiphysis. The perichondrial ring, which surrounds the physes, as well as the perichondrium around the epiphyses and periosteum, which surrounds the metaphysis and diaphyseal regions of the bone, contributes to appositional or circumferential growth.

Bones without physes, such as the pelvis, scapulae, carpals, and tarsals, grow by appositional bone growth from their surrounding perichondrium and periosteum. Other bones, such as the metacarpals, metatarsals, phalanges, and spine, grow by a combination of both appositional and endochondral ossification.

Trauma, infections, nutritional deficiencies (rickets), regional soft tissue processes, inborn errors of metabolism (mucopolysaccharidosis, mucolipidosis, Gaucher disease, and disorders of collagen or cartilage), and other metabolic processes may affect each of these growth processes, producing a distinct alteration in the particular growth function.

Developmental Milestones.

Neurologic maturation, marked by the passage of motor milestones at regular intervals, is important for normal musculoskeletal development. The milestones for locomotion include independent sitting at 6 mo of age, crawling at 9 mo, walking without assistance at 12–15 mo, and running at 18 mo (see Chapters 10 through 12). There is a distinct relationship between skeletal form and gross motor function. Any process that produces a neurologic abnormality may cause a secondary delay in developmental milestones and an alteration of normal skeletal growth.

Chapter 663 - Evaluation of the Child

George H. Thompson

The key to an accurate diagnosis is a careful history, a thorough physical examination, appropriate radiographic imaging, and, occasionally, laboratory testing. A glossary of common orthopedic terminology is provided in Table 663–1 .

History.

The history of the complaint is often the most important part of the evaluation. This is usually obtained from the parents or guardian, but the child, if old enough and cooperative, can also give useful information. The chief complaint is established first. This may include pain, deformity, joint stiffness, gait disturbance (limp, toe walking, in-toeing, out-toeing), swelling, or generalized muscle weakness. One must ascertain location and duration of symptoms; antecedent factors such as fever, trauma, radiation of pain, and neurologic symptoms; factors aggravating or alleviating the symptoms; and previous evaluations or treatment.

In children with chronic symptoms, the past medical history is also important. The prenatal or pregnancy history should be obtained (see Chapters 83.1 , 85.5 and 89). This includes maternal diseases or illnesses, vaginal bleeding, oligohydramnios, ingestion of toxic substances or medications, and trauma. The birth history should determine the length of pregnancy; duration of labor; type of difficulty, if any, with delivery; birth presentation; birthweight; and Apgar score (see Chapters 85 , 86 , and 89). The condition of the child during the neonatal period is important (see Chapter 86). In older infants and young children, evaluation of the presence and delay of developmental milestones for posture, locomotion, dexterity, social activities, and speech is important.

TABLE 663-1 -- **Glossary of Orthopedic Terminology**

Term	Definition
Abduction	Movement away from the midline
Adduction	Movement toward and possibly across the midline
Anteversion	Increased angulation of the femoral head and neck with respect to the knee in the frontal plane
Apophysis	Bone growth center that is not a growth plate or physis and that has a strong muscle insertion (e.g., greater trochanter of femur)
Arthroplasty	Surgical reconstruction of a joint
Arthrotomy	Surgical incision into a joint
Calcaneus	Dorsiflexion of hindfoot
Cavovarus	High longitudinal or medial arch of foot with plantarflexed supinated forefoot and hindfoot varus
Cavus	High longitudinal arch of the foot (usually plantarflexed forefoot)
Dislocation	Complete loss of contact between two joint surfaces
Equinus	Plantarflexion of the forefoot, hindfoot, or entire foot
Extension	To straighten; the reverse of flexion
External or lateral rotation	Outward rotation away from the midline
Flexion	To bend
Internal or medial rotation	Inward rotation, toward the midline
Subluxation	Incomplete loss of contact between two joint surfaces
Valgum	Angulation of a bone or joint in which the apex is toward the midline; genu valgum results in knock-knee because the angulation of the knee is toward the midline
Varum	Angulation of a bone or joint away from the midline; genu varum results in bowleg because the angulation is away from the midline

The family history may give clues to possible genetic disorders such as congenital syndromes, muscular dystrophy, skeletal dysplasias, and other disorders affecting the musculoskeletal system. It is important to inquire about specific problems, similar or not, on both the paternal and maternal sides of the family.

Physical Examination.

The physical examination of a child with a musculoskeletal disorder must be thorough. It includes the careful evaluation of the musculoskeletal and neurologic systems as well as an appropriate general physical examination. Many common musculoskeletal disorders can be diagnosed by the history and physical examination alone. The examination of the musculoskeletal system includes four parts: observation, palpation, assessment of joint range of motion, and gait assessment in

ambulatory children.

OBSERVATION.

The first part of the musculoskeletal examination begins with inspection of the body. This must be accomplished by observing the child undressed. If the child can stand, posture, truncal alignment, and symmetry of the extremities can be evaluated. The skin is assessed for cutaneous lesions. The presence of café-au-lait spots may indicate neurofibromatosis, whereas a maculopapular rash may indicate juvenile rheumatoid arthritis. Infants or young children may be examined on their parent's lap so that they feel more secure and are more likely to be cooperative.

PALPATION.

The involved joint, area of the extremity, or trunk that is of concern should be palpated for tenderness, masses, soft tissue swelling, and increased warmth. Abnormal joints should also be palpated for effusion, synovial thickening, increased warmth, and areas of tenderness.

JOINT RANGE OF MOTION.

The range of motion of the involved joint or joints should be assessed and recorded. If the opposite joint is normal, this range should also be recorded for comparison purposes. It must be remembered that the range of motion of joints changes from infancy through childhood and into adolescence.

GAIT ASSESSMENT.

Gait disturbances are one of the most common parental concerns in children. It is, therefore, important to have a thorough understanding of the development of normal gait. Human gait is dynamic, complex, and repetitive. The gait cycle is the time between right heel strike followed by left toe-off, left heel strike, and right toe-off and ends with right heel strike. The five events describe one gait cycle and include two phases: stance and swing. The stance phase is the period of time during which one of the two feet is on the ground. The swing phase is the portion of the gait cycle during which a limb is being advanced forward without ground contact.

Neurologic maturation is necessary for the development of gait and the normal progression of developmental milestones. The normal 1-yr-old child has a wide-based stance and rapid cadence with short steps. The elbows are flexed and reciprocal arm motion is not present. Foot strike occurs without initial heel strike. A 2-yr-old child shows increased velocity and step length and diminished cadence compared with a 1-yr-old. Most of the adult gait patterns are present in children by 3 yr of age, with changes of velocity, stride, and cadence continuing to 7 yr. The gait characteristics of a 7-yr-old child are similar to those of an adult.

Common gait disturbances include limp, torsional variations (in-toeing and out-toeing), and toe walking. In evaluating gait disturbance, it is important to observe the child walking and running. The child must be sufficiently undressed to allow visualization of the lower extremities and trunk during ambulation.

Limping.

Limping is categorized into either painful (antalgic) or nonpainful (Trendelenburg gait) on the basis of the length of the stance phase. In a painful gait, the stance phase is shortened as the child decreases the time spent on the painful extremity. In a nonpainful gait, which is indicative of underlying proximal muscle weakness or hip instability, the stance phase is equal between the involved and uninvolved sides, but the child will lean or shift the center of gravity over the involved extremity for balance. If the disorder is bilateral, it produces a waddling gait. The differential diagnosis of limping is extensive. The vast majority of causes involve the lower extremity, but it must be remembered that spinal disorders, especially spinal cord or peripheral nerve disorders, can also produce limping and difficulty walking. Antalgic gaits are predominantly a result of trauma, infection, neoplasia, and rheumatologic disorders. Trendelenburg gaits are generally due to congenital, developmental, or muscular disorders. Thus, antalgic gaits are acute processes, whereas Trendelenburg gaits are chronic. The differential diagnosis of limping is presented in Table 663–2 , and causes of limping according to age are seen in Table 663–3 . Limping may also be due to nonskeletal disease such as testicular torsion, inguinal hernia, or appendicitis.

Torsional Variations.

Torsional variations—in-toeing and out-toeing—are the most common gait disturbances that cause parents to seek advice from their pediatrician (see Chapters 664 and 665). Many do not require treatment because they are physiologic in origin and improve and resolve with normal growth and development. They produce significant anxiety and require the pediatrician to have a clear understanding of the cause and natural history to reassure the family. The common causes of in-toeing and out-toeing are presented in Table 663–4 . The presence of in-toeing and out-toeing does not imply an abnormality of the foot but rather only the direction in which the foot is pointing during ambulation. The causes for torsional variations can occur from proximal (hip) to distal (foot) in the involved extremity. Some causes, such as clubfoot, are obvious, whereas others can be subtle.

Toe Walking.

Toe walking or equinus gait is a less common cause of gait disturbance. It can be a normal finding in children up to 3 yr of age. Persistent toe walking thereafter or acquired toe walking at a later age is considered abnormal and requires careful evaluation. The common causes of unilateral and bilateral toe

walking are listed in Table 663–5 . The differential diagnosis for persistent or acquired toe walking include (1) neuromuscular disorders, such as cerebral palsy, Duchenne muscular dystrophy, or spinal cord abnormalities (tethered cord); (2) congenital tendo-Achilles contracture; (3) leg-length discrepancy; and (4) habit.

NEUROLOGIC EVALUATION.

A careful neurologic evaluation must be performed and includes muscle strength testing, sensory assessment, and evaluation of deep tendon and pathologic reflexes, such as the Babinski reflex. The pertinent negative and positive findings should be recorded. The neurologic

evaluation should also assess the spine and identify the presence of deformity, such as scoliosis or kyphosis, as well as spinal mobility. The child's ability to forward flex and reverse the normal lumbar lordosis is a sign of normal mobility. Areas of tenderness and muscle spasm are determined by palpation.

Radiographic Assessment.

Radiography is the principal method for the evaluation of the pediatric musculoskeletal system. This can include routine radiographs as well as special procedures such as technetium bone scans, CT, MRI, and ultrasonography.

ROUTINE RADIOGRAPHY.

Routine radiographs are the first step and consist of anteroposterior and lateral views of the involved joint, bone, or area. Comparison views of the opposite side, if uninvolved, may be helpful in difficult situations but are usually not necessary. The type of radiographs for each anatomic area is discussed in the sections on specific disorders.

TECHNETIUM BONE SCANS.

These are particularly useful in looking for occult lesions when routine radiographs are normal. Common indications for bone scans include (1) early septic arthritis or osteomyelitis; (2) neoplasia, such as osteoid osteomas and leukemia; (3) metastatic lesions; (4) occult fractures, such as child abuse or a toddler fracture of the tibia; and (5) inflammatory disorders.

COMPUTED TOMOGRAPHY.

Coronal and axial cross-section studies with CT can be beneficial in evaluating complex disorders of the spine, pelvis, and feet. It allows visualization of the bone anatomy and the relationship of bones to contiguous structures, which routine radiographs do not.

MAGNETIC RESONANCE IMAGING.

This avoids ionizing radiation and is presumed not to produce biologically harmful effects. It produces excellent anatomic images of the musculoskeletal system, including the spinal cord and brain. It is especially useful for soft tissue lesions, allowing distinction among different muscles or muscle groups. Cartilage structures can be visualized, and different forms can be distinguished (articular cartilage of the knee can be distinguished from the fibrocartilage of the meniscus). MRI is helpful in visualizing joints that are unossified, which may occur in the shoulders, elbows, and hips of young infants. MRI distinguishes physiologic changes that occur in the bone marrow with respect to age and disease such as avascular necrosis. In children, MRI can be useful in the evaluation of (1) avascular necrosis of bone, especially the capital femoral epiphysis or femoral head; (2) bone and soft tissue neoplasms; (3) intra-articular abnormalities of the knee joint; (4) assessment of intraspinal pathologic conditions; and (5) deep tissue infections (fasciitis and myositis).

ULTRASONOGRAPHY.

Ultrasonography has no ionizing radiation, no contrast material to be administered, and no biologically harmful effects and can be repeated as often as necessary. The equipment is portable; scans can be obtained in any plane. The disadvantages of ultrasonography include (1) bone is not penetrated, (2) static images are difficult to interpret, and (3) the results are operator dependent. The major indications for ultrasonography are (1) fetal studies of the extremities and spine, (2) developmental dysplasia of the hip, (3) joint effusions, (4) occult neonatal spinal dysraphism; (5)

foreign bodies in soft tissues, and (6) popliteal cysts of the knee.

Laboratory Studies.

Occasionally, hematologic tests are necessary in the evaluation of the pediatric musculoskeletal system. These may include a complete blood cell count, erythrocyte sedimentation rate, C-reactive protein determination, and blood culture for infectious disorders, such as septic arthritis or osteomyelitis. Rheumatoid factor, antinuclear antibodies, and human leukocyte antigen B27 screens are necessary for children with suspected rheumatologic disorders. Creatine kinase, aldolase, aspartate aminotransferase, and dystrophin testing are indicated in children with suspected disorders of striated muscle such as Duchenne or Becker muscular dystrophy.

Talking with Parents.

Many problems are normal or physiologic variations that resolve with growth and development and require only observation. This is particularly true in torsional variations of the lower extremities, which can produce significant anxiety in the family. Establishing a strong rapport with the family is an important component in the patient-family-physician relationship. Active treatment is indicated when the disorder has the potential to produce disability and also when the treatment is effective in altering the natural history. In many instances, the treatment may not significantly improve the child's condition initially, but by altering the natural history, problems in adult life, such as degenerative osteoarthritis, will be avoided.

Several steps are helpful in establishing a working relationship with parents. The diagnosis should be accurate and accompanied by a clear explanation of the cause and natural history of the disorder. Treatment options, including observation, should be discussed along with the expected results, both short and long term. If observation is recommended, a follow-up evaluation should be performed to document resolution and give the family additional reassurance.

Finally, not all physiologic conditions resolve. A small percentage of these disorders may persist into adolescence. These may require treatment if problems are to be avoided in adult life. The longer a problem persists, the greater is the chance that the problem will not resolve and may require treatment.

Chapter 664 - The Foot and Toes

George H. Thompson

The foot and toes are important in stance and locomotion. Abnormalities affecting the foot can produce pain and abnormal shoe wear and can adversely affect function. The foot articulates with the lower end of the tibia. The ankle joint is a box joint, which allows foot dorsiflexion and plantarflexion with essentially no rotation. The talus articulates with the distal end of the tibia. Support is achieved through the medial malleolus of the tibia and the lateral malleolus of the distal fibula. The foot is divided into three regions: hindfoot, midfoot, and forefoot. The toes are a portion of the forefoot.

The hindfoot is composed of the talus and calcaneus. The latter forms the heel. The joint between these two bones is the talocalcaneal or subtalar joint. This joint has a gliding and rotatory motion, which allows inversion and eversion of the hindfoot. This is important for walking on uneven ground.

The midfoot is composed of the navicular, cuboid, and the three cuneiform bones. The midfoot and hindfoot articulate through the transverse tarsal joint (calcaneocuboid and talonavicular joints). This joint is important for midfoot rotation and for walking on uneven ground. Deformity or malalignment of subtalar, talonavicular, or calcaneocuboid joints can have a significant effect on the alignment and function of the foot and produces abnormal stress on the ankle joint.

The forefoot is composed of the metatarsals and toes. The 1st metatarsal is unique because it has a single physeal plate that is located proximally. The lateral four metatarsals have a single physis located distally. The great toe is composed of proximal and distal phalanges and a single interphalangeal joint. The lateral four toes have proximal, middle, and distal phalanges that articulate through a proximal interphalangeal joint and a distal interphalangeal joint. All phalanges have their physeal plates

located proximally. Normal function of the foot and toes requires a coordinated action between the extrinsic muscles of the calf and intrinsic muscles of the foot.

664.1 Metatarsus Adductus

Congenital metatarsus adductus, a common problem among infants and young children, is also known as metatarsus varus if the forefoot is supinated as well as adducted. It occurs equally in males and females and is bilateral in approximately 50% of patients. There are hereditary tendencies; it tends to be more common in firstborn than in later children as a result of the increased molding effect from the primigravida uterus and abdominal wall. Approximately 10% of children with metatarsus adductus may have acetabular dysplasia. Careful examination of the hips is necessary in any child with metatarsus adductus. Pelvic radiographs are obtained in suggestive cases.

Clinical Manifestations.

The forefoot is adducted and occasionally supinated. The hindfoot and midfoot are normal. The lateral border of the foot is convex, and the base of the 5th metatarsal appears prominent (Fig. 664–1). The medial border of the foot is concave. There is usually an increased interval between the 1st and 2nd toes, with the great toe being held in a greater varus position. Ankle dorsiflexion and plantarflexion are normal. Forefoot mobility can vary from flexible to rigid. This is assessed by stabilizing the hindfoot and midfoot in a neutral position with one hand and applying pressure over the 1st metatarsal head with the other. In the walking child with an uncorrected metatarsus adductus deformity, an in-toe gait and abnormal shoe wear may occur.

Radiographic Evaluation.

Radiographs of the foot are not routinely necessary in metatarsus adductus because they do not demonstrate forefoot mobility. Anteroposterior (AP) and lateral weight-bearing or simulated weight-bearing radiographs are indicated when there is rigidity or failure of spontaneous improvement with growth. The AP radiographs demonstrate adduction of the metatarsals at the tarsometatarsal articulation and an increased intermetatarsal angle between the 1st and 2nd metatarsals. The lateral four metatarsals appear to have increased closeness and occasionally overlap at their base. The hindfoot and midfoot are normal.

Treatment.

The treatment of metatarsus adductus is predominantly nonoperative. There are limited indications for surgery.

NONOPERATIVE.

Most children with metatarsus adductus deformities respond to conservative treatment. The feet may be

Figure 664.1-1 Metatarsus adductus. A line bisecting the hindfoot should pass through the second toe or between the second and third toes.

classified into three groups depending on forefoot flexibility. Type I feet are flexible and actively and passively overcorrect into mild abduction. Voluntary correction can be elicited by stimulating the peroneal musculature by stroking the lateral border of the foot. These feet usually require no treatment. Type II feet correct to the neutral position both passively and actively. These feet may benefit from an orthosis or corrective shoes such as straight or reverse last shoes. These are worn full-time (22?hr/day), and the condition is re-evaluated in 4–6 wk. If improvement occurs, treatment can be continued. If there is no improvement, serial plaster casts are necessary. Type III feet are rigid and do not correct to neutral. These feet are treated with serial casts. The best results are obtained when casting is initiated before 8 mo of age. Once correction has been achieved, orthoses or corrective shoes may be used for an additional 1–2 mo to maintain correction. Mild hallux varus, the “searching toe,” may persist for several years after conservative correction and may be of concern to the parents. However, it eventually disappears with growth and the wearing of shoes.

OPERATIVE.

Significant residual metatarsus adductus in children 4 yr of age and older may require surgical intervention. Children 4–6 yr of age usually require only a soft tissue release. Serial casting is performed postoperatively until forefoot correction has been obtained. This usually requires 2–3 mo. Children 6 yr of age or older require base of the metatarsal osteotomies or other osseous procedures to achieve satisfactory correction. The sequelae of mild residual metatarsus adductus are minimal.

664.2 Calcaneovalgus Feet

The calcaneovalgus foot is a relatively common finding in the newborn and is secondary to in utero positioning. A hyperdorsiflexed foot with forefoot abduction and increased heel valgus manifests this condition. It is usually associated with external tibial torsion. It is often unilateral but occasionally may be bilateral. In utero, the plantar surface of the foot was against the wall of the uterus, forcing it into a hyperdorsiflexed, abducted, and externally rotated position. The position also produces the external tibial torsion. When these two conditions are combined with the normal newborn increased external rotation of the hip (tight posterior capsule), it results in a lower extremity that appears excessively externally rotated.

Clinical Manifestations.

The infant typically presents with an out-toe position of the involved extremity. The dorsum of the foot can easily be brought into contact with the anterior aspect of the lower leg; the forefoot is abducted, and the heel is in valgus. This should not be confused with the neonatal maturity classification of Dubowitz (see Chapter 86). External tibial torsion (20–50 degrees) is a common associated finding. Ankle motion shows normal or almost normal plantarflexion.

Three conditions must be distinguished from the calcaneovalgus foot: (1) congenital vertical talus, (2) posteromedial bow of the tibia, and (3) neuromuscular abnormalities with paralysis of the gastrocnemius muscle. The differentiation can usually be made during the physical examination.

Radiographic Evaluation.

Anteroposterior and lateral simulated weight-bearing radiographs of the feet may be necessary to differentiate between the calcaneovalgus foot and a congenital vertical talus. In a calcaneovalgus foot, the radiographs are normal or there may be increased hindfoot valgus and forefoot abduction. If a posteromedial bow of the tibia is suspected, anteroposterior and lateral radiographs of the tibia and fibula are necessary.

Treatment.

The typical calcaneovalgus foot requires no treatment. The hyperdorsiflexion of the foot resolves during the 1st 6 mo of life. The external tibial torsion, however, persists and follows the same natural history as internal tibial torsion.

Spontaneous improvement does not occur until the child begins to pull to stand and walk independently. It takes 6–12 mo thereafter for complete correction to occur. The majority of infants with calcaneovalgus feet and external tibial torsion have normally aligned feet and lower extremities by 2 yr of age.

664.3 Talipes Equinovarus (Clubfoot)

A clubfoot is a common foot deformity that involves not only the foot but also the entire lower leg. It can be classified into three groups: (1) congenital, (2) teratologic, and (3) positional. The congenital clubfoot is usually an isolated abnormality, whereas the teratologic form is associated with a neuromuscular disorder, such as myelodysplasia, arthrogryposis multiplex congenita, or a syndrome complex. The congenital form has also been called *idiopathic* or *neurogenic* on the basis of possible causes. The positional clubfoot is a normal foot that has been held in a deformed position in utero.

The *cause* of clubfoot is unknown. There are inheritance factors, and these are currently considered multifactorial with a major influence from a single autosomal dominant gene. Biopsy studies of the extrinsic muscles of the calf have indicated a probable neuromuscular cause. There are fiber type disproportions and increased neuromuscular junctions within these muscles. These findings are in contrast to previous etiologic theories in which deformity of the talus was believed to be the primary abnormality. Although the talus is certainly deformed with medial deviation of the head and neck, this is considered to be a secondary deformity.

Clinical Manifestations.

The congenital form of clubfoot, which constitutes approximately 75% of all cases, is characterized by (1) the absence of other congenital abnormalities, (2) variable rigidity of the foot, (3) mild calf atrophy, and (4) mild hypoplasia of the tibia, fibula, and bones of the foot. It occurs more commonly in males (2:1) and is bilateral in 50%

of cases. The probability for a random occurrence is approximately 1 in 1,000 births; within involved families, the probability is approximately 3% for subsequent siblings and 20–30% for offspring of involved parents.

Examination of the infant clubfoot demonstrates hindfoot equinus, hindfoot and midfoot varus, forefoot adduction, and variable rigidity. All these findings are secondary to the medial dislocation of the talonavicular joint. In the older child, the calf and foot atrophy are more obvious than in the infant, regardless of how well corrected or functional the foot. These findings are due to the causative aspects of clubfoot, not the method of treatment.

Radiographic Evaluation.

Anteroposterior and lateral standing or simulated weight-bearing radiographs and maximum dorsiflexion lateral radiograph are used in the assessment of clubfeet. Non–weight-bearing radiographs are not helpful. Multiple different radiographic measurements can be made. The navicular bone, which is the primary site of deformity, does not ossify until 3 yr in the female and 4 yr in the male. This necessitates line measurements to determine the position of the unossified navicular bone and the overall alignment of the foot.

Treatment

NONOPERATIVE.

Conservative treatment is initiated in all infants, although a significant proportion of children later require surgery. Nonoperative treatment includes taping, the use of malleable splints, and serial plaster casts. Taping and malleable splints are particularly useful in premature infants until they attain an appropriate size for casting. Serial plaster casts are the major method of nonoperative treatment. Before the cast is applied, the foot is gently manipulated toward the corrected position. The cast is then applied and changed at 1–2 wk intervals. Complete correction, both clinically and radiographically, should be achieved by 3 mo of age. If this is accomplished, holding casts are then used for an additional 3–6 mo followed by orthoses or corrective shoes until the child is walking well. Failure to achieve clinical and radiographic correction by 3 mo of age is an indication for surgical treatment. Further attempts at conservative management may result in articular damage and a midfoot breech (rocker-bottom deformity).

OPERATIVE.

The current method of surgical treatment is a complete soft tissue release. This is usually performed between 6 and 12 mo of age. Satisfactory long-term results can be expected in 80–90% of cases. Unsatisfactory results that require additional treatment are usually secondary to extrinsic muscle imbalance rather than incomplete correction. The use of tendon transfers and bone procedures, including arthrodeses (fusions), are primarily for salvage of recurrent clubfoot or incompletely corrected feet. Centralization of the tibialis anterior tendon has been particularly beneficial in young children with a dynamic pes varus, the most common residual abnormality. Triple arthrodeses are indicated in painful, deformed feet in adolescence.

664.4 Congenital Vertical Talus

Congenital vertical talus is an uncommon foot deformity with causes similar to those of talipes equinovarus. It must be distinguished from a calcaneovalgus foot, which is much more common. Typically, a congenital vertical talus is a rigid rocker-bottom deformity. The majority of these infants have an underlying disorder such as teratologic malformation (myelodysplasia and arthrogryposis multiplex congenita) or a syndrome such as trisomy 18.

Clinical Manifestations.

The characteristic of a congenital vertical talus is a rocker-bottom foot. There is hindfoot equinovalgus, a convex plantar surface, forefoot abduction and dorsiflexion, and rigidity. A careful physical examination must be performed on all children to look for an underlying disorder or syndrome.

Radiographic Evaluation.

Radiographic evaluation of a congenital vertical talus consists of an anteroposterior and lateral weight-bearing or simulated weight-bearing radiograph of the foot as well as a maximal plantarflexed lateral view. This typically reveals the vertically oriented talus, the dorsal displacement and abduction of the midfoot on the hindfoot, hindfoot valgus, and mobility.

Treatment.

As in clubfeet, nonoperative treatment is the initial method of treatment of congenital vertical talus, although most cases later require surgical correction.

NONOPERATIVE.

Serial casting after manipulation of the feet is performed beginning at birth. The forefoot is manipulated into equinus in an attempt to reduce the navicular onto the head of the talus. The success rate with nonoperative treatment is exceedingly low.

OPERATIVE.

The operative management of congenital vertical talus is predominantly through a complete soft tissue release performed as a one-stage or two-stage procedure. Occasionally, in severe deformities, a naviculectomy may be necessary to realign the midfoot and hindfoot adequately. Fortunately, this is rarely necessary. In older children with persistent hindfoot valgus and pronation, a subtalar arthrodesis or a triple arthrodesis may be necessary to realign the foot and provide stability.

The goals of treatment of congenital vertical talus are pessimistic and include a plantigrade, pain-free foot that is able to wear shoes. Orthotic management is frequently necessary for a prolonged period postoperatively, if not for life, because of

associated muscle weakness resulting from an underlying disorder.

664.5 Hypermobile Pes Planus (Flexible Flatfeet)

Hypermobile flatfeet or pronated feet are common sources of concern of parents. In general, these children are asymptomatic and have no functional limitations. Flatfeet are common in neonates and toddlers because of an associated laxity in the bone-ligament complexes of the feet and fat in the area of the medial longitudinal arch. These children usually demonstrate significant improvement by 6 yr of age. In the older child, flexible flatfeet are usually secondary to generalized ligamentous laxity, an autosomal dominant condition.

Clinical Manifestations.

In the non–weight-bearing position in the older child with a flexible flatfoot, the normal medial longitudinal arch is present, but in the weight-bearing position, the foot becomes pronated with varying degrees of pes planus and heel valgus. Instead of weight-bearing over the lateral column of the foot, weight is shifted medially, producing pronation. Subtalar motion is normal or slightly increased. Loss of subtalar motion indicates a rigid flatfoot. Common causes of rigid flatfeet include a tendo-Achilles contracture, tarsal coalitions, neuromuscular abnormalities (cerebral palsy), and familial trait.

Radiographic Evaluation.

Routine radiographs of asymptomatic flexible flatfeet are usually not indicated. Anteroposterior and lateral weight-bearing radiographs are obtained if there is rigidity or symptoms. On the anteroposterior radiograph, there is excessive heel valgus. The lateral view shows distortion of the normal straight line relationship between the long axis of the talus and the 1st metatarsal with either a sag of the talonavicular or naviculocuneiform joint, resulting in flattening of the normal medial longitudinal arch.

Treatment.

The treatment of flexible flatfeet is conservative. Affected children do not have symptoms predictably. Therefore, modified shoes and orthoses do not significantly alter the clinical or radiographic appearance of the feet. It should be emphasized that the diagnosis of flexible flatfeet is usually not possible until after 6 yr of age. Treatment is indicated for abnormal shoe wear or symptoms not attributable to other causes. Feet that are symptomatic with vigorous physical activities usually respond readily to the use of a commercially available medial longitudinal arch support. Custom-made supports are much more expensive and, in most cases, not any more effective. Surgery, including subtalar joint inserts, is rarely indicated.

664.6 Tarsal Coalition

Tarsal coalition, also known as peroneal spastic flatfoot, is a relatively common foot disorder characterized by a painful, rigid flatfoot deformity and peroneal (lateral calf) muscle spasm but without true spasticity. It represents a congenital fusion or failure of segmentation between two or more tarsal bones. Any condition that alters the normal gliding and rotatory motion of the subtalar joint may produce the clinical appearance of a tarsal coalition. Thus, congenital malformations, arthritis or inflammatory disorders, infection, neoplasms, and trauma can be possible causes.

The most common tarsal coalitions occur at the medial talocalcaneal (subtalar) facet and between the calcaneus and navicular (calcaneonavicular) tarsal bones. Coalitions can be fibrous, cartilaginous, or osseous. Tarsal coalition occurs in approximately 1% of the general population; it appears to be inherited as a unifactorial autosomal dominant trait with nearly full penetrance. Approximately 60% of calcaneonavicular and 50% of the medial facet talocalcaneal coalitions are bilateral.

Clinical Manifestations.

The onset of symptoms usually occurs during the 2nd decade of life. Although mild limitation of subtalar motion and the flatfoot may have been present since early childhood, the onset of symptoms varies with the age at which the fibrous or cartilaginous bar begins to ossify and further decrease motion. The talonavicular coalition ossifies between 3 and 5 yr of age, the calcaneonavicular coalition between 8 and 12 yr, and the medial facet talocalcaneal coalition between 12 and 16 yr. The pain is typically felt laterally in the hindfoot and radiates proximally along the lateral malleolus and distal fibula (peroneal muscle spasm). Symptoms are frequently aggravated by sports or walking on uneven ground. Clinically, the foot is flat or pronated both in the weight-bearing and the non–weight-bearing positions. Subtalar and transverse tarsal joint motion is diminished or absent, and attempts at motion may produce pain.

Radiographic Evaluation.

The diagnosis of a tarsal coalition is confirmed radiographically. Anteroposterior and lateral weight-bearing radiographs and an oblique radiograph of the foot should be obtained. Beaking of the anterior aspect of the talus on the lateral view is suggestive of a tarsal coalition. The oblique view demonstrates a calcaneonavicular coalition. Axial views through the hindfoot can be useful in the diagnosis of the medial facet talocalcaneal coalition. However, CT is the procedure of choice in the evaluation of coalitions, especially those involving the subtalar joint.

Treatment.

The treatment of symptomatic tarsal coalitions varies according to the type of coalition, age of the patient, extent of the coalition, presence or absence of degenerative osteoarthritis, and degree of disability. The treatment may be nonoperative or operative. Nonoperative treatment may consist of cast immobilization, shoe inserts, or orthotics. Operative management consists of excision of the coalition and interposition of muscle (calcaneonavicular) and fat or split flexor hallucis longus tendon (medial facet talocalcaneal) to prevent hematoma

formation and reossification of the coalition (Fig. 664–2). Resections are effective in relieving pain, improving subtalar motion, and allowing resumption of normal activities. However, if degenerative osteoarthritis is present, a triple arthrodesis may be necessary.

664.7 Cavus Feet

Cavus feet represent an exaggeration in the medial longitudinal arch associated with hindfoot varus and occasionally adduction of the forefoot. When the latter occurs, the deformity is called a *cavovarus deformity.* This type of deformity appears most commonly during the middle childhood years. Both idiopathic and neuromuscular types (hereditary motor-sensory neuropathies) may be seen. In either case, a cavovarus foot is usually a progressive deformity, leading to considerable compromise of foot function. These deformities tend to be rigid. The most important aspect of the evaluation of a patient with a cavovarus foot is to establish an accurate diagnosis. Possible causes include spinal cord disease and peripheral neuropathies, such as Charcot-Marie-Tooth disease.

Treatment.

Aggressive treatment is usually necessary for moderate to severe cavus feet. This usually involves reconstructive surgery. Special shoes and shoe modifications are not helpful from a therapeutic standpoint but sometimes may be warranted to provide relief from abnormal pressure during weight-bearing. Surgical correction by soft tissue balancing and occasionally by osseous procedures is usually necessary.

664.8 Osteochondroses

Osteochondroses are pathologic processes that involve infarction, revascularization, resorption, and replacement of the

Figure 664.8-2 *A*, Standing lateral radiograph of the foot of a 12-yr-old girl with limited, painful subtalar joint motion. There is an extension of the anterior process of the calcaneus toward the navicular. This has been called the “anteater's nose” and is indicative of calcaneonavicular coalition. *B*, The oblique radiograph demonstrates the calcaneonavicular coalition. The small, unossified area in the center of the coalition is actually cartilaginous and will ultimately form a complete osseous bridge. *C*, Oblique radiograph after excision of the coalition and interposition of the extensor digitorum brevis muscle to prevent re-formation. This procedure restores subtalar joint motion and relieves discomfort.

affected bone. This is commonly termed *idiopathic avascular necrosis.* Both the tarsal navicular (*Köhler disease*) and the head or epiphysis of the 2nd metatarsal (*Freiberg disease*) may sustain avascular necrosis. These conditions are relatively uncommon and both produce pain, especially with activities. Symptomatic treatment is based on the severity of the child's complaint. Occasionally, a short-leg cast and a non–weight-bearing stance with crutches may be helpful in relieving symptoms.

As the older child enters the period of pubescent growth spurt, the fibrocartilaginous insertion of major muscle groups to bone is vulnerable to microfracture, resulting in inflammatory and healing responses. The usual site of microfractures in the foot is the attachment of the tendo-Achilles (heel cord) to the posterior aspect of the calcaneus. This produces another osteochondrosis: *Sever disease,* which is a common cause of heel pain. Symptoms wax and wane depending on the level of activity; and until skeletal maturity is achieved, the usual residual manifestation, if any, is bony enlargement at the tendon insertion site secondary to overgrowth during the healing response. Treatment is again symptomatic and includes the use of an anti-inflammatory agent and heel cord stretching.

664.9 Puncture Wounds of the Foot

For most puncture wound injuries, extensively cleansing the wound, ensuring prophylaxis for tetanus, and administering a broad-spectrum oral antibiotic are all that is needed. When infection occurs despite these measures, *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the usual offending organisms. In pseudomonal osteomyelitis, the puncture usually injured the bone, cartilage, or joint. This is most common when the puncture wound is through the sole of a sneaker. The heat and perspiration and the material within the sneakers tend to promote the growth of this organism. Treatment of established infections includes wound debridement to remove necrotic tissue. Broad-spectrum antibiotics are administered, including methicillin and gentamicin, pending the outcome of the cultures. Subsequent antibiotic treatment is based on the results of these tests. After surgery, further microbial therapy is continued for 10–14 days. Most patients have a satisfactory response to this therapy.

664.10 Toe Deformities

ADOLESCENT BUNIONS

Adolescent bunions, a common pediatric foot deformity, are more common in girls (3:1); there is frequently a positive family history. There are both intrinsic and extrinsic factors associated with this deformity. The intrinsic factors include metatarsus primus varus, oblique 1st metatarsal-medial cuneiform articulation, short 1st metatarsal, and pes planus. Extrinsic factors include abnormal shoe wear (narrow toe box with an elevated heel) and a subtle underlying neurologic disorder, such as mild cerebral palsy.

Clinical Manifestations.

An adolescent presenting with bunions requires careful evaluation. It must be determined whether it is the symptoms or the deformity, or both, that are of concern to the patient and the family. If pain is present, it must be ascertained whether it is due to activities and whether it produces functional limitation. It is also important to know what types of shoes are being worn when symptoms are present. When evaluating the foot, weight-bearing alignment, walking alignment, mobility of the 1st metatarsophalangeal joint, presence or absence of callus formation, and preferred

shoe style must be determined.

Radiographic Evaluation.

Anteroposterior and lateral weight-bearing radiographs of the feet are necessary in the assessment of adolescent bunions. This allows measurement of the (1) intermetatarsal angle, (2) hallux valgus angle, (3) distal metatarsal articular angle, (4) alignment of the 1st metatarsal-medial cuneiform joint, and (5) pes planus. The normal intermetatarsal angle between the long axes of the 1st and 2nd metatarsals is 10 degrees or less, and the normal hallux valgus angle is 25 degrees or less. A short 1st metatarsal can be diagnosed from these radiographs.

Treatment

NONOPERATIVE.

Conservative management of adolescent bunions consists primarily of shoe modifications. It is important that footwear accommodate the width of the forefoot. Adolescents should be discouraged from wearing narrow-toed shoes with elevated heels. In the presence of a pes planus, an orthotic to restore the medial longitudinal arch may be beneficial.

OPERATIVE.

The indications for surgical correction include an intermetatarsal angle between 12–18 degrees and failure of nonoperative management. The major indication for surgical treatment is symptoms, not cosmesis. Surgery rarely restores the foot to a completely normal appearance but is effective in narrowing the width of the forefoot, correcting the hallux valgus, improving weight-bearing alignment, and relieving symptoms. Surgery typically consists of a combination of a soft tissue and bone procedure. The osseous procedures are numerous and can be performed on the 1st metatarsal or medial cuneiform, or both.

CURLY TOES

The most common lesser toe deformity of childhood is curly toes. These represent a flexion deformity at the proximal interphalangeal joint with lateral rotation and varus alignment of the toe (Fig. 664–3). The 4th and 5th toes are the most commonly involved. Occasionally, the 2nd and 3rd toes are involved. The disorder is usually familial, bilateral, symmetric, and asymptomatic. The condition is secondary to short, tight flexor digitorum longus and flexor digitorum brevis tendons. The tightness in these tendons can be demonstrated by dorsiflexing the foot, which will increase the curling of the toes. Plantarflexion usually results in improvement. Radiographic evaluation of curly toe deformities is not necessary.

Treatment.

In infants and young children, curly toe deformities should be observed because 25–50% resolve spontaneously. Taping or splinting is ineffective. At 3–4 yr of age, an open tenotomy of the toe flexor tendons can be performed. In older children and adolescents, a proximal interphalangeal joint fusion may be necessary.

OVERLAPPING FIFTH TOE

An overlapping 5th toe is a relatively common condition in which the 5th toe is adducted and overrides the 4th toe. It

Figure 664.10-3 *A*, Bilateral curly toe deformities in a 4-yr old. There is flexion and varus rotation of the lateral three toes. *B*, The frontal view better demonstrates the curling of the toes, especially the third toes.

results in abnormal shoe wear and pain in approximately 50% of patients.

Examination of the 5th toe shows an extensor digitorum longus contracture. There is also a dorsal metatarsophalangeal joint contracture. The 5th toe is adducted, extended, and laterally rotated. It may be possible to realign the toe passively, but the corrected position cannot be maintained. Radiographs are not necessary in the evaluation of an overlapping fifth toe.

Treatment.

Nonoperative treatment is ineffective; it can be corrected surgically. The most common procedure consists of a racket-shaped incision around the base of the toe. The extensor digitorum longus tendon is released along with the dorsal joint contracture. This allows the toe to be placed into its normal position.

POLYDACTYLY

Polydactyly is a relatively common deformity. It usually involves the 5th toe. It occurs in approximately 2 in 1,000 births. Approximately 30% of patients have a positive family history. It is important to assess for syndromes and other organ anomalies as well as other digit deformities such as polydactyly of the hand and syndactyly of adjacent toes. Duplication of the great toe is also possible. There may be associated metatarsal abnormalities.

Anteroposterior and lateral weight-bearing radiographs of both feet are obtained in the management of children with polydactyly. This demonstrates whether the duplication is articulated or rudimentary and whether there are metatarsal abnormalities.

Treatment.

Rudimentary-type digits can be ligated at birth and allowed to autoamputate. Those

that are articulated require excision at approximately 1 yr of age. The guidelines in polydactyly are to save the digit with best axial alignment, resect the projecting symptomatic toe, repair the capsule, balance the soft tissues, and shave any metatarsal prominences.

SYNDACTYLY

Syndactyly is a relatively common lesser toe condition. Cases of syndactyly are usually asymptomatic, and there may be a positive familial history. They can be classified into *zygosyndactyly* and *polysyndactyly.* In zygosyndactyly, there is complete or incomplete webbing. This usually occurs between the 2nd and 3rd toes. In polysyndactyly, there may be a duplication of the 5th toe, with a syndactyly between the 4th and 5th toes. Synostosis of the lateral metatarsals is common.

Treatment.

Zygosyndactyly does not require treatment, but polysyndactyly may because of the associated anomalies.

HAMMER TOE

A hammer toe is similar to a curly toe except there is no malrotation of the involved toe. There is a flexion deformity at the proximal interphalangeal joint, and the metatarsophalangeal

joint is extended. The metatarsal head may appear depressed. It is usually symmetric and bilateral, with the 2nd toe most commonly involved. The major problems with this deformity are painful calluses over the proximal phalangeal joint.

Treatment.

Passive stretching and taping may be helpful in infants and young children. However, the majority requires surgical correction of the contracted flexor digitorum longus and flexor digitorum brevis tendons. Occasionally, tendon transfers are required.

MALLET TOE

Mallet toe is a flexion deformity at the distal interphalangeal joint. It may become symptomatic in adolescents as a result of a dorsal callosity or perhaps from nail bed irritation.

Treatment.

Nonoperative treatment is usually ineffective. Correction is usually obtained by the release of the flexor digitorum longus tendon. Occasionally, in the adolescent, a distal interphalangeal joint fusion may be necessary.

CLAW TOE

Claw toes represent an extension contracture with dorsal subluxation of the metatarsophalangeal joint in association with flexion deformities of both the proximal and distal interphalangeal joints. They can occur idiopathically, but the majority is associated with a pes cavus deformity and is secondary to an underlying neurologic disorder, such as Charcot-Marie-Tooth disease. These deformities are complex and require careful assessment to determine the underlying cause.

Treatment.

Claw toes are treated surgically, usually with soft tissue rebalancing and, occasionally, fusions of the proximal interphalangeal joint.

ANNULAR BANDS

Annular bands or constriction rings are relatively common congenital disorders that involve the toes and fingers. They may consist of simple constriction rings or rings with deformity of the distal part of the toe with swelling and lymphedema. Occasionally, the rings may be deep enough to have produced an amputation. Sometimes there will be an associated syndactyly with the adjacent toe. Annular bands of the lower extremity are frequently associated with clubfeet.

Treatment.

The treatment of annular or constriction bands is predominantly observation. If there are deep rings with swelling and lymphedema, surgery may be necessary to relieve the congestion.

SUBUNGUAL EXOSTOSES

Subungual exostosis is an uncommon problem that primarily involves the great toe. It may simulate an ingrown toenail. On physical examination, there is a palpable mass beneath the toenail. The toe may appear irritated and similar to an infection; however, palpation reveals a mass rather than granulation tissue. Radiographs of the toe demonstrate exostosis of the distal phalanx.

Treatment.

Subungual exostoses are managed by partial excision of the nail bed and removal of the underlying exostosis.

INGROWN TOENAIL

Ingrown toenails are relatively common in infants and young children and later in adolescents. These typically involve the medial and lateral borders of the great toe.

Treatment.

Conservative treatment is usually effective. This consists of appropriate shoe modification, warm soaks, antibiotics, elevation of the nail edge, and proper nail-cutting techniques. If this fails, surgery with wedge section of the involved border, including the nail matrix, is usually effective.

STUBBED GREAT TOE

Stubbed toes are common and in most patients heal spontaneously and rapidly. A Salter-Harris I fracture to the growth plate may occur, which also usually heals with minimal treatment.

Injuries associated with signs of nail bed bleeding or nail fold bleeding suggest the presence of an open fracture. The latter increases the risk for osteomyelitis, which may result in growth arrest of the distal phalanx of the great toe.

Persistent pain, bleeding, cellulitis, or pus drainage requires specific therapy for possible osteomyelitis, including oral or intravenous antistaphylococcal antibiotics, irrigation, and debridement.

664.11 Painful Foot

The causes of a painful foot can usually be determined from history and physical examination. The common causes are listed in Table 664–1 . The specific treatment depends on the diagnosis and occasionally on the age of the child or adolescent.

664.12 Shoes

Clothing is worn for comfort, to enhance appearance, and for protection. Shoes should be selected on the same basis. Shoes are not corrective, and the foot does not need support for normal activities. The foot requires mobility to function normally. It has been demonstrated that populations that are predominantly barefoot have better feet than those that wear shoes. The best shoes for children are those that simulate the bare foot. They should be flexible, flat, and nonconstricting and made of material that “breathes.” Shoes do not have to be expensive.

Because overuse foot symptoms are common, especially in the athletic adolescent, shock-absorbing shoes are a good choice. The thick-cushioned sole absorbs some of the shock of impact and thereby decreases discomfort.

Shoe modifications are sometimes appropriate for a specific problem. A lift may be prescribed if the limb is short, and a shoe insert may be helpful for the stiff and deformed foot or to distribute the weight load more evenly over the sole.

TABLE 664.12-1 -- **Differential Diagnosis of Foot Pain by Age**

0–6 Yr	6–12 Yr	12–20 Yr
Poor-fitting shoes	Poor-fitting shoes	Poor-fitting shoes
Foreign body	Sever disease	Stress fracture
Fracture	Enthesopathy (JRA)	Foreign body

Chapter 665 - Torsional and Angular Deformities

George H. Thompson

665.1 Normal Developmental Alignment

The most common torsion and angular changes of the lower extremity are related to normal in utero positioning or acquired disorders.

In the typical in utero position, the hips are flexed, abducted, and externally rotated; the knees are flexed and the lower legs are internally rotated; and the feet are in slight equinus, supinated, and in contact with the posterolateral aspect of the opposite thigh. The combination of external rotation of the hip and internal rotation of the lower leg produces a bowed appearance of the lower extremities when the child begins to ambulate. This is not true bowing but rather a torsional combination. *Physiologic genu varum* or bowlegs resolves with 6–12 mo of independent ambulation.

Physiologic genu valgum or knock-knees is seen between 3 and 4 yr of age. This is true genu valgum and not the result of a torsional combination. This, too, resolves with growth, with the normal adult knee alignment obtained between 5 and 8 yr of age. The mean tibiofemoral angle at birth is 15 degrees of varus (Fig. 665–1). This decreases to approximately 10 degrees by 1 yr of age. Neutral alignment occurs between 18 and 20 mo of age. The maximal valgus of 12 degrees occurs at 3–4 yr of age. The values are similar for boys and girls. By 7 yr, the valgus alignment corrects to that of a normal adult (8 degrees in women; 7 degrees in men). Overall, 95% of developmental physiologic genu varum and genu valgum cases resolve with growth. This is also true for children with more pronounced physiologic varus or valgus, although some may not be completely corrected until adolescence.

TORSIONAL PROFILE

The torsional profile is beneficial in diagnosing and monitoring children with torsional variations (Fig. 665–2). The profile includes (1) foot progression angle, (2) hip rotation in extension, (3) thigh-foot angle, and (4) shape of the foot.

Foot Progression Angle.

The foot progression angle represents the long axis of the foot with respect to the direction in which the child is walking (Fig. 665–3). Inward rotation is given a negative value, and outward rotation is given a positive value. A normal foot progression angle in children and adolescents is 10 degrees (range, -3 to 20 degrees). The foot progression angle serves only to define whether there is an in-toeing or out-toeing gait. The latter is considered abnormal when this angle exceeds 20 degrees.

Hip Rotation.

Hip rotation in extension is assessed with the child prone, the thighs together, and the knees flexed 90 degrees (Fig. 665–4). In this position, the hip is in neutral alignment. As the lower leg is rotated outward, this produces internal rotation of the hip, whereas inward rotation produces external rotation. This is due to the anatomic shape of the proximal femur. The femoral neck normally has a 135-degree angle with the femoral shaft and 15 degrees of anterior rotation between femoral neck axis and the transcondylar axis of the distal femur. This angulation is known as femoral anteversion. By 1 yr of age there is approximately 45 degrees of internal and external rotation. Hip rotation should be symmetric. Asymmetric rotation may be indicative of a hip disorder, and radiographs of the pelvis are necessary.

Figure 665.1-1 Graph demonstrating the normal development of the tibiofemoral or knee angle during growth. (Adapted from Salenius P, Vankka E: The development of the tibiofemoral angle in children. *J Bone Joint Surg Am* 1975;57A:259.)

Thigh-Foot Angle.

With the child in the prone position for assessment of hip rotation, the long axis of the foot in the simulated weight-bearing position can be compared with the long axis of the thigh (Fig. 665–5). Inward rotation is given a negative value, and outward rotation is given a positive value. Inward rotation indicates internal tibial torsion, whereas outward rotation represents external tibial torsion. Infants have a mean angle of -5 degrees (range, -35 to 40 degrees) as a consequence of normal in utero position. In middle childhood through adult life, the mean thigh-foot angle is 10 degrees (range, -5 to 30 degrees).

Foot Shape.

With the child still in the prone position, the shape of the foot is easily assessed (Fig. 665–6). This position is helpful in the assessment of metatarsus adductus or a calcaneovalgus foot. The mobility of the ankle and subtalar region can also be evaluated with the child in this position.

TORSIONAL DEFORMITIES

The common causes of in-toeing and out-toeing are presented in Table 663–4 .

665.2 Internal Femoral Torsion

Internal femoral torsion is the most common cause of in-toeing in children 2 yr of age or older. It occurs more commonly in girls than boys (2:1). The majority of children with this condition have generalized ligamentous laxity. The cause of femoral torsion is controversial. Some believe that it is congenital and a result of persistent infantile femoral anteversion, whereas others believe it is acquired secondary to abnormal sitting habits.

Clinical Manifestations.

Clinical features of internal femoral torsion demonstrate that the entire lower leg is inwardly rotated during gait. Characteristically, there will be 80–90 degrees of internal rotation of the hip in the prone position (torsional profile). External rotation, as a consequence, is limited to 0–10 degrees (Fig. 665–7). There will be features of generalized ligamentous laxity, including elbow and finger hyperextension, thumb hyperabduction, knee recurvatum, and hypermobile pes planus. Affected children commonly sit in the “television” or “W” style position. It is believed that this position allows the lower leg to act as a lever, thereby producing torsional changes in the “biologically plastic” femora. This condition is also called femoral anteversion, implying an abnormality of the proximal femur. However, the torsion actually occurs throughout the femoral shaft and results in a change in the normal alignment between the hip and the knee.

Radiographic Evaluation.

Radiographic evaluation of internal femoral torsion is not routinely necessary, although a variety of radiographic techniques to measure femoral torsion have been described. CT and ultrasonography can assess the relationship between the proximal and distal femur. These studies are rarely indicated because the clinical measurements are equally accurate.

Treatment.

The treatment of internal femoral torsion is predominantly by observation. Correction of abnormal sitting habits usually allows the torsion to resolve with normal growth and development. It takes 1–3 yr for complete correction to occur, depending on the age of the child when the sitting habits are corrected. The correction of sitting habits can be difficult in preschool-aged children and usually does not occur until they reach school age. The use of nighttime orthoses or daytime twister cables is of no value and may produce a compensatory external tibial torsion. The combination of internal femoral and compensatory external tibial torsion produces a pathologic genu valgum deformity. This can result in patellofemoral malalignment with patella subluxation or dislocation and pain.

Figure 665.2-2 Range of normal values by age and sex with respect to the alignment of the lower extremity. *A*, Torsional profile. *B*, Foot progression angle (FPA) to determine the degree of in-toeing and out-toeing during ambulation. *C* and *D*, Medial (MR) or internal rotation of the hips in girls (*C*) and boys (*D*). *E*, Lateral (LR) or external rotation of the hips. *F*, Thigh-foot angle (TFA) to determine the degree of tibial torsion. Internal or medial tibial torsion is present if the angle is more than 20–30 degrees. (From Staheli LT: Torsional deformities. *Pediatr Clin North Am* 1986;33: 1373.)

Children 10 yr of age or older may not have enough remaining musculoskeletal growth for spontaneous correction to occur, and surgical intervention may be necessary. The procedures advocated include proximal femoral varus derotation osteotomy and simple derotation osteotomy of either the proximal or the distal femur. Sufficient derotation is performed to allow equal internal and external hip rotation postoperatively.

665.3 Internal Tibial Torsion

Internal tibial torsion is the most common cause of in-toeing in children younger than 2 yr and is secondary to normal in utero positioning. This condition is commonly seen during the 2nd year of life and may be associated with metatarsus adductus.

Clinical Manifestations.

The degree of tibial torsion can be measured by the prone thigh-foot angle (torsional profile).

Radiographic Evaluation.

Radiographic assessment is of no value in this predominantly clinical disorder.

Treatment.

Treatment of internal tibial torsion is by observation. This is a physiologic condition, and spontaneous resolution with normal growth and development can be anticipated. Significant improvement usually does not occur until the child begins to pull to stand and walk independently. Thereafter, it takes 6–12 mo and occasionally longer for complete correction to occur. Night splints are of no value and should be avoided. Persistent internal tibial torsion in an older child or adolescent may require surgical derotation; however, this rarely occurs.

665.4 External Femoral Torsion

External femoral torsion, also known as femoral retroversion, is an uncommon disorder unless associated with a slipped capital femoral epiphysis (SCFE) (see Chapter 668.4).

Clinical Manifestations.

The clinical examination of external femoral torsion shows excessive hip external rotation and limitation of internal rotation. Typically, the hip will externally rotate 70–90 degrees, whereas internal rotation is only 0–20 degrees (torsional profile). When idiopathic, it is usually a bilateral disorder. If the deformity is unilateral, especially in an obese older child or young adolescent, the presence of an SCFE must be considered.

Figure 665.4-3 Foot progression angle. The long axis of the foot is compared with the direction in which the child is walking. If the long axis of the foot is directed outwardly, the angle is positive. If the foot is directed inwardly, the angle is negative and is indicative of in-toeing. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Radiographic Evaluation.

Anteroposterior and Lauenstein (frog) lateral radiographs of the pelvis are necessary in any child or adolescent presenting with external femoral torsion, especially those who are obese or who have nontraumatic anterior thigh or knee pain (referred pain) or when the deformity is unilateral, to assess for a possible SCFE.

Treatment.

The treatment of idiopathic external femoral torsion is usually observation because it ordinarily causes no significant functional impairment. An SCFE is treated surgically, and any proximal femoral retroversion improves with remodeling during subsequent growth.

Figure 665.4-4 Hip rotation in extension. This is measured with the child in the prone position and the knee flexed 90 degrees. The lower leg is vertically oriented. This is considered the neutral position. On outward rotation *(A)*, the leg produces internal hip rotation; and on inward rotation *(B)*, the leg produces external hip rotation. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Occasionally, persistent femoral retroversion after SCFE can produce functional impairment such as a severe out-toe gait and difficulty opposing one's knees in the sitting position. The latter can be disabling to adolescent females. Should this occur, a derotation osteotomy is beneficial.

665.5 External Tibial Torsion

External tibial torsion is a relatively common disorder and is frequently associated with a calcaneovalgus foot. It is secondary to a normal variation in in utero positioning.

Clinical Manifestations.

External tibial torsion is indicated by an abnormally positive thigh-foot angle (torsional profile), typically 30–50 degrees. There is a calcaneovalgus foot (Fig. 665–8).

Radiographic Evaluation.

Radiographic assessment for external tibial torsion is not necessary because there is no demonstrable radiographic abnormality.

Treatment.

The treatment of external tibial torsion is observation. This condition follows the same clinical course as that of internal tibial torsion. Significant improvement does not occur during the 1st yr of life. However, with the onset of independent ambulation, spontaneous improvement begins to occur and is typically complete by 2–3 yr of age.

665.6 Genu Varum (Bowlegs)

The classification of genu varum is presented in Box 665–1 . Physiologic genu varum and tibia vara (Blount disease) are the most common disorders.

PHYSIOLOGIC GENU VARUM

Physiologic bowlegs is a common torsional combination that is secondary to normal in utero positioning (Fig. 665–9). The tight posterior hip capsule results in an external rotation contracture. When it is combined with internal tibial torsion, it gives the clinical appearance of a bowleg deformity. Because it is physiologic, spontaneous resolution with normal growth and development can be anticipated. Significant improvement does occur during the 1st yr of life. By 2 yr of age, the majority of children have straight or neutrally aligned lower extremities.

Figure 665.6-5 Thigh-foot angle. With the child in the prone position and the knees flexed and approximated, the long axis of the foot can be compared with the long axis of the thigh. The long axis of the foot bisects the heel and the second toe or lies between the second and third toes. External tibial torsion *(A)* produces excessive outward rotation. Normal alignment *(B)* is characterized by slight external rotation. Internal tibial torsion produces inward rotation of the foot and is a negative angle *(C)*. (From Thompson GH: Gait disturbances. In Kliegman RM, Nieder ML, Super DM [editors]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

TIBIA VARA

Idiopathic tibia vara, or Blount disease, is an uncommon disorder characterized by abnormal growth of the medial aspect of the proximal tibial epiphysis, resulting in progressive varus angulation below the knee. Tibia vara can occur in any age group in a growing child and is classified as infantile (1–3 yr), juvenile (4–10 yr), and adolescent (11 yr or older). The juvenile and adolescent forms are commonly combined as late-onset tibia vara. All three groups share common characteristics, whereas the radiographic changes in the late-onset groups are less pronounced than those in the infantile form. Although the

Figure 665.6-6 Foot shape. Using the same position for measurement of the thigh-foot angle, the shape of the foot can also be evaluated. In this illustration, the left foot has normal alignment, whereas the right foot demonstrates metatarsus adductus. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

exact cause of tibia vara remains unknown, it appears to be secondary to growth suppression from increased compressive forces across the medial aspect of the knee.

Clinical Manifestations.

The infantile form of tibia vara is the most common; its characteristics include female and black predominance, marked obesity, approximately 80% bilateral involvement, a prominent medial metaphyseal beak, internal tibial torsion, and leg-length discrepancy. The characteristics of the juvenile and adolescent forms (late-onset) include male and black predominance, marked obesity, normal or greater than normal height, approximately 50% bilateral involvement, slowly progressive genu varum deformity, pain rather than deformity as the primary initial complaint, no palpable proximal medial metaphyseal beak, minimal internal tibial torsion, mild medial collateral ligament laxity, and mild lower extremity length discrepancy. The differences among the three groups appear to be primarily due to age at onset, the amount of growth remaining, and the magnitude of the medial compression forces. The infantile group has the potential for the greatest deformity, and the adolescent group has the least.

Radiographic Evaluation.

Children with tibia vara are usually assessed radiographically with an anteroposterior standing radiograph of both lower extremities and a lateral radiograph of the involved extremity. Positioning the child in weight-bearing stance allows maximal presentation of the clinical deformity. The metaphyseal-diaphyseal angle can be measured and is useful in distinguishing between physiologic genu varum and early tibia vara. The latter is difficult to diagnose radiographically before 2 yr of age. Fragmentation with a protuberant step deformity and beaking of the proximal medial tibial metaphysis are the major features of the infantile group. The changes in the proximal medial tibial metaphysis are less conspicuous in the late-onset forms, which are characterized by wedging of the medial portion of the epiphysis, a mild posteromedial articular depression, a serpiginous cephalad curved physis, and mild or no fragmentation or beaking of the proximal medial metaphysis (Fig. 665–10).

Occasionally, arthrography, MRI, or CT may be necessary to assess the meniscus, the articular surface of the proximal tibia, or the integrity of the proximal tibial physis. These tests are usually reserved for the more severe deformities.

Figure 665.6-7 *A*, A 5-yr-old girl with bilateral internal femoral torsion. She has approximately 80 degrees of internal rotation bilaterally. *B*, External rotation is limited to approximately 15 degrees for a total arc of hip rotation of 90–95 degrees. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Figure 665.6-8 *A*, A 6-mo-old girl with an excessive external tibial torsion. This reverse, or anterior, thigh-foot angle shows approximately 50 degrees of external tibial torsion. *B*, The same infant demonstrates a calcaneovalgus foot with forefoot abduction and increased hindfoot valgus. There is also hyperdorsiflexibility of the foot in the ankle mortise. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Treatment.

The management of tibia vara may be both nonoperative and operative in the infantile form. Late-onset tibia vara is managed operatively.

NONOPERATIVE.

Orthotic management can be considered for children with infantile tibia vara who are 3 yr of age or younger with mild deformities. In approximately 50% of children meeting these criteria, the deformity may be adequately corrected. A knee-ankle-foot orthosis should be used with a single medial upright, without a knee hinge. Pads and straps should be placed over the distal femur and proximal tibia to apply a valgus force. The orthosis should be worn 22–23?hr each day. A maximal trial of 1 yr of orthotic management is currently recommended. If complete correction is not obtained after 1 yr or if progression occurs during this time, a corrective osteotomy is indicated.

OPERATIVE.

The indications for surgical treatment of infantile tibia vara include age of 4 yr or more, failure of orthotic management, and more severe deformities. Proximal tibial valgus osteotomy and associated fibular diaphyseal osteotomy are usually the procedures of choice (Fig. 665–11). In late-onset tibia vara, correction is also necessary to restore the mechanical axis of the knee. The same surgical options as presented for older children with infantile tibia vara are applicable in these age groups. A proximal tibial valgus osteotomy and diaphyseal fibular osteotomy are the most common procedures.

665.7 Genu Valgum (Knock-Knees)

The classification of genu valgum is presented in Box 665–2 . Fortunately, the pathologic causes, with the exception of post-traumatic disorders, are uncommon. As the spontaneous correction of physiologic bowlegs continues, there is typically an overcorrection, of variable degree, into mild genu valgum,

The osteotomy is healed, and relatively normal growth is occurring in the proximal tibial epiphysis. *D*, Postoperative clinical photograph demonstrating symmetric alignment of the lower extremities.

or knock-knees. This physiologic angular variation is commonly seen between 3 and 5 yr of age. It is a true angular deformity that resolves spontaneously, with normal knee alignment being attained between 5 and 8 yr. Rarely is a knock-knee orthosis indicated. Surgery may be required in adolescence for a persistent deformity. Options include medial physeal stapling, medial hemiepiphysiodesis, and corrective osteotomy.

665.8 Congenital Angular Deformities of the Tibia and Fibula

The differential diagnosis of congenital angular deformities of the lower leg (Box 665–3) includes posteromedial angulation, which is a benign process, and anterolateral angulation, which is a pathologic process.

Congenital Posteromedial Tibial Angulation (Bowing).

This is an uncommon angular deformity that involves the distal one third of the tibia and fibula. There is a posteromedial bowing in association with a calcaneovalgus foot. The clinical appearance can be dramatic. The diagnosis is confirmed radiographically and shows the posteromedial angulation without other osseous abnormalities. A significant portion of the calcaneovalgus foot is due to the position of the distal tibia and ankle.

The *cause* of the congenital posteromedial bowing is unknown. The natural history is characterized by spontaneous resolution by 3–5 yr of age. However, there is residual shortening in the tibia and fibula. The fibula is usually slightly shorter than the tibia. The mean growth inhibition is 12–13% (range, 5–27%). The mean leg-length discrepancy at maturity is 4?cm (3–7?cm).

The *treatment* of congenital posteromedial bowing of the tibia and fibula is observation. All components of the deformity with the exception of leg-length inequality resolve with growth and development. The child should have periodic radiographic leg-length measurements to determine the degree of discrepancy and to predict the maximal discrepancy at maturity. This also

allows information regarding the appropriate age for surgical intervention. Operative intervention for a defect other than leg-length discrepancy is rarely indicated. A corrective osteotomy may be necessary in patients with severe deformity that is not improving with growth and development. Patients with discrepancies greater than 5?cm may be candidates for tibial lengthening.

Congenital Anterolateral Tibial Angulation (Bowing).

This type of bowing is associated with an underlying pathologic disorder (see Box 665–3). The diagnosis is made radiographically. *Congenital fibular hemimelia* represents a congenital absence of the fibula and usually the lateral portion of the foot, especially the fourth and fifth rays. *Congenital tibial hemimelia* represents a congenital absence of the tibia, either partial or total. Surgical reconstruction of these deformities is difficult, and most defects require amputation to achieve satisfactory function. *Congenital pseudoarthrosis* of the tibia is usually associated with neurofibromatosis. It represents a defect in the tibia that predisposes to pathologic fractures, which heal poorly. A variety of surgical techniques, including intramedullary rodding, electrical stimulation, and vascularized fibular transplants, have been used with varying success in this complex problem.

Chapter 666 - Leg-Length Discrepancy

George H. Thompson

Etiology.

The common causes of leg (also called lower extremity)-length discrepancy are presented in Box 666–1 .

Clinical Manifestations and Diagnosis.

Signs and symptoms associated with leg-length discrepancy, other than limping, are usually related to the underlying cause. Approximately 65% of the growth of the entire lower extremity comes from the distal femoral (37%) and proximal tibial (28%) physes. Thus, growth disturbances around the knee can have the most adverse effect on leg length. Determination of the *skeletal,* or *bone, age* allows for a relatively accurate assessment of remaining growth. The *Gruelich and Pyle Atlas* (1950) remains the standard by which bone age is determined from an anteroposterior radiograph of the left hand and wrist. It is possible to estimate the *ultimate discrepancy at maturity* using growth-remaining tables such as the Moseley straight-line graph (Fig. 666–1) and the Green-Anderson table. The former, the most commonly used today, uses scanographic and bone age data to determine the ultimate discrepancy. It can also be used to follow the response of treatment. The clinical methods available are less accurate than the radiographic techniques, but they are useful. The most common clinical measurement is leveling the pelvis. Blocks of various thickness may be placed beneath the foot on the involved side until the iliac crests are level. The thickness indicates the amount of discrepancy.

Adult sitting height is approximately 52% of total height in the male and 53% in the female. Thus, two times the predicted length of the normal leg at maturity gives a close approximation of the *anticipated adult height.* This height plays an important role in determining equalization. Lengthening procedures are more applicable in predicted short adults, whereas shortening procedures are generally used for predicted normal height or taller

Figure 666-1 The Moseley straight-line graph for the assessment of leg-length inequalities. This allows simultaneous correlation of the normal leg, short leg, and bone age of the child. It will accurately predict lengths of each extremity at skeletal maturity. The reference slopes are used as a guide in determining when appropriate treatment should be performed.

individuals. In either case, acceptable body proportions must be maintained.

Children with *neuromuscular disorders* such as spastic hemiplegia benefit from 1–2?cm of shortening on the involved side to improve the swing phase of gait and increase toe clearance. Only extremities that are neurologically normal should be considered for equalization of leg lengths.

Angular deformities and coexistent joint abnormalities are important considerations in children with leg-length discrepancies. This is especially true when lengthening procedures are being considered. A child with a dysplastic acetabulum may subsequently experience a hip dislocation if femoral lengthening is attempted. Thus, any significant angular deformities or joint abnormalities should be corrected either before or simultaneously with leg-length equalization.

Radiographic Evaluation.

Radiographic evaluations are the most accurate methods of assessing leg lengths. Four different types of radiographic techniques are available. The *teleoroentgenogram* is a single exposure of both lower extremities. Its primary indication is for young children, usually younger than 5 yr. There is a small amount of magnification error present, but it has the advantage of demonstrating any associated angular deformity. The *orthoroentgenogram* consists of three separate, slightly overlapping exposures of the hips, knees, and ankles on a long cassette. Bone length is measured directly on the radiograph. There is less magnification, and it is relatively accurate and demonstrates angular deformities. The *scanogram* is a simple, accurate method

of assessment. It consists of three narrow exposures of the hips, knees, and ankles on a standard cassette with a radiographic ruler laying next to the extremity. Thus, minimal magnification is present and accurate measurements can be made. However, angular deformities cannot be fully visualized and, if present, can lead to errors in measurement. CT is the most accurate technique and also shows angular deformity.

Treatment.

The psychologic status of the child as well as that of the parents is an important consideration in treatment selection. Some equalization techniques are simple and safe, whereas others, especially lengthening procedures, are complex with high complication rates that require strict cooperation by the child and parents. Discrepancies of greater than 2?cm at skeletal maturity usually require treatment because these often cause the patient to limp. Equalization can be achieved by nonsurgical and surgical methods. In general, the goals are to maintain an appropriate adult height (5?ft 6 inches in males, 5?ft in females) and adequate body proportions. Shortening procedures are preferred, and lengthening procedures should be used cautiously.

ORTHOTICS AND PROSTHETICS.

Orthotic devices are generally indicated for discrepancies between 2 and 3?cm in skeletally mature individuals. A heel lift is frequently all that is necessary to provide the patient with a normal gait. Because of normal pelvic rotation during the gait cycle, complete equalization is not necessary. The smallest lift that will allow the patient to walk without a limp is all that is necessary. Prostheses are necessary for severe discrepancies or uncorrectable deformities.

EXTREMITY SHORTENING PROCEDURES.

Three procedures are used to shorten the longer extremity. *Epiphysiodesis* is indicated in children who have 5?cm or less predicted discrepancy at maturity, have adequate remaining growth for satisfactory correction, and have a predicted relatively normal, corrected adult height. It requires accurate timing to achieve equalization of the leg lengths at maturity. The disadvantages of epiphysiodesis include shortened stature, surgery on the unaffected extremity, the possibility of an angular growth deformity, and the irreversibility of the procedure itself. Percutaneous epiphysiodesis under fluoroscopic control is the most popular technique. This is an outpatient procedure that is effective and has a low complication rate. *Epiphyseal stapling* is performed to slow the rate of physeal growth. Three staples inserted extraperiosteally on each side of the physis are required to retard growth adequately. Once equalization has been achieved, the staples are removed, allowing normal growth to resume. Stapling on one side of the physis can be used to correct angular deformities around the knee. *Bone resection* is indicated for ultimate discrepancies of 5–6?cm in adults or adolescents who have inadequate remaining growth to undergo an epiphysiodesis. The femur can be shortened up to 6?cm and the tibia-fibula up to 3?cm before irreversible muscle weakness occurs.

EXTREMITY LENGTHENING PROCEDURES.

The advantages of lengthening are equalization of significant leg-length discrepancies, maintenance of ultimate adult height, preservation of normal body proportions, surgery on the affected limb, correction of existing angular deformities, and elimination of orthoses. The disadvantages are that it is technically difficult to perform and has a significant complication rate. Common complications include pin tract infection, wound infection, hypertension, hip and knee subluxation, ankle equinus, loss of correction, delayed union, metal failure, and fatigue fractures after metal removal. *Transiliac or pelvic lengthening osteotomies* can provide a gain of up to 3?cm in length. These procedures are generally reserved for individuals with mild discrepancies who have ipsilateral shortening with acetabular dysplasia, an asymmetric pelvis, or possibly decompensated scoliosis. The callotasis technique allows progressive *lengthening of the femur or tibia.* An osteotomy is performed after application of an external fixator lengthening system. There is no initial lengthening. After 7–10 days, lengthening is begun at 1.0?mm/day (0.25?mm every 6?hr). This allows elongation of the forming callus. Significant lengthening of the bone can be achieved with this technique. Once the desired length has been achieved, the callus is allowed to consolidate. The lengthening device is removed after consolidation. The entire process requires approximately 1 mo per centimeter lengthened. The advantages of this procedure over previous lengthening techniques is that it requires only one procedure, allows greater lengthening, and has a lower complication rate. Occasionally, *a combination of a transiliac, femoral, or tibial diaphyseal lengthening and possibly leg-shortening procedures* such as epiphysiodesis is necessary to equalize leg lengths. The combination of femoral diaphyseal lengthening and contralateral epiphysiodeses is useful for discrepancies of 8–10?cm when a single lengthening is insufficient for complete correction.

Chapter 667 - The Knee

George H. Thompson

The knee is a unique joint because the tibiofemoral articulation is constrained only by soft tissues rather than by geometric fit. The distal femur is cam-shaped, allowing it to have a gliding, hinged motion. The major constraints of the knee are the medial and lateral collateral ligaments, the anterior and posterior cruciate ligaments, and the medial and lateral menisci. Weight is transmitted through both the articular cartilage and the menisci. A second important area of the knee is the patellofemoral joint. It is the common site of problems especially in adolescence.

Pain around the knee is one of the most common presenting complaints in older children and adolescents. This may be insidious in onset or the result of trauma. *Accumulation of fluid* (effusion) in the knee indicates an abnormal intra-articular process. Fluid accumulating after injury is usually blood (hemarthrosis) and indicates a potentially serious injury to one or more of the ligaments or menisci or an occult fracture. Recurrent effusions may indicate a chronic internal derangement such as a meniscal tear. Unexplained accumulation of fluid may occur with arthritis (septic, viral, postinfectious, juvenile rheumatoid arthritis, systemic lupus erythematosus), hemorrhage secondary to hemophilia, and overactivity. Occasionally, this fluid requires aspiration to relieve discomfort and to help establish the diagnosis. The presence of fat globules in the blood aspirated from a hemarthrosis may indicate an occult fracture. The presence of purulent material indicates septic arthritis or osteomyelitis.

PEDIATRIC KNEE DISORDERS

Overuse syndromes, ligament injuries, and meniscal tears may occur in children and adolescents and are discussed later in this section (see Chapter 676 and Chapter 681).

667.2 Discoid Lateral Meniscus

Clinical Manifestations and Diagnosis.

Each meniscus is semilunar or C-shaped, but occasionally the lateral meniscus persists as a solid disk of cartilage and is referred to as a discoid lateral meniscus. The normal meniscus is attached around its periphery and glides anteriorly and posteriorly with knee motion, but a discoid meniscus is less mobile and may be torn. Occasionally, there is no peripheral attachment around the posterolateral aspect of the meniscus, which may allow it to become displaced anteriorly with knee flexion, producing a loud click or clunk. A tear or anterior displacement is most likely to occur in late childhood or early adolescence (11–15 yr). Physical examination may show a mild effusion and a positive McMurray test in which the displacement of the meniscus is both palpable and audible. Anteroposterior radiography of the knee may show only widening of the lateral aspect of the knee joint. MRI or arthrography is required for definitive diagnosis.

Treatment.

The treatment of discoid menisci is to excise tears and reshape the meniscus arthroscopically. Meniscal instability can occasionally be repaired or reconstructed concomitantly. Complete excision may be necessary if other procedures are unsuccessful.

667.3 Popliteal Cyst

Popliteal cyst (Baker cyst) is commonly seen during the middle childhood years. There is distention of the gastrocnemius and semimembranous bursa along the posterior aspect of the knee by synovial fluid from a tendon sheath or the knee joint. It is not associated with intra-articular pathologic conditions. Knee radiographs are normal. The diagnosis may be confirmed by ultrasonography or aspiration. *Treatment* is by observation, especially in children 10 yr of age and younger, because resolution over several years usually occurs. The only indications for surgical excision are the presence of symptoms or progressive enlargement.

667.4 Osteochondritis Dissecans

Osteochondritis dissecans commonly involves the knee and occurs when an area of bone adjacent to the articular cartilage becomes avascular and ultimately separates from the underlying bone. The exact cause is unknown, but trauma from the adjacent tibial spines is commonly implicated. The lateral portion of the medial femoral condyle is the most common site.

Clinical Manifestations and Diagnosis.

The child or adolescent typically presents with a vague knee pain. Occasionally, a mild effusion may be present. With the knee fully flexed, it is possible to palpate the involved area directly on the articular cartilage of the medial femoral condyle. This is usually tender.

Anteroposterior, lateral, and tunnel radiographs of the knee are necessary to establish the diagnosis and to follow the disease process. In younger children, the overlying articular cartilage usually remains intact. As revascularization occurs, the bone heals spontaneously. With increasing age, the risk increases for articular cartilage fracture and separation of the bony fragment, producing a loose body. MRI is helpful in determining the integrity of the articular cartilage.

Treatment.

In children 11 yr of age and younger, the treatment is primarily by observation. Periodic radiographs and occasionally MRI may be necessary to assess the degree of healing. In adolescents 13 yr of age and older, especially those with a suspected loose body, arthroscopic surgical intervention may be necessary. This may consist of (1) excision of the loose body, (2) replacement and internal fixation, or (3) drilling of an intact lesion to promote revascularization and healing.

667.5 Osgood-Schlatter Disease

The patellar tendon inserts into the tibia tubercle, which is an extension of the proximal tibial epiphysis. This area is vulnerable to microfracture during late childhood or adolescence, especially in athletes, producing Osgood-Schlatter disease. It is most common in males. The natural history is usually benign. Physical examination demonstrates swelling, tenderness, and increased prominence of the tibia tubercle. Radiographs are usually necessary to rule out other lesions. Rest, restriction of activities, and, occasionally, a knee immobilizer may be necessary, combined with an isometric exercise program. Anti-inflammatory medications usually are not beneficial. Complete resolution of symptoms through physiologic healing (physeal closure) of the tibia tubercle usually requires 12–24 mo.

PATELLOFEMORAL DISORDERS

The patellofemoral joint depends on balance among the restraining ligaments, muscle forces, and the articular anatomy of the patellofemoral groove. The patella has a V-shaped bottom that guides it through the matching groove (trochlea) in the distal femur. The force of the muscles pulling through the quadriceps mechanism and the patellar tendon does not act in a straight line because the patellar tendon inclines in a slightly lateral direction with respect to the line of the quadriceps. This lateral movement, coupled with the movement of the restraining ligaments, tends to move the patella in a lateral direction. The vastus medialis muscle is necessary to counteract the laterally acting forces. An abnormality of any one or a group of these factors may make the patellofemoral joint function abnormally. The usual clinical manifestation is knee pain that is aggravated by vigorous activities.

667.6 Idiopathic Adolescent Anterior Knee Pain Syndrome

The idiopathic adolescent anterior knee pain syndrome is a common patellofemoral disorder that was previously known as *chondromalacia patellae*. The term was used to describe a deranged patellar articular surface. Evidence suggests that the articular surface is actually normal. The cause of the knee pain, which commonly occurs in early adolescence, is unknown.

Clinical Manifestations and Diagnosis.

The anterior peripatellar knee pain is poorly localized. Symptoms are usually produced by vigorous physical activities such as running. Typically, there is no history of injury. The child does not complain of locking, giving way, or recurrent effusion. Gait, range of motion, alignment of the lower extremity, knee stability, patellar tracking, and areas of focal tenderness should be evaluated. The presence of patellofemoral crepitation is common in normal individuals and does not indicate underlying knee disease. Routine radiographs, including anteroposterior, lateral, and tunnel views, are not particularly helpful in evaluating the cause of adolescent anterior knee pain, except that they may eliminate other sources of pain.

Treatment.

The treatment is predominantly conservative and may include flexibility exercises, strengthening exercises (isometric quadriceps), contrast therapies (ice and heat), orthoses, and medications (nonsteroidal anti-inflammatory drugs). A success

rate of 70–90% can be anticipated. Rarely will arthroscopic evaluation of the knee and patellofemoral joint be necessary.

667.7 Patella Subluxation and Dislocation

Patella maltracking is usually due to a congenital deficiency or malalignment within the patellofemoral joint. This can consist of a high-riding patella (patella alta), genu valgum, hypoplasia of the lateral femoral condyle, ligamentous laxity, and malignant malalignment with internal femoral and external tibial torsion. Traumatic patella subluxation and dislocation can occur as a result of a direct blow to the patella along its medial aspect, but this is uncommon.

Clinical Manifestations and Diagnosis.

Examination of a child with a maltracking patella that is predisposed to dislocation usually shows terminal subluxation of the patella when the knee is brought into full extension. There may be tenderness to palpation over the inferior surface of the lateral facet of the patella. Attempting to displace the patella laterally yields a subjective feeling of subluxation, resulting in the patient grabbing the examiner's hand. This has been termed the *apprehension sign.* The torsional profile should be performed for possible rotational abnormalities of the femur or tibia, or both. After an acute dislocation, there may be a hemarthrosis from capsular tearing or an osteochondral fracture.

Radiographs are necessary in the evaluation of patella subluxation or after an acute dislocation. They should include anteroposterior, lateral, and skyline tangential views of the patella to assess for an osteochondral fracture from the lateral femoral condyle or the patella.

Treatment.

The majority of children presenting with acute patella dislocation can be treated nonoperatively. This normally consists of immobilization with the knee in extension for approximately 6 wk. The patient is started on isometric, straight leg-raising exercises as soon as possible. Once the immobilization is discontinued, the isometric exercise program should be continued until the knee is fully rehabilitated. Using this method, approximately 75% of patients do not have recurrent dislocations.

If patella subluxation is due to dynamic muscle imbalance, a specific muscle rehabilitation program, such as strengthening the vastus medialis, may be successful.

In children and adolescents with recurrent dislocations or failure of conservative management for patella subluxation, operative stabilization may be necessary. Depending on the disease, this may consist of an arthroscopic lateral release and, occasionally, a soft tissue reconstruction. The latter can be performed either proximally or distally depending on the age of the patient and the nature of the disease. Derotational osteotomies of the distal femur or proximal tibia, or both, are indicated if there is torsional malalignment.

Chapter 668 - The Hip

George H. Thompson

The hip is a ball-and-socket (femoral head and acetabulum, respectively) joint that allows for geometric motion, including flexion, extension, abduction, adduction, and internal and external rotation. The bulk of the femoral head is composed of the capital femoral epiphysis (CFE). The femoral head and acetabulum have a trophic relationship and are interdependent for normal growth and development. When this relationship is interrupted, abnormal hip development follows. Muscle balance and activity related to appropriate gross motor function are essential to the normal development of the hip.

The blood supply to the CFE is unique. The retinacular vessels lie on the surface of the femoral neck but are intracapsular. They enter the epiphysis from the periphery. This makes the blood supply vulnerable to damage from septic arthritis, trauma, thrombosis, and other vascular insults. If the blood supply is lost, avascular necrosis or osteonecrosis may occur. This can result in deformity, either acutely or as a consequence to abnormal growth and development, and predisposes to abnormal hip function and degenerative osteoarthritis as an adult.

668.1 Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) usually occurs in the neonatal period. The hips at birth are rarely dislocated but rather “dislocatable.” Dislocations tend to occur after delivery and, thus, are postnatal in origin, although the exact time when dislocations occur is controversial. Because they are not truly congenital in origin, the term *developmental dysplasia of the hip* should be used. DDH is classified into two major groups: typical, in a neurologically normal infant, and teratologic, in which there is an underlying neuromuscular disorder, such as myelodysplasia, arthrogryposis multiplex congenita, or a syndrome complex. Teratologic dislocations are less common, occur in utero, and are therefore congenital.

Etiology.

DDH has physiologic, mechanical, and postural etiologic factors.

The positive family history (20%) and the generalized ligamentous laxity are related

factors. The majority of children with DDH have generalized ligamentous laxity, which can predispose to hip instability. Maternal estrogens and other hormones associated with pelvic relaxation result in further, although temporary, relaxation of the newborn hip joint. There is a 9:1 female predominance.

Approximately 60% of children with typical DDH are firstborns, and 30–50% were in the breech position. The frank breech position with the hips flexed and the knees extended is the position of highest risk. The breech position results in extreme hip flexion and limitation of hip motion. Increased hip flexion results in stretching of the already lax capsule and ligamentum teres. It also produces posterior uncoverage of the

---

femoral head. Decreased hip motion leads to a lack of normal development of the cartilaginous acetabulum. There is also an association of congenital muscular torticollis (14–20%) and metatarsus adductus (1–10%) with DDH. The presence of either condition requires a careful examination of the hips.

Postnatal factors are also important determinants. Maintaining the hips in the position of adduction and extension may lead to dislocation. This puts the unstable hip under pressure because of the normal hip flexion and abduction contractures. An unstable femoral head, as a consequence, can be displaced from the acetabulum over several days or weeks.

Pathoanatomy.

Because hips are not dislocated at birth, the components of the hip joint, excluding the hip capsule and ligamentum teres, are relatively normal. There may be some variations in the shape of the cartilaginous acetabulum, especially if the child was in a breech position in utero. If a dislocation is allowed to occur, acetabular dysplasia and maldirection, excessive femoral anteversion (torsion), and hip muscle contractures develop.

Clinical Manifestations.

All neonates should be screened for DDH (Fig. 668–1 (Figure Not Available)). The Barlow test is the most important maneuver in examining the newborn hip. This provocative test to dislocate an unstable hip is performed by stabilizing the pelvis with one hand and then flexing and adducting the opposite hip and applying a posterior force (Fig. 668–2). If the hip is dislocatable, it is usually readily felt. After release of the posterior force, the hip usually relocates spontaneously. It has been estimated that only 1 in 100 newborn infants have clinically unstable hips (subluxation or dislocation), whereas only 1 in 800–1,000 of these infants eventually experience a true dislocation. The Ortolani test is a maneuver to reduce a recently dislocated hip. It is most likely to be positive in infants who are 1–2 mo of age because adequate time must have passed for the true dislocation to occur. In performing this test, the thigh is flexed and abducted and the femoral head is lifted anteriorly into the acetabulum (Fig. 668–2). If reduction is possible, the relocation will be felt as a "clunk," not an audible "click." After 2 mo of age, manual reduction of a dislocated hip is usually not possible because of the development of soft tissue contractures.

Limitation of hip abduction is indicative of soft tissue contractures and may indicate DDH. Conversely, hip abduction contractures may indicate dysplasia of the contralateral hip. An asymmetric number of thigh skinfolds and apparent shortening of an extremity and uneven knee levels when the supine infant's feet are placed together on the examining table with the hips and knees flexed (Galeazzi sign) indicate DDH with proximal displacement of the femoral head. Absent normal knee flexion contracture also occurs.

A common concern is the presence of audible *hip clicks* in infants. Hip clicks per se are not usually pathologic and are secondary to (1) breaking the surface tension across the hip joint, (2) snapping of gluteal tendons, (3) patellofemoral motion, or (4) femorotibial (knee) rotation.

In older or walking children, complaints of limping, waddling, increased lumbar lordosis, toe walking, and leg-length discrepancy may indicate an unrecognized DDH.

Radiographic Evaluation.

Hip stability as well as acetabular development may be assessed accurately in neonates and young infants by dynamic ultrasonography. Radiographic evaluation in older infants and children includes anteroposterior and Lauenstein (frog) lateral radiographs of the pelvis. The ossific nucleus of the femoral head does not appear until 3–7 mo of age, and it may be further delayed in DDH. Line measurements are usually made to determine the relationship of the femoral head to the acetabulum (acetabular index, quadrant assessment, Shenton's line, and the center edge angle of Wiberg) (Fig. 668–3). Arthrography, CT, and MRI scans may be beneficial in difficult cases, especially those involving older infants and children.

Treatment.

The treatment of DDH should be individualized and depends on the patient's age and whether the hip is subluxated or dislocated.

BIRTH.

When an unstable hip is recognized at birth, maintenance of the hip in the position of flexion and abduction ("human" position) for 1–2 mo is usually sufficient. This position maintains reduction of the femoral head and allows for tightening of the ligamentous structures as well as stimulation of normal growth and development. Methods that can be used to maintain the hip in this position include the Pavlik harness, Frejka splint, and a variety of abduction orthoses. Double and triple diapers, although controversial, are commonly used in newborns with dislocatable hips for 2–3 wk because the splints and harnesses usually do not initially fit satisfactorily. Treatment is continued until there is clinical stability of the hip and ultrasonographic

or radiographic measurements are normal.

AGE 1–6 MONTHS.

During this age, a true dislocation may develop. As a consequence, treatment is directed toward reduction of the femoral head into the acetabulum. The Pavlik harness is the treatment of choice in this age group. The harness attempts to place the hips in the human position by flexing them more than 90 degrees (preferably 100–110 degrees) and maintaining relatively full, but gentle abduction (50–70 degrees). This redirects the femoral head toward the acetabulum. Usually, spontaneous relocation of the femoral head occurs within 3–4 wk. The Pavlik harness is approximately 95% successful in dysplastic or subluxated hips and 80% successful in true dislocations. If reduction is achieved, use of the harness is continued until radiographic parameters have returned to normal. If a spontaneous reduction does not occur, a surgical closed reduction is indicated. This consists of (1) preliminary skin traction for 1–3 wk to bring the femoral head opposite the acetabulum, (2) percutaneous adductor tenotomy, (3) closed reduction, (4) arthrography to assess the concentricity of the reduction, and (5) application of a hip spica cast in the "human" position. Treatment is continued until the radiographic parameters are within normal limits.

AGE 6–18 MONTHS.

In the older infant, surgical closed reduction is the major method of treatment. If at the time of reduction there is significant instability, an open reduction may be indicated. This can be through a medial or anterior approach.

AGE OF 18 MONTHS–8 YEARS.

After 18 mo of age, the progressive deformities are so severe that open reduction followed by pelvic (innominate) osteotomy or femoral osteotomy, or both, is necessary to realign the hip. A femoral shortening derotation osteotomy is performed concomitantly if the reduction is tight, if there is excessive femoral anteversion, or if the child is 3 or 4 yr of age or older. Postoperatively, a hip spica cast is worn for 6–8 wk to allow healing. Thereafter, the child may be permitted to return to full activities gradually. Implanted metal is removed shortly after healing to prevent incorporation into the growing bone. Eighteen months of age is not an arbitrary age for these procedures. It has been demonstrated that approximately 25% of children who have a closed reduction performed between 9–12 mo of age, 50% who have one between 12–18 mo, and 75% who have one between 18 and 36 mo have residual acetabular dysplasia requiring a pelvic or femoral osteotomy at a later date.

Complications.

The most important and severe complication of DDH is avascular necrosis of the CFE. This is an iatrogenic complication; reduction of the femoral head under pressure produces cartilaginous compression, and this can result in occlusion of the intra-articular, extraosseous epiphyseal vessels and produce CFE infarction, either partial or total. Revascularization follows, but abnormal growth and development may occur, especially if the physis is severely damaged. The hip is vulnerable to this complication before the development of the ossific

Figure 668.1-1 (Figure Not Available) Screening for developmental hip dysplasia—clinical algorithm. (From Committee on Quality Improvement, Subcomittee on Developmental Dysplasia of the Hip: Clinical Practice Guideline: Early detection of developmental dysplasia of the hip. *Pediatrics* 2000;105: 896–905.)

nucleus (4–6 mo). The management outlined previously is designed to minimize this complication; with appropriate use of these treatments, the incidence of avascular necrosis is 5–15%. Other potential complications in DDH include redislocation, residual subluxation, acetabular dysplasia, and postoperative complications, such as wound infections.

SEPTIC ARTHRITIS AND OSTEOMYELITIS

See Chapter 674 for a full discussion of septic arthritis and osteomyelitis. Diagnosis of septic arthritis and osteomyelitis is made by hip aspiration (arthrocentesis). This can be technically difficult and must always be performed under fluoroscopic

---

Figure 668.1-2 Newborn hip examination. *A*, The infant is laid on her back with the hips and knees flexed, and the examiner places the middle finger of each hand over each greater trochanter. *B*, The thumb of each hand is applied to the inner side of the thigh opposite the lesser trochanter. *C*, In a difficult infant, the pelvis may be steadied between a thumb over the pubis and fingers under the sacrum while the hip is tested (Barlow and Ortolani test) with the other hand. *D*, Limitation of hip abduction is also an early sign of developmental dislocation of the hip. Note the restriction in abduction of the right hip.

control. If no fluid is obtained from the hip joint, an arthrogram should be obtained, documenting that the hip joint has been entered.

668.2 Transient Monoarticular Synovitis

Transient synovitis of the hip is one of the more common causes of limping in a normal child. It is characterized by acute onset of pain, limp, and mild restriction of motion, especially abduction and internal rotation. Septic arthritis and osteomyelitis of the hip must be excluded before this diagnosis can be confirmed. The cause remains uncertain, but possibilities include (1) active or recent systemic viral syndrome, (2) trauma, and (3) allergic hypersensitivity. Biopsy specimens from the hip joint have demonstrated synovial hypertrophy secondary to nonspecific inflammatory reaction.

Clinical Manifestations.

Transient monoarticular synovitis can occur in all age groups, but the mean age at

onset is 6 yr; it occurs predominantly in the 3–8 yr age group. Approximately 70% of affected children have had a nonspecific upper respiratory tract infection 7–14 days before the onset of symptoms. There is usually an acute onset of symptoms with pain felt in the groin, anterior thigh, or knee; nontraumatic anterior thigh or knee pain may be referred from the hip. These children are usually ambulatory, and the hip is not held flexed, abducted, and laterally rotated unless a significant effusion is present. However, they walk with a painful, limping gait. They are usually afebrile or have a low-grade fever (temperature less than 38°C).

Laboratory values are usually normal, but occasionally a slight elevation in the erythrocyte sedimentation rate is seen. Arthrocentesis produces normal results, although a joint effusion of 1–3?mL is common.

Radiographic Evaluation.

Anteroposterior and Lauenstein (frog) lateral radiographs of the pelvis may be obtained and are usually normal. Ultrasonography of the hip may demonstrate a hip joint effusion. Ultrasound-guided hip joint fluid aspiration may be needed in some cases to determine if a septic hip is present. Technetium bone scan or MRI may be of value in ruling out the presence of other lesions, such as septic arthritis, tumor, fracture, slipped capital femoral epiphysis, or early Legg-Calvé-Perthes disease (LCPD). Transient monoarticular synovitis is a diagnosis of exclusion. High-risk criteria for septic arthritis include high fever and elevations of the erythrocyte sedimentation rate, serum C-reactive protein, and white blood cell counts.

Treatment.

Treatment of monoarticular synovitis of the hip is conservative. Bed rest and no weight bearing until the pain resolves followed by limited activities thereafter is the treatment of choice. Most children are maintained on bed rest for less than 1 wk. They are then maintained on limited activities for 1–2 additional wk. This sometimes is difficult because children want to return to normal activities when their symptoms resolve. However, if the child is allowed to return to normal activities too early, exacerbation of symptoms may occur. Ibuprofen may shorten the duration of pain.

668.3 Legg-Calvé-Perthes Disease

LCPD is idiopathic osteonecrosis or avascular necrosis of the CFE, and the associated complications thereof, occurring in an immature, growing child. This osteochondrosis is caused by an interruption of the CFE blood supply. Its cause is unknown, but

Figure 668.3-3 Pelvic radiographs demonstrating development dysplasia of the left hip. *A*, The Hilgenreiner method for identification of dysplasia of the hip before ossification of the capital femoral epiphysis; a' is greater than a, indicating greater obliquity of the acetabular roof. *d*, is greater than *d*, indicating lateral displacement of the femur. *h* is greater than *h*, indicating cephalad displacement of the femur. These relationships indicate dysplasia of the patient's left hip. *B*, Developmental dislocation of the left hip. The bony roof of the left acetabulum is quite oblique, and there is the beginning of a false acetabulum above its most lateral aspect. The left femur is displaced laterally and superiorly. The ossification center of the left capital femoral epiphysis is smaller than that of the right.

an association among protein C and protein S deficiency, thrombophilia, and hypofibrinolysis has been observed. It is primarily a disorder affecting males (4–5:1) and is bilateral in approximately 20% of children. Children with LCPD often have delayed bone age, disproportionate growth, and mild short stature.

Clinical Manifestations.

The clinical onset of LCPD occurs between the ages of 2 and 12 yr (mean, 7 yr). Most children present with mild or intermittent pain in the anterior thigh and a limp. The classic presentation has been described as a “painless limp.” The pertinent early physical findings include antalgic gait; muscle spasm with mild restriction of motion, especially abduction and internal rotation; proximal thigh atrophy; and mild shortness of stature.

Radiographic Evaluation.

Anteroposterior and Lauenstein (frog) lateral radiographs of the pelvis should be obtained to establish the diagnosis (Fig. 668–4). The radiographic characteristics can be divided into five distinct stages representing a continuum of the disease process: (1) cessation of CFE growth, (2) subchondral fracture, (3) resorption (fragmentation), (4) reossification, and (5) healed or residual stage.

There are three radiographic classification systems of the extent of CFE involvement. Catterall developed a four-group classification on the basis of the appearance of the CFE at maximal resorption. Although this classification has been helpful in the retrospective analysis of results, it has limited prognostic value because it is difficult to apply in the earliest phases of the disease process. Salter-Thompson used two groups, and Herring and colleagues used three groups, depending on involvement or extent of involvement or the radiographic appearance of the lateral portion of the CFE. When intact, this area acts as a supporting column or pillar that shields the involved portion of the CFE from compression, which can produce collapse, deformity, and possible extrusion. Involvement results in a poorer prognosis.

The short-term prognosis relates to the femoral head deformity at the completion of the healing stage. Adverse risk factors include older age at clinical onset, extensive CFE involvement, loss of femoral head containment, reduced range of hip motion, and premature CFE closure. The long-term prognosis relates to the potential for osteoarthritis of the hip in adulthood. Older children with significant residual femoral head deformity are at risk for degenerative arthritis; the incidence is essentially 100% in children who are 10 yr of age or older at onset and who have residual femoral head deformity. This compares with a negligible risk in children who are 5 yr of age and younger at onset and 38% when onset occurs between 6 and 9 yr of age.

Two radiographic classifications evaluate the sphericity of the femoral head at the completion of the disease process, which correlates with the risk for degenerative osteoarthritis as an adult. In the Mose circle criteria, a transparent template with concentric circles is placed over the anteroposterior and Lauenstein lateral

radiographs. If the variation of sphericity of the femoral head in the two views is 0–2?mm, the result is good; 2–3?mm, fair; and 3?mm or more, poor. Stulberg and colleagues' five-group classification is based on the shape of the femoral head and congruency with the acetabulum: class I, a spherical femoral head that is equal in size to the opposite uninvolved hip; class II, a spherical femoral head with coxa magna; class III, an oval femoral head with a congruent acetabulum; class IV, a flat femoral head with abnormalities of the femoral neck and acetabulum; and class V, a flat femoral head with a normal acetabulum. Classes I and II are spherical congruent hips; class III, a nonspherical congruent hip; and classes IV and V, incongruent hips.

Treatment.

LCPD is a local, self-healing disorder. Prevention of femoral head deformity and secondary osteoarthritis are the only justifications for treatment. The treatment goals are (1) elimination of hip irritability; (2) restoration and maintenance of a good range of hip motion; (3) prevention of CFE collapse, extrusion,

Figure 668.3-4 Anteroposterior radiograph of the right hip of an 8-yr-old boy with Legg-Calvé-Perthes disease. There is a collapsed yet dense capital femoral epiphysis with early fragmentation. The small medial triangle of the capital femoral epiphysis is uninvolved in the disease process.

or subluxation; and (4) attainment of a spherical femoral head at healing. Treatment uses the concept of containment (i.e., the femoral head is contained within the acetabulum so that the latter acts as a mold for the reossifying CFE). This may be accomplished by nonsurgical and surgical techniques.

OBSERVATION.

Expectant observation is appropriate for all children younger than 6 yr at clinical onset regardless of the extent of CFE involvement. These children must be monitored closely, both clinically and radiographically.

INTERMITTENT SYMPTOMATIC TREATMENT.

Temporary or periodic treatment with bed rest or abduction stretching exercises to maintain mobility can be used in conjunction with observation. Recurrent episodes of hip irritability with a temporary decrease in motion commonly occur during the phases of subchondral fracture and fragmentation, and the child may benefit from symptomatic treatment.

DEFINITIVE EARLY TREATMENT.

Nonsurgical or surgical containment of the femoral head in the course of the disease is indicated when (1) the age at clinical onset is 6 yr or older (possibly 5 yr in girls), (2) the lateral portion of the CFE is involved, or (3) there is a loss of containment, as manifested by extrusion of the femoral head on anteroposterior radiograph.

Nonsurgical Containment. Abduction casts (Petrie) or orthoses can be used to contain the femoral head within the acetabulum. Containment is continued only until there is early radiographic subchondral reossification. Because this usually occurs 12–18 mo after clinical onset, nonsurgical containment methods can be limited to 18 mo or less with no adverse effect on the outcome. The Atlanta Scottish Rite Hospital orthosis is the most widely used because it allows reciprocal motion and ambulation without crutches or external support. The success of nonsurgical containment has been challenged on the grounds that it does not alter the natural history of untreated LCPD.

Surgical Containment. A pelvic or femoral osteotomy can be used to contain the femoral head. The results of surgical containment appear to be better than those of nonsurgical containment; approximately 85% of patients have Stulberg class I, II, or III.

LATE SURGICAL MANAGEMENT FOR DEFORMITY.

If significant femoral head deformity prevents reduction of the femoral head into the acetabulum, an alternative method must be considered. Several surgical procedures at least partially correct the various existing deformities, thereby alleviating the associated symptoms.

668.4 Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is the most common adolescent hip disorder. Its cause is unknown, but an endocrine basis has been suggested because SCFE is frequently accompanied by abnormalities of growth. Sex hormones, growth hormone, and other hormones alter the rate of growth in the CFE and the rate of skeletal growth. SCFE occurs in adolescents who are either obese and have delayed skeletal maturation or who are tall and thin and have had a recent growth spurt. In obese adolescents, a low level of sex hormones has been postulated, whereas in tall, thin individuals, an overabundance of growth hormone is implicated. SCFE can also occur as a complication of an underlying endocrine disorder such as hypothyroidism, pituitary disorders, pseudohypoparathyroidism, and others. When a SCFE occurs before puberty (10 yr of age or younger), an endocrine disorder (hypothyroidism, growth hormone deficiency) should be suspected.

Radiographic Evaluation.

Anteroposterior and Lauenstein (frog) lateral radiographs of the pelvis are used for assessment of SCFE (Fig. 668–5). Both hips must be evaluated and compared. The earliest sign of SCFE is widening of the physis without slippage, a preslip condition. As slippage occurs, the CFE remains in the acetabulum and the femoral neck rotates predominantly anteriorly (although occasionally superiorly), resulting in a varus, retroverted femoral head and neck. The degree of slippage between the CFE and the femoral neck can be classified as mild (0–33%), moderate (34–50%), and severe (greater than 50%) by radiographic measurement techniques.

Diagnostic Classification.

SCFE is classified as stable or unstable depending on the integrity between the CFE and femoral neck.

STABLE SLIPPED CAPITAL FEMORAL EPIPHYSIS.

This is the most common type. Initially, the physis is wide but slippage has not occurred. There may be mild discomfort, but the physical examination is usually normal. Preslips are commonly seen in the opposite hip of an adolescent with a previous SCFE. The symptoms typically worsen as the slip develops and progresses. However, because there is continuity between the femoral neck and CFE, the symptoms are not severe, and the child is able to walk with a mildly antalgic, externally rotated gait (Fig. 668–6).

UNSTABLE SLIPPED CAPITAL FEMORAL EPIPHYSIS.

In unstable SCFE, there are no or only mild antecedent symptoms such as pain or limp. Slippage then occurs suddenly, usually without trauma, and the pain is so severe that the child is usually unable to stand or bear weight even with external support on the involved extremity. The stability between the CFE and femoral neck is disrupted.

Figure 668.4-5 Slipped capital femoral epiphysis, anteroposterior view. A line superimposed on the superior femoral neck normally intersects part of the head (*B* and *D* are normal). With a slipped epiphysis, the line does not intersect the femoral head (*A* and *C*). Occasionally, the frog-leg view (*C* and *D*) is needed to demonstrate the slip. (From Chung S: Diseases of the developing hip joint. *Pediatr Clin North Am* 1986;33:1457.)

Clinical Manifestations.

The physical findings in SCFE depend on the degree of slippage and the classification. In the unstable SCFE, the physical examination is limited as a result of severe pain with any attempted hip motion. In a stable SCFE, the patient has an antalgic gait and the affected extremity is externally rotated. Hip range of motion demonstrates a lack of internal rotation and increased external rotation. Also, as the hip is flexed, it becomes progressively externally rotated. Limitation of flexion and abduction may also be present if there is a severe varus deformity of the proximal femur. Twenty per cent of patients complain of knee pain only, although they have decreased hip rotation on physical examination. Adolescents, especially those who are obese, with nontraumatic anterior thigh or knee pain (referred pain) should be carefully evaluated for a SCFE.

Treatment.

The goals of treatment for SCFE are to prevent further slippage and minimize complications. This is accomplished by performing an epiphysiodesis (closure) of the CFE. In situ pinning with one or two cannulated screws is the most popular technique. The screws can be inserted percutaneously under fluoroscopic control. Screw removal after CFE closure is controversial.

Complications.

The two serious complications in SCFE are osteonecrosis and chondrolysis. Osteonecrosis or avascular necrosis occurs as a result of injury to the retinacular vessels. This can be due to forced manipulation of an acute or unstable SCFE, compression from intracapsular hematoma, or direct injury during surgery. Partial forms of osteonecrosis may also occur after internal fixation as a result of disruption of the intraepiphyseal blood vessels. Chondrolysis is a degeneration of the articular cartilage of the hip. Its cause is unclear, but it (1) is

Figure 668.4-6 Anteroposterior radiograph of the right hip of a 13-yr-old boy with a moderately severe chronic (stable) slipped capital femoral epiphysis. Observe the physeal widening and the distorted relationship between the capital femoral epiphysis and femoral neck.

associated with more severe slips, (2) occurs more frequently among blacks and females, and (3) is associated with pins or screws protruding out of the femoral head. **REFERENCES**

Chapter 669 - The Spine

George H. Thompson

Abnormalities in the vertebral column are a common nontraumatic pediatric musculoskeletal problem. They may be present at birth or may develop during childhood or adolescence. Some disorders worsen with growth and may lead to an unacceptable appearance, alterations in pulmonary function, and early degenerative osteoarthritis of the spine. A simplified classification of the common spinal abnormalities is presented in Box 669–1 .

In the anteroposterior (frontal) plane, the vertebral bodies of the normal spine are stacked squarely one on the other with little or no deviation from vertical alignment. The vertebral end-plates are parallel and the intervertebral disks are symmetric in height. In the sagittal plane, the spine has normal curvatures that provide balance and stability. The cervical and lumbar spine displays anterior convexity, termed *lordosis*; the thoracic spine and sacrum display posterior convexity and are *kyphotic*.

Alterations in normal spinal alignment that occur in the frontal plane are termed *scoliosis*. The majority of scoliotic deformities are idiopathic. Others can be congenital, associated with a neuromuscular disorder or syndrome, compensatory from a leg-length discrepancy, or caused by an intraspinal abnormality.

669.1 Idiopathic Scoliosis

Etiology and Epidemiology.

Idiopathic scoliosis is the most common form of scoliosis. It occurs in healthy, neurologically normal children; its cause is unknown. The incidence is only slightly greater in girls than in boys, but scoliosis is more likely to progress and require treatment in girls than in boys. There appears to be a genetic component, but the disorder is not transmitted in a pure mendelian fashion. The daughters of affected mothers are more likely than other children to have scoliosis, but identical twins are not uniformly affected. The magnitude of curvature in an affected individual is not related to the magnitude of curvature in relatives. Involved children also tend to show subtle changes in proprioception and vibratory sensation, suggesting that abnormalities of spinal cord posterior column function may have a causative role.

Idiopathic scoliosis can be divided into three groups on the basis of age at onset: infantile (birth–3 yr), juvenile (4–10 yr), and adolescent (11 yr and older). Adolescent idiopathic scoliosis is much more common than juvenile-onset scoliosis; infantile idiopathic scoliosis is extraordinarily rare.

Clinical Manifestations.

A thorough history and physical examination is the first step in the evaluation of patients with suspected idiopathic scoliosis. Asymmetry of the posterior chest

wall on forward bending (the Adams test) is the most striking and consistent abnormality in patients with scoliosis (Fig. 669–1). Rotation of the vertebral bodies within a curve toward the side of convexity of curvature displaces the attached ribs and overlying paraspinal musculature posteriorly on the convex side of the curve and creates a depression on the concave side. Associated findings include asymmetry in shoulder height, apparent leg-length discrepancy, flank asymmetry, and asymmetry of the anterior chest wall.

When the trunk is viewed from the side with the patient in the forward flexed position, the degree of *kyphosis* and *lordosis* can be evaluated. The upper region of the thoracic spine normally has a smooth, rounded curve that extends down to the midthoracic region. Flexible roundback that corrects easily when a child stands upright is common in adolescents. Sharp, abrupt, or accentuated forward angulation in the thoracic or thoracolumbar region is indicative of a kyphotic deformity. In the erect position, the lower lumbar spine is normally concave (lordotic). The magnitude of lordosis varies with age and among individuals of the same age. Children normally have less cervical lordosis and more lumbar lordosis than do adults or adolescents.

Figure 669.1-1 Structural changes in idiopathic scoliosis. *A*, As curvature increases, alterations in body configuration develop in both the primary and compensatory curve regions. *B*, Asymmetry of shoulder height, waistline, and elbow-to-flank distance are common findings. *C*, Vertebral rotation and associated posterior displacement of the ribs on the convex side of the curve are responsible for the characteristic deformity of the chest wall in scoliosis patients. *D*, In the school screening examination for scoliosis, the patient bends forward at the waist. Rib asymmetry of even a small degree is obvious. (From Scoles PV: Spinal deformity in childhood and adolescence. In Behrman RE, Vaughn VC III

[editors]: *Nelson Textbook of Pediatrics*, Update 5. Philadelphia, WB Saunders, 1989.)

A careful neurologic evaluation is essential, especially in patients with apparent juvenile-onset scoliosis, atypical curve patterns, or back pain. The presence of café-au-lait spots, sacral dimpling, midline hairy patches, shoe size asymmetry, foot deformity, or a history of back pain or urinary incontinence suggests a nonidiopathic cause for the deformity.

School screening programs for early detection of scoliosis are common in North America. The forward bend test is the method employed; inclinometers to estimate the height of rib asymmetry are used in some centers. The sensitivity and specificity of the forward bend test depend on the skill of the examiner and the degree of curvature considered to be significant. Virtually all children with spinal curves greater than 20 degrees are identified by trained observers; unfortunately, a large number of normal children are identified as well. Estimates of the incidence of curvature greater than 20 degrees range from 0.1–1.0%, whereas positive screening rates run as high as 30%. In light of such information, the benefits of screening programs must be weighed against the costs of referral and the potential adverse effects of unnecessary radiographic examination.

Radiographic Evaluation.

Radiographic examination is the reference standard for evaluation of patients with suspected spinal deformity. If there is clinical evidence of spinal deformity, standing posteroanterior (PA) and lateral standing radiographs of the entire spine should be obtained. Supine and side-bending radiographs are not necessary for initial assessment of scoliosis, kyphosis, or lordosis. The degree of curvature is determined by measuring the angular relationships between the most tilted vertebrae at either end of the apparent curve (the Cobb method). A line is drawn across the proximal end-plate of the superior end vertebra and the distal end-plate of the inferior end vertebra, and perpendicular lines are erected. The angle at the intersection of the perpendicular lines determines the degree of curvature. Another method to classify spinal curves is noted in Figure 669–2 . The use of other imaging modalities, such as CT and MRI, should be reserved for cases in which nonidiopathic curvature is suspected.

Treatment.

The risk for curve progression varies according to sex, age, menarchal status, and curve magnitude at initial discovery. Premenarchal girls with curves between 20 and 30 degrees have a significantly higher risk for progression than do girls 2 yr after menarche with similar curves; curve progression is likely in the first group and uncommon in the second. Boys with curvature of the same magnitude appear to have similar risks of progression when judged by other maturation standards. Curves less than 30 degrees rarely progress after skeletal maturation is complete; curves greater than 45 or 50 degrees often continue to progress during adult life.

The rationale for treatment of patients with idiopathic scoliosis is based on the assumption that patients with progressive scoliosis will acquire unacceptable deformities, premature degenerative joint disease, and progressive cardiorespiratory compromise and that treatment can positively affect these outcomes. Although there are conflicting data on the long-term outcome of untreated scoliosis, it appears reasonable to assume that patients with high-magnitude deformities will both look and feel different than their age- and sex-matched peers.

The generally accepted methods of treatment of progressive idiopathic adolescent scoliosis are bracing and surgical correction. There is no evidence that chiropractic treatment or exercise programs alter the outcome of scoliosis; transcutaneous electrical stimulation has been shown to have no effect. Most orthopedic surgeons recommend a trial of brace treatment for immature patients with curves less than 40 degrees. Although the efficacy of brace treatment has been questioned, current studies suggest a small decrease in the likelihood of progression for patients treated with bracing when compared with age-, sex, and curve-matched peers followed by observation alone.

Figure 669.1-2 Criteria for curve classification. (From Edgar M: A new classification of adolescent idiopathic scoliosis. *Lancet* 2002; 360:270–1, with permission.)

Bracing does not correct curvature; although improvement in Cobb angles is often noted during the active period of brace treatment, there are no studies that demonstrate consistent long-term maintenance of correction. A variety of spinal orthoses are employed; retrospective studies suggest little difference in outcome by brace type.

Surgical treatment is usually considered for patients with idiopathic curves greater than 45 degrees. Surgical treatment usually combines correction of deformity with permanently implanted internal fixation rods and posterior fusion of the involved vertebrae (Fig. 669–3). Occasionally, anterior spinal fusion and instrumentation may be indicated, especially in thoracolumbar and lumbar curves.

669.2 Congenital Scoliosis

Abnormalities of vertebral development during the first trimester of pregnancy often result in structural deformities of the spine that are evident at birth or become obvious in early childhood. Congenital scoliosis can be classified as (1) partial or complete failure of vertebral formation (wedge vertebrae or hemivertebrae), (2) partial or complete failure of segmentation (unsegmented bars), or (3) mixed. It may occur as an isolated deformity or in combination with other organ system malformations that are differentiating at the same time as the spine.

Congenital genitourinary malformations occur in 20% of children with congenital scoliosis. Unilateral renal agenesis is the most common abnormality. Duplication of ureters, horseshoe kidney, and genital anomalies also occur. Approximately 2% of children with associated genitourinary abnormalities have a silent, obstructive uropathy. Renal ultrasonography should be performed in all children with congenital scoliosis to assess for possible genitourinary problems. Other procedures, such as intravenous pyelography or MRI, may be necessary if the ultrasonogram is abnormal. Congenital heart disease occurs in 10–15% of children with congenital

scoliosis.

A high percentage of patients with congenital scoliosis have associated defects of the spinal cord. *Spinal dysraphism* is the general term applied to such lesions; MRI studies suggest that they are present in as many as 40% of patients with congenital scoliosis. Spina bifida occulta is the most common and benign defect; myelomeningocele is the most severe. Other lesions include intradural and extradural lipomas, cysts and teratomas, and spinal cord tethers. In addition to spine asymmetry, physical examination in these patients often shows hairy patches, skin dimples, hemangiomas, and abnormalities of the feet and lower extremities. Asymmetric foot size, cavus feet, and calf atrophy strongly suggest the presence of spinal dysraphism in patients with congenital scoliosis. MRI is the procedure of choice for evaluating possible spinal dysraphism.

Figure 669.2-3 *A*, Preoperative standing posteroanterior radiograph of a 13-yr-old girl with a severe right thoracic section. Note the Cobb measurement technique. The numbers in parentheses indicate the degree of correction of the deformity on side-bending radiographs. *B*, Postoperative radiograph demonstrating a selective right thoracolumbar fusion and instrumentation from T3 to L2. Note the spontaneous improvement in the compensatory left lumbar curve after correction of the structural right thoracolumbar curve.

The risk for progression of spinal deformity in a child with congenital scoliosis depends on the growth potential of the malformed vertebra. Defects, such as block vertebra, have little growth potential and usually do not cause significant spinal deformity. Hemivertebrae may or may not cause significant deformity depending on location and their potential for growth. Unilateral unsegmented bars almost always produce progressive deformities. Approximately 25% of patients with congenital scoliosis do not demonstrate curve progression and do not require treatment. Most patients demonstrate some progression, and many require treatment. Patients are most at risk during periods of rapid growth before 2 and after 10 yr of age.

Early diagnosis and prompt treatment of progressive curves is essential. Orthotic treatment is of limited value because of the structural nature of congenital curvature. Often a combined anterior and posterior spinal fusion across the area of the deformity is required to halt progression and counteract the strong forces of growth. Anterior and posterior convex epiphysiodeses have been used to produce partial correction with growth. Hemivertebrae excision can also be considered. It is a serious mistake to defer treatment of progressive spinal curvatures while awaiting further spinal growth.

669.3 Neuromuscular Scoliosis, Genetic Syndromes, and Compensatory Scoliosis

Neuromuscular Scoliosis.

Scoliosis is a common complication of many neuromuscular disorders of childhood. Muscle imbalance, soft tissue contracture, and progressive weakness predispose patients with disorders such as cerebral palsy, muscular dystrophies, and spinal muscular atrophy to scoliosis. In patients with myelodysplasia, structural malformations of the vertebral column complicate the problem. In general, the magnitude of the deformity depends on the severity of involvement, the pattern of weakness, and the progressive nature of the underlying disease process. Ambulatory patients with minimal involvement and cerebral palsy are much less likely to have significant spinal deformity than nonambulatory patients with profound involvement.

Progression of deformity in patients with neuromuscular scoliosis has serious consequences. Sitting and standing balance are altered, adversely affecting ambulation in marginal walkers and complicating seating support in nonambulators. Patients who must use their arms for trunk support lose a significant degree of

independence. Severe curves decrease pulmonary reserve, compounding pre-existent respiratory problems.

Neuromuscular scoliosis can be treated safely and effectively in most instances, but the success of treatment depends on early recognition. Because scoliosis in most patients with neuromuscular disease progresses relentlessly once curvature begins, there is little reason to delay treatment once the deformity is identified. The forward bending test can be used for screening; the test may be performed in the sitting position for patients who cannot stand. Any asymmetry is an indication for radiographic evaluation. This should include posteroanterior and lateral standing radiographs of the entire spine. If the child or adolescent cannot stand, a sitting or supine (anteroposterior) radiograph is necessary.

The goal of treatment of neuromuscular scoliosis is to restore spinal alignment, stabilize respiratory function, and prevent progressive loss of independence. Nonambulatory patients are usually most comfortable, are more independent, and have better respiratory function when they are able to sit erect without external support. Unfortunately, options for treatment in neuromuscular scoliosis are limited. Orthotic management or bracing is usually not effective as definitive treatment in neuromuscular scoliosis. In young children, brace treatment may slow the rate of curve progression, allowing further spinal growth and delaying surgical intervention. For most patients with progressive deformity, surgery is necessary when treatment is indicated. Instrumentation systems provide effective correction and eliminate the need for external support in the postoperative period. Most patients may be out of bed immediately after surgery.

Syndromes.

Children with certain syndromes are also at increased risk for spinal deformities. Common syndromes include neurofibromatosis and Marfan syndrome. These children require periodic evaluation and prompt referral for orthopedic evaluation at the first sign of a spinal deformity.

Compensatory Scoliosis.

Leg-length inequality is a common cause of false-positive screening examinations (see Chapter 666). Discrepancies as small as 0.5?cm may produce asymmetry. The pelvis in such patients tilts toward the short side, producing a postural curve in the opposite direction. Because children with leg-length inequality may also have idiopathic or congenital scoliosis, careful evaluation is necessary. Any child with a lower extremity–length inequality should be referred for orthopedic evaluation.

669.4 Kyphosis (Round-Back)

The normal thoracic spine has a convex alignment in the sagittal plane, termed *kyphosis*. The normal radiographic range of kyphosis is 20–40 degrees; individuals with increased kyphotic alignment have the clinical sign of round-back. Round-back may be flexible or structural; structural round-back may be idiopathic or congenital in origin. Idiopathic round-back is sometimes referred to as Scheuermann disease.

FLEXIBLE KYPHOSIS

Round-back is a common concern of many parents of adolescents. They often are perceived by parents and teachers to sit and stand in a slouched position, and round-back is a common cause of referral from spine screening programs. Adolescents with postural round-back can correct the round-back appearance voluntarily in both the standing and prone positions. The overall angle of kyphosis may be increased on the standing lateral radiograph, but no vertebral abnormalities are present. A supine hyperextension lateral radiograph shows complete correction. It is commonly thought that such a posture leads to permanent deformity. Fortunately, there is no evidence that flexible round-back posture has adverse physical effects. A thoracic hyperextension exercise program may assist in strengthening the extensor muscles of the spine, but the patient has the ultimate responsibility for his or her posture. Orthotic treatment is not indicated for patients with flexible round-back.

STRUCTURAL KYPHOSIS

Scheuermann Disease (Idiopathic Kyphosis)

The term *Scheuermann kyphosis* is used for nonflexible (structural) kyphosis that develops during adolescence in previously normal children. Mild increases in structural kyphosis are equally common in girls and boys; the condition may worsen slightly more often in boys than in girls. The absolute incidence of the disorder is unknown because small degrees of structural kyphosis are neither clinically obvious nor significant. Cadaver studies indicate that the vertebral changes associated with structural round-back occur in 7–8% of the population. The cause is unclear, but histologic specimens obtained at the time of surgical correction of severe deformity suggest that a disordered pattern of endochondral ossification similar to that found in slipped capital femoral epiphysis and tibia vara may be responsible. This may be the result of increased pressure on the anterior vertebral growth plates in some individuals with severe flexible round-back, but the relationship has not been clearly established.

Clinical Manifestations.

Patients with Scheuermann kyphosis present with thoracic kyphosis of greater degree and sharper contour than that seen in normal individuals. Unlike flexible round-back patients, affected individuals cannot actively correct the deformity. Many patients complain of occasional mild aching pain in the area of the kyphosis, but it is rarely severe or limiting. Careful neurologic examination is essential, but fortunately neurologic complications of Scheuermann kyphosis are rare.

Radiographic Evaluation.

Radiographic assessment for kyphosis includes posteroanterior and lateral standing radiographs of the entire spine (Fig. 669–4). In addition to increased kyphotic angle, radiographic findings include (1) narrowing of disk space, (2) loss of the normal anterior height of the involved vertebra and elongation of the vertebral centrum, (3) wedging of 5 degrees or more in three or more vertebrae, and (4) irregularities of the end-plates, sometimes called *Schmorl nodes.*

Treatment.

Treatment depends on the age of the patient, the degree of deformity, and the presence or absence of pain in the apical region. Scheuermann kyphosis appears to be primarily a cosmetic problem. There is little evidence that patients with kyphotic curves less than 70 or 80 degrees experience late progression, disabling pain, or neurologic compromise. Kyphotic deformities greater than 90 degrees are more likely to be aesthetically unacceptable, symptomatic, and progressive. There are few absolute guidelines for treatment, and decisions must be individualized. Mature patients with little or no pain and acceptable cosmetic alignment need no treatment. Immature patients with mild deformity may benefit from a hyperextension exercise program, whereas those with kyphotic deformities greater than 60 degrees require bracing if treatment is considered appropriate. Thoracic kyphosis usually requires a Milwaukee brace; in patients with thoracolumbar kyphosis, an underarm hyperextension orthosis can be used. Surgical treatment of Scheuermann disease is usually reserved for patients with severe and painful deformity who have completed growth. This usually involves a combination of anterior spinal release and fusion and posterior spinal fusion and instrumentation.

Figure 669.4-4 Standing lateral radiograph of a 14-yr-old boy with severe Scheuermann kyphosis. This measures 92 degrees between T3 and T12. Note the wedging of the vertebrae at T6, T7, T8, and T9. The normal thoracic kyphosis is 40 degrees or less.

Congenital Kyphosis

Congenital kyphosis, or kyphotic deformity, is the result of vertebral malformations

that occur during the first trimester. The most common abnormalities are congenital failure of formation of all or part of the vertebral centrum and failure of anterior segmentation of the spine (anterior unsegmented bar). Severe deformities are usually recognized at birth and rapidly progress thereafter. The less obvious deformities may not become obvious until later in childhood. Progressive congenital kyphosis is a serious problem; paraplegia may develop as a result of compression of the spinal cord against the apex of the deformity. Patients with congenital kyphosis should be referred for specialty evaluation as soon as the deformity is recognized. Brace treatment is not effective. Surgical intervention is often necessary, and the results of surgery are best if performed before significant deformity has developed.

669.5 Back Pain in Children

Back pain in children is unusual and should be viewed with concern. In contrast to adults, in whom back pain is frequently mechanical or psychologic in origin, back pain in children is frequently due to organic causes, especially in preadolescent children. Back pain lasting more than a few days requires careful investigation. It has been reported that approximately 85% of children with back pain lasting more than 2 mo have a specific diagnosable lesion: 33% post-traumatic (occult fracture, spondylolysis); 33% developmental (kyphosis, scoliosis); and 18% infection or tumor. Only in the remaining 15% is the diagnosis nonspecific.

Clinical Manifestations.

When confronted with a child with back pain, a careful history and physical evaluation are mandatory. The history includes the onset and duration of symptoms; antecedent factors; general health; family history; location, character, and radiation of pain; and neurologic symptoms, such as muscle weakness, sensory changes, and bowel or bladder dysfunction. Physical examination includes a complete musculoskeletal and neurologic evaluation. Spinal alignment, mobility, muscle spasm, and areas of tenderness are evaluated and recorded. The danger signs in childhood back pain include (1) persistent or increasing pain; (2) systemic symptoms, such as fever, malaise, or weight loss; (3) neurologic symptoms or findings; (4) bowel or bladder dysfunction; (5) young age, especially less than 4 yr (suspect tumor); and (6) painful left thoracic spine curvatures.

Radiographic and Laboratory Evaluation.

Plain radiographs are the first diagnostic procedure to use in the evaluation of pediatric back pain, usually posteroanterior and lateral standing radiographs of the spine with right and left oblique views of the involved area. MRI or bone scans may be necessary depending on the location of the pain and the differential diagnoses. Laboratory studies, such as a complete blood cell count with differential, erythrocyte sedimentation rate (ESR), and tests for the juvenile forms of arthritis (juvenile rheumatoid arthritis and ankylosing spondylitis) may be necessary in certain cases (see Chapter 146). Cerebrospinal fluid should be evaluated if myelography is performed.

Differential Diagnosis.

The differential diagnosis in pediatric back pain is extensive and is presented in Box 669–2 .

669.6 Spondylolysis and Spondylolisthesis

Spondylolysis is the term used to refer to a defect in the pars interarticularis, the posterior plate of bone that connects the superior and inferior articular facets of a vertebral body. The abnormality most commonly occurs in the L5 vertebra and is sometimes associated with forward slip of the affected vertebra relative to the body of the first sacral vertebra, termed *spondylolisthesis*. Spondylolysis may be congenital or acquired. Cadaver studies indicate that 5–7% of the general population has pars interarticularis defects; asymptomatic spina bifida occulta at L5 or S1 often accompanies the lesion. Most individuals with congenital spondylolysis have little or no pain and do not acquire spondylolisthesis. In such a patient, the abnormality is usually noted as an incidental finding on radiographs made for other reasons. A small percentage of patients with spondylolysis acquire the lesion as a result of repetitive flexion exercises from activities such as gymnastics or diving. The lesion in such patients resembles a stress fracture and is more likely to be symptomatic. Spondylolisthesis, when present, is usually graded by the degree of slippage of one vertebra on the other: grade 1, less than 25%; grade 2, 25–50%; grade 3, 50–75%; grade 4, 75–100%; and grade 5, complete displacement.

Clinical Manifestations.

Symptomatic patients with spondylolysis usually present with low back pain and hamstring muscle spasm. Radicular symptoms are not common. Urinary retention

Box 669.6-2. Differential Diagnosis of Back Pain

INFLAMMATORY DISEASES

- Diskitis (common before 6 yr)
- Vertebral osteomyelitis (pyogenic, tuberculous)
- Spinal epidural abscess
- Pyelonephritis
- Pancreatitis

RHEUMATOLOGIC DISEASES

- Pauciarticular juvenile rheumatoid arthritis
- Reiter syndrome
- Ankylosing spondylitis
- Psoriatic arthritis

DEVELOPMENTAL DISEASES

- Spondylolysis (common in adolescents)
- Spondylolisthesis (common in adolescents)
- Scheuermann syndrome (common in adolescents)
- Scoliosis (especially left thoracic)

MECHANICAL TRAUMA AND ABNORMALITIES

- Hip-pelvic anomalies

MECHANICAL TRAUMA AND ABNORMALITIES

- Hip-pelvic anomalies

- Herniated disk
- Overuse syndromes (common with athletic training and in gymnasts and dancers)
- Vertebral stress fractures
- Upper cervical spine instability

NEOPLASTIC DISEASES

- Primary vertebral tumors (e.g., osteogenic sarcoma)
- Metastatic tumor (e.g., neuroblastoma)
- Primary spinal tumor (e.g., neuroblastoma, lipoma)
- Malignancy of bone marrow (e.g., acute lymphocytic leukemia, lymphoma)
- Benign tumors (e.g., eosinophilic granuloma, osteoid osteoma)

OTHER

- After lumbar puncture
- Conversion reaction
- Juvenile osteoporosis

or incontinence are uncommon but, when present, imply serious compromise of the sacral nerve roots. Physical examination shows limitation of lumbar flexibility and tight hamstring muscles. When spondylolisthesis accompanies spondylolysis, lumbar lordosis is often reduced rather than accentuated, and sacral kyphosis is often present. The buttocks appear flattened and prominent, and the anterior abdominal wall is prominent. A palpable “step-off” at the lumbosacral area may be noted in patients with high-grade spondylolisthesis. The forward bend test for scoliosis should be performed because patients with spondylolysis may also have scoliosis. Careful neurologic examination is essential.

Radiologic Evaluation.

Initial radiographic examination in patients with suspected disorders of the lumbosacral region should include anteroposterior, lateral, and oblique radiographs of the lumbosacral spine. Large cassette films of the spine should be obtained if there is a suspicion of scoliosis. When there is a history of urinary dysfunction or physical signs of nerve root compromise, MRI of the thoracolumbar spine should be performed.

Treatment.

Treatment of spondylolysis depends on the presence of symptoms. Progressive slippage has been reported in children and adolescents with asymptomatic spondylolysis, and such patients should be re-examined at 6-mo intervals. Repeat radiographs are probably not necessary in the absence of symptoms or physical signs of progression. When indicated, a single standing lateral film of the lumbosacral junction provides information for routine follow-up. Patients with painful spondylolysis, especially when a stress fracture is suspected, may benefit from a period of immobilization in a body jacket or underarm orthosis. If this does not relieve pain, surgical intervention may be required to repair the defect or stabilize the affected vertebrae.

Progressive spondylolisthesis causes deformity and disability. Because surgical reduction of severe slip is difficult and carries significant risks, progressive slips are best treated before a severe deformity develops. Painful spondylolisthesis, or asymptomatic spondylolisthesis with greater than 25% slip, is usually treated by an in situ posterior spinal fusion regardless of the age of the patient.

669.7 Disk Space Infection

Intervertebral diskitis is the term used for the association of back pain, progressive loss of intervertebral disk height, and erosion of adjacent vertebral end-plates usually in lumbar regions. The clinical findings and radiographic signs may be common manifestations of a number of underlying processes. Rarely, patients have severe back pain, high fever, and signs of bacteremia consistent with acute osteomyelitis. In most, the inflammatory process is much less severe, even though blood cultures (rarely) or aspirates of the involved area may occasionally yield bacteria. In some patients, there are few symptoms and signs and no evidence of systemic or local infection despite progressive radiographic changes. In these instances, the lesion may be of traumatic or rheumatic origin.

Clinical Manifestations.

Symptoms in patients with intervertebral diskitis vary with age, and a high index of suspicion is required to establish the diagnosis. Very young children may simply be fussy and refuse to eat. Toddlers may cease walking. Older children and adolescents complain of back, abdominal, or pelvic pain. The physical findings in a child with a disk space infection are usually characteristic. The child maintains the spine in a straight, stiff, or splinted position and refuses to flex the lumbar spine. The normal lumbar lordosis is reversed, and there may be paravertebral muscle spasm. Fever is variable, and the systemic white blood cell count may be only mildly elevated. The ESR is usually elevated. The differential diagnosis includes vertebral body osteomyelitis which is associated with an older age at onset (7 vs 2 yr), longer duration of illness (33 vs 22 days), and the presence of fever, leukocytosis and bone destruction.

Radiographic Evaluation.

The radiographic features vary according to the interval between the onset of symptoms and the diagnosis. Radiographic signs lag behind clinical symptoms. The characteristic findings of disk space (narrowing and irregularity of the adjacent vertebral body end-plates) are not often present at the time of initial presentation. Technetium bone scans and MRI scans become abnormal early in the disease and may establish the diagnosis in patients with suggestive symptoms and signs. MRI may show a paravertebral inflammatory mass in diskitis. MRI is most helpful in distinguishing diskitis from vertebral osteomyelitis.

Treatment.

In patients with constitutional symptoms and signs suggestive of a bacterial cause, initial treatment should include a combination of immobilization and antibiotics. *Staphylococcus aureus* is the usual organism isolated in those patients with a clear bacterial cause, and appropriate antibiotic coverage should be initiated. Blood cultures may be helpful in identifying the organism. Aspiration needle biopsy of the disk space by CT guidance is not necessary and is usually reserved for children who do not respond to initial treatment with antibiotics. A minimum of 4–6 wk of antibiotic therapy should be used for patients with positive cultures, high white blood cell counts, or persistent elevation of the erythrocyte sedimentation rate. The appropriateness of antibiotics is less certain in patients with minimal symptoms, few signs, and normal laboratory studies. Immobilization alone may suffice in such cases. Surgical drainage is usually reserved for

---

patients who do not respond to initial therapy or who have MRI evidence of abscess formation in the paravertebral area.

669.8 Intervertebral Disk Herniation

Intervertebral disk rupture is rare in children and uncommon in adolescents. In the United States, less than 1% of patients undergoing diskectomy are younger than 16 yr. The frequency of symptomatic intervertebral disk herniation is more common in Asiatic populations than in whites, perhaps because of the smaller size of the spinal canal.

Clinical Manifestations.

Symptoms of intervertebral disk herniation in adolescents are similar to those in

adults. The majority of affected patients report back pain; most have sciatic pain. About 30% complain of decreased sensation or paresthesia in the lower extremities. On physical examination, lumbar muscle spasm, scoliosis, and a decreased range of lumbar motion are common findings. A positive straight leg-raising test is present in most patients. Abnormal reflex patterns and lower extremity weakness are much less likely to be present in young patients than in adults. A history of trauma is occasionally present, and patients tend to be taller and slightly heavier than their peers. A positive family history of intervertebral disk disease is frequently present.

Radiographic Evaluation.

Radiographs often show loss of lumbar lordosis and lumbar scoliosis. Loss of intervertebral disk height is rarely noted on plain films. MRI is currently the study of choice for localization of the lesion.

Treatment.

Most symptoms respond to bed rest followed by gradual resumption of activities. When sciatic pain, loss of reflexes, or weakness persist, surgical excision of the intervertebral disk is indicated. Fusion is not necessary unless there is accompanying evidence of spinal instability. Good results can be expected about 75% of the time. The incidence of recurrent symptoms requiring repeat surgery is about 25%.

669.9 Tumors

Back pain may be the presenting complaint in children who have a tumor involving the vertebral column or the spinal cord. Other associated symptoms may include weakness of the lower extremities, scoliosis, and loss of sphincter control. Both benign and malignant tumors may occur; most are benign (see Chapter 493). Common benign tumors include osteoid osteomas, osteoblastoma, solitary bone cysts, and eosinophilic granuloma. Malignant tumors may be osseous (osteogenic or Ewing sarcoma), neurogenic (neuroblastoma), or metastatic in origin. Because the onset of symptoms usually precedes radiographic abnormality, radioisotope bone scans or MRI is necessary for localization and diagnosis. The treatment of tumors of the spinal column is complex and may involve a combination of surgery, radiotherapy, and chemotherapy. Side effects are common when combination therapy is required, and growth disturbances can be expected.

Chapter 670 - The Neck

George H. Thompson

Nonosseous and osseous abnormalities of the neck are relatively common in children. These are predominantly soft tissue, congenital, and neurologic in origin.

670.1 Torticollis

Torticollis (*torqueo*, “to twist” + *collum*, “neck”) is the term applied to the clinical finding of a twisted neck. In most instances, the head is tipped toward one side and the chin rotated toward the other. Torticollis is a sign, not a disease, and may be the result of a wide range of underlying pathophysiologic processes. Torticollis that is present at birth may be the result of in utero positional (postural) effects or traumatic lesions of the sternomastoid muscle or of congenital abnormalities of the cervical spine. Torticollis in later childhood may be the result of trauma, inflammatory processes, spinal syrinx, or central nervous system neoplasia. The differential diagnosis of torticollis is extensive and is presented in Box 670–1 .

Muscular torticollis is the most common variety and is presumed to result from injury to the sternocleidomastoid muscle during delivery. Large infants who have had difficult vertex deliveries as well as those who are breech or those with hip dysplasia are at special risk. In affected infants, normal rotation of the neck during delivery may produce bleeding within the substance of the sternocleidomastoid muscle (tumor) and a localized increase in pressure within the muscular compartment contained by the sternocleidomastoid fascia. Increased pressure produces focal ischemia; secondary fibrosis and contracture within the muscle result in the clinical finding of torticollis. Some infants have no tumor and may have torticollis secondary to in utero positioning.

Box 670.1-1. Differential Diagnosis of Torticollis (Wryneck)

CONGENITAL

Muscular torticollis

Positional deformation

Hemivertebra (cervical spine)

Unilateral atlanto-occipital fusion

Klippel-Feil syndrome

Unilateral absence of sternocleidomastoid

Pterygium colli

TRAUMA

Muscular injury (cervical muscles)

Atlanto-occipital subluxation

Atlantoaxial subluxation

C2-3 subluxation

Rotary subluxation

Fractures

INFLAMMATION

Cervical lymphadenitis

Retropharyngeal abscess

Cervical vertebral osteomyelitis

Rheumatoid arthritis

Spontaneous (hyperemia, edema) subluxation with adjacent head and neck infection (rotary subluxation

Rheumatoid arthritis

Spontaneous (hyperemia, edema) subluxation with adjacent head and neck infection (rotary subluxation
syndrome)

Upper lobe pneumonia

NEUROLOGIC

Visual disturbances (nystagmus, superior oblique paresis)

Dystonic drug reactions (phenothiazines, haloperidol, metoclopramide)

Cervical cord tumor

Posterior fossa brain tumor

Syringomyelia

Wilson disease

Dystonia musculorum deformans

Spasmus nutans

OTHER

Acute cervical disk calcification

Sandifer syndrome (gastroesophageal reflux, hiatal hernia)

Benign paroxysmal torticollis

Bone tumors (eosinophilic granuloma)

Soft tissue tumor

Hysteria

Swelling within the sternocleidomastoid muscle may be palpable in neonates with muscular torticollis; swelling diminishes shortly after birth, and the lesion may not be

present in older infants. Contracture of the muscle results in the typical head tilt and rotation. In patients with a suggestive history and appropriate physical findings, programs of positioning and stimulation and gentle passive stretching exercises started within the first month of life often result in resolution. The parents should be instructed to rotate the chin gently toward the side of head tilt while simultaneously bringing the head to the upright position. As range of motion improves, the chin can be rotated past neutral and the head tilted toward the opposite side. Significant correction usually occurs within the first few months of life in patients with muscular torticollis. When deformity persists, the patient should be referred for orthopedic evaluation. Soft collars are not effective in treatment, and rigid devices produce secondary mandibular deformity. Surgical release of the sternocleidomastoid muscle is occasionally required in such patients and should be performed before the development of secondary facial asymmetry (plagiocephaly).

Congenital malformations of the cervical spine may also produce torticollis. Malformation or congenital cervical scoliosis result in deformity of the neck that will not respond to stretching exercise programs. Infants with torticollis, in whom there is no history of possible birth trauma and no evidence of a mass within the sternocleidomastoid muscle, should have anteroposterior and lateral cervical spine radiographs before a program of manipulation is recommended. At best, such infants respond

minimally to stretching exercises; at worst, passive manipulation may injure the cervical spinal cord.

Torticollis arising later in childhood in previously normal children requires careful evaluation. The most common causes are minor cervical muscle trauma or inflammation of the cervical muscles secondary to upper respiratory illness. Inflammation of the head and neck region may produce a nontraumatic atlantoaxial subluxation. Most children with inflammatory torticollis do not have subluxation. Torticollis may be a manifestation of more serious abnormalities of the brain, especially a posterior fossa tumor, or spinal cord. Untreated torticollis in older children may result in loss of the normal rotational motion of the upper cervical spine or rotational subluxation of the upper cervical segments. The evaluation and treatment of suspected rotational fixation and subluxation in children is complex and should be performed by experienced specialists. Inflammatory torticollis responds to rest, anti-inflammatory agents, antibiotics if indicated, a soft collar, and, if needed, muscle relaxants (diazepam).

670.2 Klippel-Feil Syndrome

The clinical triad of short neck, low hairline, and restriction of neck motion in a patient with multiple coalitions of the cervical vertebrae defines this syndrome. There is an association of the Klippel-Feil triad with congenital abnormalities of the genitourinary tract, auditory system, spinal cord, and cardiovascular system, as well as with other abnormalities of the musculoskeletal system. **Sprengel anomaly** (congenital elevation of the scapula) is a common associated finding, and affected patients have a higher than expected incidence of scoliosis.

Affected children characteristically have low hairlines and short, sometimes webbed, necks. Decreased active and passive motion of the cervical spine is usually present, although the extent of restriction depends on the severity of the vertebral defects and may be difficult to detect in minimally affected patients. Torticollis may be present. Initial evaluation should include anteroposterior, lateral, and oblique views of the cervical spine. Flexion-extension lateral views, odontoid view, and CT may be necessary if instability is suspected. MRI is recommended for patients with neurologic deficits.

Thirty to 40% of patients with Klippel-Feil abnormality have structural abnormalities of the urinary tract. Double collecting systems, renal aplasia, horseshoe kidney, and recurrent pyelonephritis are common. Patients may die of uremia. The extent of the cervical abnormality correlates poorly with the severity of the underlying genitourinary abnormality, and thorough evaluation of the genitourinary tract is indicated in all patients.

670.3 Atlantoaxial Instability

Instability of the upper cervical spine in children is uncommon but potentially devastating. In the normal upper cervical spine, flexion and extension take place at the occiput-first cervical vertebra (C1) articulation and rotation occurs at the C1-2 joint. Neither joint is intrinsically stable, and both depend on the integrity of the ligaments and joint capsules that surround the joints to constrain motion. Developmental, traumatic, inflammatory, or metabolic lesions that affect the stability of the occiput-C1 or C1-2 joint have serious implications. Progressive myelopathy may develop in patients with chronic instability; acute impingement and death are possible in patients with severe instability.

Hypoplasia and Absence of the Odontoid Process.

Rudimentary formation (os odontoideum) or absence of the odontoid process is well documented in disorders such as Morquio syndrome but has been also reported in children with no demonstrable genetic or metabolic disorders. Absence of the odontoid may therefore be traumatic or congenital and is associated with varying degrees of upper cervical spine instability. In such patients, the proximal pole of the odontoid is absent and the base of the odontoid is rounded off below the arch of the first cervical vertebra, thereby resulting in C1-2 instability.

Symptoms vary depending on the degree of C1-2 instability. Preliminary evaluation should include controlled flexion and extension lateral radiographs of the cervical spine. MRI of the cervical spine performed in the neutral, flexed, and extended positions provides precise information on the size of the cervical canal, the position of the spinal cord within the canal, and the presence of spinal cord impingement. If available, anteroposterior and lateral tomography is also an excellent technique to identify small proximal ossicles. Transverse CT and sagittal reconstruction provide detailed information regarding the craniovertebral junction.

In normal asymptomatic patients without radiographic evidence of instability, restriction of contact sports and close observation is appropriate. In patients with

Morquio syndrome, cervical stabilization should be considered even when such patients are asymptomatic and have little instability. In patients with cervical instability or abnormal neurologic findings, stabilization of the cervical spine is essential.

Down Syndrome.

The association of trisomy 21 (Down syndrome) with instability of the upper cervical spine is well known; estimates of the incidence of instability range from 10–25%. Reported abnormalities include occipitoatlantal instability, atlantoaxial instability, occipitalization of the atlas, and os odontoideum. The number of patients with *symptoms* related to C1-2 instability or other anomalies of the cervical spine is much lower. A minority of Down syndrome patients with cervical instability have neurologic symptoms (see Chapter 70).

Patients with Down syndrome and upper cervical instability who have abnormal neurologic signs have highly variable manifestations. Obvious abnormalities such as incontinence, gait disturbances, and seizures may be the presenting symptoms in some patients, whereas others may be noted to have intermittent balance problems or decreased exercise tolerance. The incidence of instability increases with age. Unfortunately, significant neurologic injury, including quadriparesis or death, has been reported in previously asymptomatic patients.

The Orthopedic Section of the American Academy of Pediatrics has recommended screening of patients with Down syndrome with neurologic examination and lateral radiographs in the neutral, flexed, and extended positions. Patients with no neurologic abnormalities but with radiographic evidence of instability require further evaluation; at the least, they should be restricted from contact sports and followed periodically.

Patients with myelopathy and those with marked instability without myelopathy are candidates for cervical spine fusion. Decision-making is complicated by the lack of knowledge of the long-term outcome of patients with myelopathy treated nonoperatively and by the variability of outcome in patients treated surgically. Unfortunately, the results of surgical treatment of instability in Down syndrome are less predictable than that of instability in other conditions. Failure of fusion and graft resorption may occur, and the incidence of complications is high. It is not likely that pre-existent myelopathic changes will improve. Based on these findings, it has been recommended that patients with instability and no neurologic abnormality be treated nonoperatively. When operative intervention is necessary, all parties must be aware of the high potential for serious complications.

The occurrence of sudden death in previously normal patients with Down syndrome and the documented development of instability with increasing age raise the issue of whether all patients with Down syndrome should be restricted from potentially

dangerous activities. Given the incomplete state of knowledge at this time, this judgment appears best made on a case-by-case basis.

Chapter 671 - The Upper Limb

George H. Thompson

Upper limb disorders, with the exception of fractures, are less common in children and adolescents than are those involving the other areas of the musculoskeletal system.

SHOULDER

The shoulder joint is composed of the relatively small glenoid fossa of the scapula, which articulates with a proportionally larger hemispherical humeral head. The stability of the shoulder joint is provided by muscular and tendinous (rotator cuff) attachments. The shoulder has a relatively large range of motion because of this small articular surface and large muscle mass. Shoulder motion is a combination of glenohumeral and scapulothoracic motion.

671.1 Sprengel Deformity

Failure of the scapula to descend to its normal location is termed *Sprengel deformity.* The scapula is located at an abnormally high position with respect to the child's neck and thorax. This uncommon abnormality occurs with varying degrees of severity. Webbing of the skin between the neck and scapula and a low posterior hairline may be associated findings. In the severe form, a bone (omovertebral) may connect the scapula with the cervical spine and prevent scapulothoracic movement. There may also be associated muscle anomalies that further limit strength and stability of the shoulder girdle. In severe cases, the scapula is very high, producing a significant cosmetic deformity with markedly limited shoulder range of motion, particularly forward flexion and abduction. In the mild form, the scapula rides slightly high with less than normal motion. A Klippel-Feil anomaly (congenital fusion of one or more of the cervical spine vertebra) may also occur with Sprengel deformity.

Treatment.

The best outcome in severe Sprengel deformity is achieved by surgically repositioning or, occasionally, partially resecting the scapula. An osteotomy of the clavicle is frequently necessary to bring the scapula to a more normal position. This improves the cosmetic appearance and increases shoulder motion, especially

abduction.

671.2 Shoulder Dislocation

Traumatic dislocation of the shoulder is uncommon in childhood but increases in frequency during adolescence. Anterior dislocation is the most common type. It usually occurs when the shoulder is forced into abduction and external rotation. In young children, a Salter-Harris type II epiphyseal fracture is more likely to occur. Once a traumatic dislocation has occurred, there is damage to the anterior capsule and the associated musculature that may predispose to recurrent dislocation. The younger individuals are at the time of the initial dislocation, the more likely they are to experience recurrent dislocations.

Treatment.

Closed reduction and immobilization in a shoulder immobilizer for 3–6 wk followed by rehabilitation is recommended for the first dislocation. Some favor early reconstruction rather than instituting conservative treatment because of the risk of recurrent dislocations.

ELBOW

The elbow joint is composed of three bones: the distal humerus, the proximal radius, and the ulna. There are three articulations: the radiohumeral, the ulnohumeral, and the proximal radioulnar. There are anterior and posterior indentations on the distal surface of the humerus: the anterior coronoid and the posterior olecranon fossa. These accept the coronoid and olecranon processes of the proximal ulna. It allows the elbow to flex 150 degrees and extend to neutral. The proximal radius is a relatively flat, circular structure that allows pronation and supination of the forearm to occur with approximately 90 degrees of motion at each. Abnormalities involving the elbow typically produce pain and loss of motion.

671.3 Nursemaid's Elbow

The radial head is not as bulbous in infants and young children as it is in older children. During early childhood, the annular ligament that passes around the neck of the proximal radius just below the radial head provides stability between the radius and ulna. When longitudinal traction is applied to the upper extremity with the elbow in extension, the annular ligament can slide over the radial head and become partially entrapped in the radiohumeral joint (Fig. 671–1). This is known as nursemaid's elbow or subluxation of the radial head. It represents a soft tissue interposition in the elbow joint. The subluxation of the annular ligament is initiated by either a jerk on the arm when the child

Figure 671.3-1 The pathology of nursemaid's, or pulled, elbow. The annular ligament is partially torn when the arm is pulled. The radial head moves distally and, when traction is discontinued, the ligament is carried into the joint. (From Rang M: *Children's Fractures*, 2nd ed. Philadelphia, JB Lippincott, 1983, p 193.)

falls while the hand is being held by a parent or when the child is forcibly lifted by the hand. It may also occur if the child falls and holds onto an object for support but allows longitudinal traction to be applied across the elbow. The hand typically is held in a pronated position, and the child may refuse to use the hand and may cry when the elbow is moved.

Treatment.

Rotating the hand and forearm to a supinated position with pressure over the radial head usually reduces the annular ligament and restores full, normal use of the extremity. With reduction of the annular ligament, there is a palpable “click” felt along the lateral aspect of the elbow. Radiographs are not usually necessary to make the diagnosis. When a child is sent for radiographic evaluation before the annular ligament is reduced, this click may inadvertently occur during positioning.

The parents should be educated about the mechanism of injury and encouraged to avoid lifting or holding the child up by the hands or forearm. Once a subluxation has occurred, there is a propensity for recurrent episodes. Usually, there is sufficient development of the radial head to prevent subluxation of the annular ligament by 4 yr of age.

671.4 Panner Disease

Panner disease is an osteochondrosis that involves the ossific nucleus of the capitellum, the lateral aspect of the distal humeral epiphysis. This disorder is most common in adolescence and occurs predominantly in those engaged in sport activities that involve throwing. Adolescents complain of pain and may have crepitation and loss of motion, particularly pronation and supination.

The diagnosis can usually be made from anteroposterior and lateral radiographs of the elbow. Occasionally, oblique radiographs may be beneficial. Additional radiographic studies, such as MRI, may be helpful in identifying the extent of the lesion and determining whether the overlying articular cartilage is intact or disrupted.

Treatment.

The treatment is usually conservative with restriction of activities. If the overlying articular cartilage is disrupted and joint fluid flows beneath the lesion, it may ultimately become a loose body. A loose osteocartilaginous fragment may be excised through an arthrotomy or arthroscopy. Occasionally, it is possible to repair the lesion by drilling it to allow for ingrowth of new blood vessels or by internal fixation with absorbable pins, which may allow the lesions to heal.

WRIST

The wrist is the articulation between the hand and the distal radius and ulna. The proximal row of carpal bones (scaphoid, lunate, and hamate) composes the articular

surface of the hand. Anatomically, the distal radius has a 25-degree ulnar tilt and 12-degree volar angulation. The distal ulna is relatively flat, with the exception of the ulnar styloid, and has a small, triangle-shaped meniscus between its articulation with the hamate. There are three articulations: radiocarpal, ulnocarpal, and radioulnar. The wrist is not a common site for pediatric musculoskeletal disorders, with the exceptions of fractures involving the distal radius and ulna.

671.5 Ganglion

A synovial fluid-filled cyst around the wrist, a ganglion, is common in childhood. The usual site is the dorsum of the wrist near the radiocarpal joint; a common second site is over the volar radial aspect of the wrist. The disease is a defect in one of the joint capsules, which allows herniation of the synovium through the defect. If the synovium is ruptured, the fluid may be pumped into the soft tissues through the action of wrist motion; the fluid is subsequently walled off by reactive fibrous tissue.

Treatment.

In children, ganglia are benign and tend to disappear over time. If a ganglion is sufficiently large, causes pain, or interferes with normal tendon functioning, aspiration of the cyst is sometimes helpful. Surgical excision of the cyst accompanied by removal of the tract that extends into the joint is curative.

671.6 Radial Clubhand

Absence of the radius, either total or partial, results in radial deviation of the hand and abnormal function. The ulna is usually hypoplastic as well as bowed, contributing to the shortness and deformity of the forearm and hand. This is an uncommon disorder but may be associated with a variety of other syndromes such as the VATER syndrome (vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial and renal anomalies) or the Holt-Oram syndrome. Any child with a radial clubhand requires a careful evaluation for other disorders. The diagnosis is usually evident on physical examination, but radiographs show whether the radius is completely absent or whether there is a proximal remnant. Congenital absence of the thumb is a common accompaniment.

Treatment.

The treatment of radial clubhand in infancy begins with serial casting or splinting in an attempt to center the carpus on the end of the ulna. Usually, a surgical procedure is ultimately necessary to centralize the hand adequately, provide stability, and place it into a position to maximize function. If the thumb is absent, a pollicization of the index finger can be performed to improve hand function.

HAND AND FINGERS

The hand and fingers are composed of the carpal and metacarpal bones proximally and the phalanges distally. The thumb has two phalanges (proximal and distal), whereas the fingers have three phalanges (proximal, middle, and distal). Thus, the thumb has an interphalangeal joint and the fingers have proximal and distal interphalangeal joints. The thumb and fingers articulate with the metacarpals at the metacarpophalangeal joints. The hand has a delicate balance among the intrinsic muscle system, a powerful extrinsic muscle system, fine sensory innervation, and specialized skin to allow it to be a highly mobile, sensitive, delicate, yet powerful appendage. Thumb and finger disorders, other than trauma, are relatively uncommon. When present, they tend to be due to congenital rather than developmental abnormalities.

671.7 Polydactyly

Extra digits, or polydactyly, occur as both simple and complex deformities. Skin tags and digit remnants are typically seen near the metacarpophalangeal joint of the small finger or the thumb. They do not have palpable bone in the base or possess voluntary motion and may simply be ligated or excised in the newborn period. Complex varieties require formal amputation, which is usually performed at approximately 1 yr of age. Syndromes in which polydactyly commonly occurs are listed in Box 671–1 .

671.8 Syndactyly

Syndactyly also occurs in both simple and complex patterns. There should be concern about sharing of common important structures between the digits, such as the neurovascular bundle. There is also a tethering effect on the growth of the affected digits. Referral for delineation of specific disease and development of treatment strategies is indicated when the condition is recognized. Syndromes associated with syndactyly are presented in Box 671–2 .

671.9 Congenital Trigger Thumb and Finger

A thickening in the tendon of the flexor hallucis longus (thumb) or the flexor digitorum longus (fingers) just below the first pulley of the digit may result in a triggering phenomenon. This thickening most likely is acquired rather than congenital. Each finger has a series of pulleys that prevent the tendons from bowstringing when flexed. This nodule may slide through the first pulley with a snapping, popping, or triggering sensation; this may or may not be painful. As the nodule enlarges because of the stimulation from triggering, it may ultimately be unable to pass beneath the pulley, resulting in a fixed flexion deformity of the interphalangeal joint of the thumb or the proximal interphalangeal joint and distal interphalangeal joints of the fingers. The nodule is typically palpable in the palm just proximal to the skin crease of the metacarpophalangeal joint. This is a clinical diagnosis and radiographs are not helpful.

Treatment.

The treatment of a congenital trigger thumb or finger is a release of the first pulley. The normal excursion of the

Chapter 672 - Arthrogryposis

George H. Thompson

Arthrogryposis multiplex congenita refers to a symptom-complex characterized by multiple joint contractures present at birth. The involved muscles are replaced partially or completely by fat and fibrous tissue. This is not a single disease because there are approximately 150 different syndromes occurring with multiple congenital contractures that are categorized as arthrogryposis. Although most children who have this nonprogressive disorder survive, some die in infancy as a result of involvement of respiratory muscles. One major form (amyoplasia) of arthrogryposis multiplex congenita refers to the classic syndrome in which there is involvement of the upper and lower extremities. Amyoplasia accounts for approximately 40% of children who have multiple congenital contractures.

672.1 Amyoplasia

The cause of amyoplasia is unknown, but children with this disorder have a decreased number of anterior horn cells in the spinal cord, suggesting a neuropathic cause. Other studies have shown that the disorder may be myopathic in origin. In the latter instance, diminution of in utero movement may be the final common pathway leading to contractures. Every child presenting with multiple joint contractures should have a complete musculoskeletal evaluation and genetics consultation.

Clinical Manifestations.

The distribution of involvement of multiple joint contractures is variable. The classic presentation involves the upper and lower extremities. The lower extremities are typically more involved than the upper extremities. Involvement of all four extremities is quadrimelic involvement. It is also possible that only the lower extremities or upper extremities (bimelic) may be involved. It is unusual to see only one extremity or a portion of one extremity (monomelic) involved.

The clinical features may include (1) adduction, internal rotation contractures of the shoulders; (2) fixed flexion or extension contractures of the elbow; (3) rigid volar flexion-ulnar deviation or dorsiflexion-radial deviation contractures of the wrists; (4) thumb and palm deformity; (5) rigid interphalangeal

joints of the thumb and fingers; (6) flexion, abduction, and external rotation hip contractures with dislocation of one or both hips; (7) fixed extension or flexion contractures of the knees; and (8) severe rigid bilateral clubfeet or congenital vertical tali.

Radiographic and Laboratory Evaluation.

Radiographs should be obtained of the involved joints in all children presenting with multiple joint contractures. Screening radiographs of the spine and pelvis are almost always necessary for evaluation of possible spinal deformity and underlying hip dysplasia. Routine laboratory studies are usually not helpful in evaluating amyoplasia. If an underlying syndrome is suspected, such as congenital muscular dystrophy, creatine kinase determinations and chromosomal studies may be helpful.

Treatment.

Correction of orthopedic deformities may be beneficial in maximizing walking or other functions. Each child must be treated individually with respect to potential rehabilitation and the possible treatment.

PHYSICAL THERAPY.

Physical therapy with passive range of motion exercises can be beneficial in improving the range of motion in involved joints. However, it rarely completely corrects the existing contractures. Splinting (daytime or nighttime, or both) of the extremities may also improve joint range of motion. This is particularly useful in the hands and wrists. Postoperative splinting is important in maintaining alignment and preventing recurrence.

SERIAL CASTING.

Serial casting can be helpful in further correcting soft tissue contractures after physical therapy has reached its maximal benefit. Serial casting is particularly useful in knee flexion contractures and in clubfeet. Casts are changed at weekly intervals, followed by a gentle manipulation of the involved area.

ORTHOSES.

Orthotics can be beneficial in providing joint stability as well as maintaining alignment after satisfactory correction of contractures. The type of orthosis depends on the individual child's particular needs. It may be an ankle-foot orthosis if there is only ankle and foot involvement, a knee-ankle-foot orthosis if there is concomitant knee involvement, or a hip-knee-ankle-foot orthosis if there is involvement of all the joints of the lower extremities. Should scoliosis develop, a spinal orthosis such as a thoracolumbar spinal orthosis may be tried; it may slow the rate of progression and

delay surgical intervention.

FRACTURE MANAGEMENT.

Perinatal fractures commonly occur in children with arthrogryposis. These should be suspected if there is localized deformity, soft tissue swelling, erythema, or irritability. Rigid joints and hypotonia contribute to the increased incidence of fractures. These typically involve the shafts as well as the epiphyseal regions and should be managed with appropriate immobilization until adequate healing has occurred. It is important that radiographs be obtained in all children suspected of having a fracture before any physical therapy is initiated.

SURGERY.

Surgery is usually necessary to achieve maximal correction of soft tissue contractures and joint deformities, reduce and stabilize dislocated hips, and correct foot deformities, and for partial correction and stabilization of spinal deformities.

Upper Extremities. Surgical treatment of upper extremity deformities depends on the type and degree of contracture as well as on the motor capabilities and functional needs of the patient. A child's compensatory or adaptive functioning of the upper extremities can be remarkable, and it is essential not to diminish function for cosmesis inadvertently. In bilateral involvement, it is preferable to have one extremity in extension and the other in flexion, but have them still be able to meet in the midline. This enhances function. Internal rotation contractures of the shoulder can be treated by soft tissue releases and proximal humeral derotation osteotomies at a level proximal to the deltoid insertion. Extension contractures of the elbow may benefit from posterior capsulotomy and triceps tenotomy or lengthening to allow restoration of passive or active flexion. Active flexion can be partially restored with a transfer of the pectoralis muscle and its neurovascular bundle. Wrist deformities may be managed by tendon transfers, proximal row carpectomy, or shortening dorsal wedge radial osteotomies.

Lower Extremities. Most infants with clubfoot or vertical tali do not completely respond to passive stretching or serial casting. Complete soft tissue releases are usually required. Occasionally in a clubfoot, excision of the talus or talar decancellation may also be required to achieve a plantigrade foot.

Knee flexion contractures that are unresponsive to serial casting may benefit by a lengthening of the hamstring in association with a posterior knee capsulotomy. If this fails to correct the deformity to within 15–20 degrees of neutral, an extension osteotomy of the distal femur may be required. The value of walking with the knee extended is extremely beneficial. A recurrent flexion deformity may occur after an extension osteotomy if it is performed before adolescence. Knee extension contractures may also require treatment, especially if the child or adolescent is a nonambulator and cannot sit comfortably because of the extended position. Lengthening of the quadriceps mechanism may be beneficial.

Hip contractures may be improved by soft tissue releases. Occasionally, extension derotation osteotomies of the proximal femur may be helpful in completing the correction of the flexion, abduction, or external rotation contractures. Controversy exists as to whether bilateral dislocations of the hip should be reduced. If there is a unilateral dislocation, treatment is usually necessary to prevent leg-length discrepancy, pelvic obliquity, and possible scoliosis. Open reduction is accompanied by soft tissue releases, shortening derotation varus osteotomies of the proximal femurs, and pelvic osteotomies.

Scoliosis. Scoliosis is common in children with amyoplasia. The age at onset and patterns of deformity are variable. Orthotic management is usually effective only in slowing the rate of progression. In the majority of children, progression occurs slowly, and they ultimately require surgical intervention. Because of the associated soft tissue contractures, it is important that these curves not be allowed to become too severe because only partial correction will be obtained. Most children can be satisfactorily managed by a posterior spinal fusion and some type of segmental spinal instrumentation.

Chapter 673 - Common Fractures

George H. Thompson

Fractures in children account for 10–15% of all childhood injuries. The skeletal system of children is anatomically, biomechanically, and physiologically different from that in adults. This results in different fracture patterns (including epiphyseal fractures), problems in diagnosis, and the use of management techniques.

The anatomic differences in the pediatric skeletal system include the presence of perosseous cartilage, physes, and a thicker, stronger, more osteogenic periosteum that produces callus more rapidly and in greater amounts. Biomechanically, the pediatric skeletal system can absorb more energy before deformation and fracture than can adult bone. This has been attributed to lower mineral content and the greater porosity of young bone. The increased porosity is caused by larger, more abundant haversian canals. This results in a lower modulus of elasticity and lower bending strength. As maturation occurs, the porosity decreases and the cortical bone becomes thicker and stronger.

Ligaments frequently insert into epiphyses. As a consequence, traumatic forces applied to an extremity may be transmitted to the physes. The strength of the physes is enhanced by interdigitating mammillary bodies and the perichondrial ring. Biomechanically, the physes are not as strong as the ligaments or metaphyseal bone. The physis is most resistant to traction and least resistant to torsional forces. The majority of injuries to the physes are secondary to rotational and angular forces.

The thick periosteum of a child's bones is a major determinant in whether a fracture becomes displaced. The thick periosteum may also act as an impediment to closed reduction because of the hinging phenomenon, or it may help stabilize a fracture after reduction.

Fracture Remodeling.

Remodeling occurs by a combination of periosteal resorption and new bone formation. Thus, anatomic alignment in certain pediatric fractures is not always necessary. The major factors affecting fracture remodeling include the child's age,

proximity of the fracture to a joint, and relationship of a residual deformity to the plane of the joint axis of motion. The amount of remaining growth provides the basis for remodeling: The younger the child, the greater is the remodeling potential. Fractures adjacent to a physis undergo the greatest amount of remodeling, provided that the deformity is in the plane of axis of motion for that joint. Fracture remodeling will be less effective in displaced intra-articular fractures, diaphyseal fractures, malrotation, and deformity not in the plane of joint axis of motion.

Overgrowth.

Overgrowth, especially in long bones such as the femur, is due to physeal stimulation from the hyperemia associated with fracture healing. Femoral fractures in children younger than 10 yr frequently overgrow 1–3?cm. This is the reason for bayonet apposition of bone to compensate for the overgrowth that occurs over the next 1–2 yr. After 10 yr of age, overgrowth is less of a problem and anatomic alignment is recommended.

Progressive Deformity.

Injuries to the physes can result in complete or partial closure. As a consequence, angular deformity or shortening, or both, can occur. The magnitude depends on the physis involved and the amount of growth remaining.

Rapid Healing.

Fractures in children heal faster than do those in adults. This is due to children's growth potential and thicker, more metabolically active periosteum. As children approach adolescence and maturity, the rate of healing slows and becomes similar to that of an adult's.

673.1 Pediatric Fracture Patterns

Pediatric fracture patterns result, in part, from the anatomic, biomechanical, and physiologic characteristics of a child's skeletal system (Fig. 673–1). The majority of pediatric fractures can be managed by closed methods.

Complete.

Complete fractures are the most common type and occur when both sides of the bone are fractured. These fractures

Figure 673.1-1 Illustration of fracture patterns. *A*, Longitudinal—fracture line parallel to bony axis. *B*, Transverse—fracture line perpendicular to bony axis. *C*, Oblique—fracture line at angle to bony axis. *D*, Spiral—fracture line runs curvilinear course to bony axis. *E*, Impacted—fractured bone ends compressed together. *F*, Comminuted—fragmentation of bone into three or more parts. *G*, Greenstick—bending of bone with incomplete fracture of convex side. *H*, Bowing—bony plastic deformation. *I*, Torus—buckling fracture. (From White N, Sty J: Radiological evaluation and classification of pediatric fractures. *Clin Ped Emerg Med* 2002;3:94–105.)

may be classified as spiral, transverse, oblique, or comminuted, depending on the direction of the fracture lines. Comminuted fractures are unusual in children.

Buckle or Torus Fracture.

Compression of bone produces a buckle or torus fracture. These fractures typically occur in the metaphyseal areas in young children, especially in the distal radius. They are inherently stable and heal in 2–3 wk with simple immobilization.

Greenstick.

When a bone is angulated beyond the limits of plastic deformation, a greenstick fracture may occur. This represents bone failure on the tension side and a plastic or bend deformity on the compression side. The energy was insufficient to result in a complete fracture.

Plastic Deformation or Bend Fractures.

Traumatic bowing or bend deformities are caused by plastic deformation of bone. The bone was angulated beyond its limit of plastic deformation, but the energy was insufficient to produce a fracture. Thus, no fracture line is visible radiographically. It is most commonly seen in the ulna and, occasionally, the fibula.

Epiphyseal Fractures.

Salter and Harris classified epiphyseal injuries into five groups: type I, separation through the physis, usually through the zones of hypertrophic and degenerating cartilage cell columns; type II, a fracture through a portion of the physis but extending through the metaphyses; type III, a fracture through a portion of the physis extending through the epiphysis and into the joint; type IV, a fracture across the metaphysis, physis, and epiphysis; and type V, a crush injury to the physis (Fig. 673–2 (Figure Not Available)). This classification allows generalized prognostic information regarding the risk for premature physeal closure and the indications for treatment. Type III and type IV epiphyseal fractures require anatomic alignment because of displacement of both the physis and the articular surface. Type V fractures are usually recognized in retrospect as a consequence of premature physeal closure. Type I and type II fractures usually can be managed by closed reduction techniques and do not require perfect alignment. A major exception is type II fractures of the distal femur. Fractures in this location have a poor prognosis unless almost anatomic alignment is obtained by either closed or open methods.

Child Abuse (see Chapter 35).

Skeletal injury is common in nonaccidental trauma. Certain fractures have a high probability of child abuse that include metaphyseal lesions (bucket-handle or corner fractures), posterior rib fractures, scapular fractures, spinous process fractures, and

sternal fractures. Multiple fractures (in different stages of healing), epiphyseal separations,

Figure 673.1-2 (Figure Not Available) The types of growth plate injury as classified by Salter and Harris. (From an instructional course study, American Academy of Orthopaedic Surgeons, and Salter RB, Harris WR: Injuries involving the epiphyseal plate. *J Bone Joint Surg Am* 1963;45:587–622.)

vertebral body fractures, complex skull fracture, and digit fractures are moderately suspicious. Spiral femur fractures in nonambulatory infants and nonsupracondylar humerus fractures are also highly suggestive of nonaccidental trauma.

673.2 Clavicular Fractures

Fractures involving the junction of the middle and lateral aspects of the clavicle are common. These can be the result of birth injuries in newborns but are more typically the result of a fall on the outstretched arm or a direct blow to the clavicle. They are rarely associated with a neurovascular injury. Diagnosis is easily made by physical and radiographic evaluation. Anteroposterior radiograph of the clavicle and, occasionally, a cephalic view demonstrate the fracture. Typically, the fracture fragments are displaced and overlap 1–2?cm.

Treatment.

The treatment of most clavicle fractures consists of an application of a figure-of-eight clavicle strap. This will extend the shoulders and minimize the amount of overlap of the fracture fragments. Rarely is anatomic alignment achieved, but this is not necessary. The fractures heal rapidly, usually in 3–6 wk. Commonly, a palpable mass of callus may be visible in thin children. This remodels satisfactorily in 6–12 mo.

673.3 Proximal Humerus Fractures

Salter-Harris type II fractures of the proximal humerus occur commonly in children and are due to a backward fall on the involved extremity with the elbow extended. Neurovascular injuries rarely occur. Diagnosis is made from anteroposterior and lateral radiographs of the shoulder or humerus.

Treatment.

The treatment of these fractures is usually simple immobilization. Occasionally, a closed reduction may be necessary. A significant amount of deformity can be accepted because of the remodeling potential of this region; 80% of the growth of the humerus occurs from the proximal humeral epiphysis. A sling and swath and, occasionally, a coaptation splint may be necessary to provide satisfactory immobilization and comfort. In severely displaced fractures, closed reduction with immobilization may be necessary.

673.4 Distal Humerus Fractures

The distal humerus is one of the most common sites for fractures in children. These include separation of the distal humeral

epiphysis (transcondylar fracture), supracondylar fractures of the distal humerus, and epiphyseal fractures, such as the lateral condyle fractures. The transcondylar fracture occurs in neonates commonly as the result of child abuse. The other fractures are more likely to occur after a fall on the outstretched arm. Anterior and posterolateral radiographs of the involved extremity are necessary for the diagnosis. If the fracture is not visible but there is an altered relationship between the humerus and the radius and ulna or the presence of a posterior fat pad sign, a transcondylar fracture or an occult fracture should be suspected. Swelling and pain with attempted motion are the typical features of these fractures. Neurologic impairment may also occur, owing to close proximity of the median, ulnar, and radial nerves to these fractures.

Treatment.

Treatment of fractures of the distal humerus is restoration of anatomic alignment. This is necessary to prevent deformity and to allow for normal growth and development. Closed reduction and frequently percutaneous internal fixation is necessary. Open reduction is necessary for fractures that cannot be reduced by closed methods.

673.5 Distal Radius and Ulna Fractures

Torus, or buckle, fractures of the distal radial metaphysis are among the most common fractures of childhood. They are usually the result of a simple fall on the hand with the wrist in dorsiflexion. This is an impacted fracture, and there is minimal soft tissue swelling or hemorrhage. It is common for a child to present 1–2 days later because the initial injury was believed to be only a sprain or contusion. The clinical characteristics are nonspecific, usually with mild tenderness to palpation directly over the fracture. Diagnosis is confirmed by anteroposterior and lateral radiographs of the wrist.

Treatment.

Treatment of torus fractures of the distal radius and ulna is by a short-arm cast. Fractures are typically healed in 3–4 wk.

673.6 Phalangeal Fractures

Phalangeal fractures in children are usually the result of a direct blow to the finger. They are typically trapped in doors or struck by another object. If the distal phalanx is involved, there may be a subungual hematoma, which can be painful. This requires drainage. If the nail bed is bleeding, avulsed, or partially detached in association with a fracture, this is an open fracture and should be treated aggressively with irrigation, tetanus prophylaxis, and appropriate antibiotics. Occasionally, physeal involvement, especially Salter-Harris type II epiphyseal fracture, may occur. Anteroposterior and

lateral radiographs of the digit confirm the fracture.

Treatment.

The treatment of phalangeal fractures is usually by splint immobilization. Rarely is a closed reduction necessary. However, if there is angulation or malrotation, this procedure may be necessary.

673.7 Toddler Fracture

Toddler fractures represent a spiral fracture of the distal one third of the tibia. They are usually the result of simple falls while running or playing. They may also occur when stepping on an object on the floor. These fractures occur in children between 2–4 yr of age and, occasionally, up to 6 yr of age. Clinical features include pain, refusal to walk, minimal soft tissue swelling, a slight increase in warmth to palpation over the fracture, and pain with palpation. These fractures may not be visible radiographically on anteroposterior and lateral radiographs of the tibia. Occasionally, oblique radiographs may reveal the fractures. The fracture can be detected by a technetium bone scan, but this is rarely necessary.

Treatment.

Application of a long-leg cast in suspected cases relieves symptoms. Within 1–2 wk there is radiographic evidence of subperiosteal new bone formation. These fractures are usually healed within 3–4 wk.

673.8 Lateral Malleolar Fractures

A Salter-Harris type I separation of the distal fibular epiphysis is common in childhood. These fractures usually appear as ankle sprains. However, it must be remembered that ligaments are stronger than bone and that the epiphysis is more likely to separate than a ligament is to tear. Children present with soft tissue swelling and pain over the lateral malleolus. Careful palpation reveals that the bone is the site of greatest tenderness rather than the area over one of the three lateral ligaments. Anteroposterior, lateral, and mortise radiographs of the ankle are typically normal. The diagnosis can be confirmed by stress radiographs, but this is rarely necessary.

Treatment.

Distal fibular epiphyseal separations require immobilization in a short-leg cast for 4–6 wk. Treatment is the same as that for a severe ankle sprain. This is why stress radiographs are rarely necessary. Follow-up radiographs show subperiosteal new bone formation in the metaphyseal region of the distal fibula.

673.9 Metatarsal Fractures

Fractures of the metatarsal shaft are usually the result of direct trauma to the dorsum of the foot. Children present with a history of injury followed by soft tissue swelling and, sometimes, ecchymosis. There is tenderness to palpation directly over the fracture. Diagnosis is obtained by anteroposterior and lateral radiographs of the foot.

Fractures of the tuberosity of the fifth metatarsal are also common. This has been termed *dancer's fracture.* It is an apophyseal avulsion fracture at the insertion of the peroneus brevis tendon. It typically occurs with the foot in an inverted position and the peroneal muscles contracting to realign the foot. The swelling, ecchymosis, and tenderness are limited to the tuberosity of the fifth metatarsal. Contraction of the peroneal musculature also increases discomfort. The diagnosis is confirmed radiographically.

Treatment.

Metatarsal fractures are treated by a short-leg cast for 4–6 wk. Weight-bearing is allowed as tolerated. The one exception is the fifth metatarsal diaphyseal shaft fracture. This has an increased incidence of nonunion and should be treated by non–weight-bearing until there is radiographic evidence of early union.

673.10 Toe Phalangeal Fractures

Fractures of the lesser toes are common and are usually secondary to direct blows. They commonly occur when the child is barefoot. The toes are swollen, ecchymotic, and tender. There may be a mild deformity. Diagnosis is made radiographically. Bleeding suggests the possibility of an open fracture.

Treatment.

The lesser toes usually do not require closed reduction unless significantly displaced. If necessary, reduction can usually be accomplished with longitudinal traction on the toe. Casting is not usually necessary. “Buddy” taping of the fractured toe to an adjacent stable toe usually provides satisfactory alignment and

relief of symptoms. Crutches may be beneficial for several days until the soft tissue swelling and the discomfort decrease.

673.11 Operative Treatment

Certain pediatric fractures have better prognoses if the fractures are reduced, by either open or closed techniques, and then internally or externally stabilized (Table 673–1). Four to 5% of pediatric fractures require surgery. The common indications for operative stabilization in children and adolescents with open physes include (1) displaced epiphyseal fractures, (2) displaced intra-articular fractures, (3) unstable fractures, (4) fractures in the multiply injured child, and (5) open fractures.

The principles of surgical management of pediatric fractures are distinctly different from those of mature adolescents and adults. Multiple closed reductions of an epiphyseal fracture are contraindicated because they may cause repetitive damage

to the germinal cells of the physis. Anatomic alignment at surgery is mandatory, especially for displaced intra-articular and epiphyseal fractures. When internal fixation is used, it should be simple (e.g., use of Kirschner wires, which can be removed as soon as the fracture is healed). Rigid fixation to allow immobilization of the extremity usually is not the goal; rather, stability sufficient to maintain anatomic alignment with supplemental immobilization, usually a plaster cast, is. Last, external fixators, when used, are removed as soon as possible and cast immobilization is substituted. The latter is indicated when soft tissue problems have been corrected or when the fracture is stable, or both.

Surgical Techniques.

Three basic surgical techniques are used in the management of pediatric fractures. Open reduction and internal fixation may be required for displaced epiphyseal fractures, especially Salter-Harris types III and IV fractures, intra-articular fractures, and unstable fractures, such as those involving the forearm diaphysis, spine, and ipsilateral fractures of the femur and tibia (floating knee). Other indications include neurovascular injuries requiring repair and, occasionally, open fractures of the femur and tibia. Closed reduction

TABLE 673.11-1 -- **Common Indications for Operative Stabilization**

Indication	Location
Displaced epiphyseal fractures (usually Salter-Harris types III and IV)	Lateral condyle Radial head Phalanx Distal femur Proximal tibia Distal tibia
Displaced intra-articular fractures	Radial neck Olecranon Femoral neck Patella
Unstable fractures	Distal humerus (supracondylar) Radius-ulna diaphysis Phalanx Spine
Multiply injured child (especially with associated head and neurologic injury)	Femoral diaphysis Tibial diaphysis Pelvis Spine
Open fractures	Upper and lower extremities Severe soft tissue injury

Adapted from Thompson GH, Wilber JH, Marcus RE: Internal fixation of fractures in children and adolescents: A comparative analysis. Clin Orthop 1984; 188:10–20.

and internal fixation is indicated for specific displaced epiphyseal, intra-articular, and unstable metaphyseal and diaphyseal fractures. Common indications include supracondylar fractures of the distal humerus, and phalangeal and femoral neck fractures. Anatomic alignment must be attained by a closed reduction before this method can be used. Failure to obtain anatomic alignment is an indication for an open reduction.

The indications for external fixation in pediatric fractures include (1) severe grade II and grade III open fractures; (2) fractures associated with severe burn; (3) fractures with bone or extensive soft tissue loss that may require reconstructive procedures, such as free vascularized grafts, skin grafts, or other procedures; (4) fractures requiring distractions such as those with significant bone loss; (5) unstable pelvic fractures; (6) fractures in children with associated head injuries and spasticity; and (7) fractures associated with vascular or nerve repairs or reconstruction. The advantages of external fixation include rigid mobilization of the fractures, separation of the management of the fractured limb and associated wounds, and patient mobilization for treatment of other injuries and transportation for diagnostic and therapeutic procedures. The majority of complications with external fixation are pin tract infections and refracture after pin removal.

Chapter 674 - Osteomyelitis and Suppurative Arthritis

Richard M. Lampe

Suppurative infections of bones and joints in children are important because of their potential to cause permanent disability. The frequency of skeletal infection is greater in infants and toddlers than in older children. Early recognition of osteomyelitis and suppurative arthritis (also called **septic arthritis**) in young patients before extensive infection develops and prompt institution of appropriate medical and surgical therapy minimize permanent damage. The risk is greatest if the physis (the growth plate of bone) or the synovium is damaged.

Etiology.

Bacteria are the most common pathogens in acute skeletal infections. In osteomyelitis, *Staphylococcus aureus* is the most common infecting organism in all age groups, including newborns. Group B streptococcus and gram-negative enteric bacilli are also prominent pathogens in neonates; group A streptococcus is next in frequency but constitutes less than 10% of all cases. After 6 yr of age, most cases of osteomyelitis are caused by *S. aureus*,

streptococcus, or *Pseudomonas aeruginosa*. Cases of *Pseudomonas* are related almost exclusively to puncture wounds of the foot, with direct inoculation of *P. aeruginosa* from the foam padding of the shoe into bone or cartilage, which develops as osteochondritis. The microbial spectrum is diverse in suppurative arthritis, but *S. aureus* infection is most common. *Haemophilus influenzae* type b accounted for more than half of all cases of bacterial arthritis in infants before universal vaccination with conjugate vaccines but is now an uncommon cause. Group A streptococcus and *Streptococcus pneumoniae* (pneumococcus) historically cause 10–20% of cases. In sexually active adolescents gonococcus is a common cause of septic arthritis. Salmonella and *S. aureus* are the two most common causes of osteomyelitis in children with sickle cell anemia.

Infection with atypical mycobacteria can occur after penetrating injuries. Fungal infections usually occur as part of multisystem disseminated disease; *Candida* arthritis or osteomyelitis sometimes complicates bloodstream infection in neonates with indwelling vascular catheters. Primary viral infections of bones or joints are exceedingly rare, but arthralgia or arthritis accompanies many viral syndromes, suggesting immune-mediated pathogenesis.

A microbial etiology is confirmed in about three fourths of cases of osteomyelitis and two thirds of cases of suppurative arthritis. Prior antibiotic therapy and the inhibitory effect of pus on microbial growth may explain the low bacterial yield. Additionally some cases treated as bacterial arthritis are actually reactive arthritis (see Chapter 147) rather than primary infection.

Epidemiology.

Osteomyelitis and suppurative arthritis are most common in young children. This is particularly true of arthritis, in which half of all cases occur by 2 yr of age and three fourths of all cases occur by 5 yr of age, compared with about one third and one half, respectively, for osteomyelitis among these age groups. Skeletal infections are consistently more common in boys than in girls, usually by a factor of 2:1. The behavior of boys may predispose to traumatic events. There appears to be no particular predilection for arthritis or osteomyelitis based on race, except for the increased incidence of skeletal infection in patients with sickle cell disease.

The majority of infections in otherwise healthy children are of hematogenous origin. Minor, closed trauma is a common preceding event in cases of osteomyelitis, occurring in about one third of patients. Infection of bones and joints can follow penetrating injuries or procedures such as arthroscopy, prosthetic joint surgery, intra-articular steroid injection, and orthopedic surgery, although this is uncommon. Impaired host defenses also increase the risk of skeletal infection.

Pathogenesis.

The unique anatomy and circulation of the ends of long bones results in the predilection for localization of blood-borne bacteria. In the metaphysis, nutrient arteries branch into nonanastomosing capillaries under the physis, which make a sharp loop before entering venous sinusoids draining into the marrow. Blood flow in this area is sluggish and provides an ideal environment for bacterial seeding. Once a bacterial focus is established, phagocytes migrate to the site and produce an inflammatory exudate. The generation of proteolytic enzymes, toxic oxygen radicals, and cytokines results in decreased oxygen tension, decreased pH, osteolysis, and tissue destruction. As the inflammatory exudate progresses, pressure increases spread through the porous metaphyseal space via the haversian system and Volkmann canals into the subperiosteal space. Purulence beneath the periosteum may lift the periosteal membrane of the bony surface, further impairing blood supply to the cortex and metaphysis.

In newborns and young infants, transphyseal blood vessels connect the metaphysis and epiphysis, so it is common for pus from the metaphysis to enter the joint space. This extension through the physis has the potential to result in abnormal growth and bone or joint deformity. During the latter part of the first year of life, the physis forms, obliterating the transphyseal blood vessels. Joint involvement once the physis forms may occur in joints where the metaphysis is intra-articular (e.g., hip, ankle, shoulder, and elbow) and subperiosteal pus ruptures into the joint space.

In later childhood the periosteum becomes more adherent, favoring pus to decompress through the periosteum. Once the growth plate closes in late adolescence, hematogenous osteomyelitis more often begins in the diaphysis and can spread to the entire intramedullary canal.

Suppurative arthritis primarily occurs as a result of hematogenous seeding of the synovial space. Less often, organisms enter the joint space by direct inoculation or extension from a contiguous focus. The synovial membrane has a rich vascular supply and lacks a basement membrane, providing an ideal environment for hematogenous seeding. The presence of bacterial endotoxin within the joint space stimulates cytokine production (tumor necrosis factor-a, interleukin-1) within the joint, triggering an inflammatory cascade. The cytokines stimulate chemotaxis of neutrophils into the joint space where proteolytic enzymes and elastases are released by neutrophils, damaging the cartilage. Proteolytic enzymes released from the synovial cells and chondrocytes also contribute to cartilage and synovium destruction. Bacterial hyaluronidase breaks down the hyaluronic acid in the synovial fluid, making the fluid less viscous and diminishing its ability to lubricate and protect the joint cartilage. Damage to the cartilage can occur through increased friction, especially for weight-bearing joints. The increased pressure within the joint space from accumulation of purulent material can compromise the vascular supply and induce pressure necrosis of the cartilage. Synovial and cartilage destruction results from a combination of proteolytic enzymes and mechanical factors.

Clinical Manifestations.

The signs and symptoms of skeletal infection are highly dependent on the age of the patient. The earliest signs and symptoms are often subtle.

Neonates may exhibit pseudoparalysis or pain with movement of the affected extremity. Half of neonates do not have fever and may not appear ill. Older infants and children are more likely to have fever, pain, and localizing signs such as edema, erythema, and warmth. With involvement of the lower extremities, limp or refusal to walk is seen in approximately half of patients.

Erythema and edema of the skin and soft tissue overlying the site of infection is seen earlier in suppurative arthritis than in osteomyelitis, since the bulging infected synovium is usually more superficial whereas the metaphysis is located more deeply. Suppurative arthritis of the hip is an exception because of the deep location of the hip joint. Local swelling and redness with osteomyelitis may mean that the infection has spread out of the metaphysis into the subperiosteal space, representing a secondary soft tissue inflammatory response.

Long bones are principally involved in osteomyelitis (Table 674–1). The femur and tibia are equally affected and together constitute almost half of all cases. The bones of the upper extremities account for one fourth of all cases. Flat bones are less commonly affected. Joints of the lower extremity constitute three fourths of all cases

of suppurative arthritis (Table 674–2). The elbow, wrist, and shoulder joints are involved in about one fourth of cases, and small joints are uncommonly infected.

There is usually only a single site of bone or joint involvement. Several bones or joints are infected in fewer than 10% of cases; notable exceptions are gonococcal infections and osteomyelitis in neonates, in whom two or more bones are involved in almost half of the cases.

Diagnosis.

Aspiration of the infected site for Gram stain and culture when the history and physical findings indicate a strong likelihood of osteomyelitis or suppurative arthritis remains the definitive diagnostic technique and provides the optimal specimen

TABLE 674-1 -- **Distribution of Affected Bones in Acute Hematogenous Osteomyelitis**

Bone	No.	Per Cent

for culture to confirm the diagnosis. For suspected osteomyelitis, a steel needle is needed to penetrate the cortex into the metaphysis. If pus is encountered in the subperiosteal space, there is no need to go farther. Most large joint spaces are easy to aspirate, but the hip can pose technical problems; ultrasound guidance facilitates aspiration. If no fluid is obtained, contrast material is injected and a radiograph is obtained to ensure that the needle tip is in the joint cavity. Aspiration of joint or bone pus provides the best specimen for bacteriologic culture of infection. If gonococcus is suspected, cervical, anal, and throat cultures should also be obtained. A blood culture should be performed in all cases of suspected osteomyelitis or septic arthritis.

Synovial fluid analysis for cell count, differential, protein, and glucose has limited usefulness because noninfectious inflammatory diseases, such as rheumatic fever and rheumatoid arthritis, can also cause exuberant reaction with increased cells and protein and decreased glucose. Synovial fluid characteristics of suppurative arthritis can suggest infection but are not sufficiently specific to exclude infection.

There are no specific laboratory tests for osteomyelitis or suppurative arthritis. Tests such as white blood cell count and differential, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are very sensitive for bone and joint infections but are nonspecific and not helpful in distinguishing between skeletal infection and other inflammatory processes. The leukocyte count and ESR may be normal during the first few days of infection, and normal test results do not preclude the diagnosis of skeletal infection. Monitoring elevated ESR and CRP may be of value in response to therapy or identifying complications.

RADIOGRAPHIC EVALUATION.

Radiologic studies play a crucial role in the evaluation of osteomyelitis and suppurative

TABLE 674-2 -- **Distribution of Affected Joints in Acute Suppurative Arthritis**

Joint	No.	Per Cent

arthritis. Conventional radiographs, ultrasound, CT, MRI, and radionuclide studies may all contribute to establishing the diagnosis. Plain radiographs are often used for initial evaluation to exclude other causes such as trauma and foreign bodies. MRI has emerged as a very sensitive and specific test and is widely used for diagnosis.

Plain Radiographs. Within 72 hours of onset of symptoms of osteomyelitis, plain radiographs of the involved site using soft tissue technique, and compared to the opposite extremity if necessary, can show displacement of the deep muscle planes from the adjacent metaphysis caused by deep tissue edema. Lytic bone changes are not visible on radiographs until 30–50% of the bony matrix is destroyed. Tubular long bones do not show lytic changes for 7–14 days after onset of infection. Flat and irregular bones can take longer.

Plain films of suppurative arthritis may show widening of the joint capsule, soft tissue edema, and obliteration of normal fat lines. Plain films of the hip can show medial displacement of the obturator muscle into the pelvis (the obturator sign), lateral displacement or obliteration of the gluteal fat lines, and elevation of the Shenton line with a widened arc.

Ultrasonography. Ultrasound is helpful in detecting joint effusion and fluid collection in the soft tissue and subperiosteal regions and may guide localization for aspiration or drainage. Ultrasound is highly sensitive in the detection of joint effusion, particularly for the hip joint, where plain radiographs may be normal in more than 50% of cases of suppurative arthritis of the hip.

Computed Tomography and Magnetic Resonance Imaging. CT can demonstrate osseus and soft tissue abnormalities and is ideal for detecting gas in soft tissues. MRI is the best radiologic imaging technique for the identification of abscesses and for differentiation between bone and soft tissue infection. MRI provides precise anatomic detail of subperiosteal pus and accumulation of purulent debris in the bone marrow and metaphyses for possible surgical intervention. In acute osteomyelitis, purulent debris and edema appear dark with decreased signal intensity on T1 weighted images, with fat appearing bright (Fig. 674–1). The opposite is seen in T2 weighted images. The signal from fat can be diminished with fat suppression techniques to enhance visualization. Cellulitis and sinus tracts appear as areas of high signal intensity on T2 weighted images.

MRI appears to have comparable positive predictive value to radionuclide imaging in acute osteomyelitis. MRI is particularly useful in the evaluation of vertebral osteomyelitis and diskitis owing to the clear delineation between the vertebral body and cartilaginous disk.

Radionuclide Studies. Radionuclide imaging can be valuable to augment MRI, especially if multiple foci are suspected. Technetium-99 methylene diphosphonate (^{99m} Tc), which accumulates in areas of increased bone turnover, is the preferred agent of choice for radionuclide bone imaging (three-phase bone scan). Osteomyelitis causes increased vascularity, inflammation, and increased osteoblastic activity, resulting in an increased concentration of ^{99m} Tc. Any areas of increased blood flow or inflammation can cause increased uptake of ^{99m} Tc in the first phase (5–10?min) and second phase (2–4?hr), but osteomyelitis causes increased uptake of ^{99m} Tc in the third phase (24?hr). Three-phase imaging with ^{99m} Tc has excellent sensitivity (84–100%) and specificity (70–96%) in hematogenous osteomyelitis and can detect osteomyelitis within 24–48?hr after onset of symptoms. The sensitivity in neonates is much lower owing to poor bone mineralization. Advantages include infrequent need for sedation, lower cost, ability to image entire skeleton for detection of multiple foci, and ability to scan multiple times after one injection.

In suppurative arthritis, three-phase imaging with ^{99m} Tc shows symmetric uptake on both sides of the joint, limited to the bony structures adjacent to the joint. Radionuclide imaging is

Figure 674-1 Pelvic osteomyelitis of the left iliac bone in a 12-yr-old girl with pain in the left hip region for 1–2 wk. *A,* Frontal radiograph of the pelvis shows mild demineralization of the acetabular portion of the iliac bone adjacent to the triradiate cartilage. There is very subtle periosteal reaction (*arrow*) along the margin of the sciatic notch. *B,* Technetium-99m bone scan shows increased uptake in the left iliac bone and mild increased uptake in the femoral head. *C,* Coronal MRI shows decreased signal from the marrow of the left iliac bone compared with the bright signal from the normal fatty marrow on the right. The femoral head is normal, and there is no joint effusion. Needle aspiration of the iliac bone yielded *Staphylococcus aureus;* the patient responded well to antimicrobial therapy. (From Markowitz RI: Diagnostic imaging. In Jenson HB, Baltimore RS [editors]: *Pediatric Infectious Diseases: Principles and Practice.* Norwalk, CT, Appleton & Lange, 1995.)

also useful to detect concomitant osteomyelitis and for evaluation of the sacroiliac joint.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of osteomyelitis includes trauma, both accidental and nonaccidental. Children with leukemia commonly have bone pain or joint pain as an early symptom. Neuroblastoma with bone involvement may be mistaken for osteomyelitis. Primary bone tumors need to be considered, but fever and other signs of illness are generally absent. Chronic recurrent multifocal osteomyelitis and synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO) syndrome are rare conditions in children characterized by recurrent osteoarticular inflammation and different skin conditions, palmoplantar pustulosis, psoriasis, severe acne, neutrophilic dermatosis (Sweet syndrome), and pyoderma gangrenosum.

The differential diagnosis of suppurative arthritis depends on the joint or joints involved and the age of the patient. For the hip, toxic synovitis, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, psoas abscess, and proximal femoral, pelvic, or vertebral osteomyelitis and diskitis should be considered. For the knee, distal femoral or proximal tibial osteomyelitis, pauciarticular rheumatoid arthritis, and referred pain from the hip should be considered. Other conditions such as trauma, cellulitis, pyomyositis, sickle cell disease, hemophilia, and Henoch-Schönlein purpura can mimic purulent arthritis. When several joints are involved, serum sickness, collagen vascular disease, rheumatic fever, and Henoch-Schönlein purpura should be considered. Reactive arthritis following a variety of bacterial and parasitic infections, streptococcal pharyngitis, or viral hepatitis can resemble acute suppurative arthritis (see Chapter 147).

Treatment.

Optimal treatment of skeletal infections requires collaborative efforts of pediatricians, orthopedic surgeons, radiologists, and physiatrists.

ANTIBIOTIC THERAPY.

The initial empirical antibiotic therapy is based on knowledge of likely bacterial pathogens at various ages, the results of the Gram stain of aspirated material, and additional considerations. In neonates, an antistaphylococcal penicillin, such as nafcillin or oxacillin (150–200?mg/kg/24?hr divided q6h IV), and a broad-spectrum cephalosporin, such as cefotaxime (150–200?mg/kg/24?hr divided q8h IV), provide coverage for the *S. aureus,* group B *Streptococcus,* and gram-negative bacilli. An aminoglycoside may be used in place of the

---

cephalosporin, but aminoglycoside antibiotics have reduced antibacterial activity in sites with decreased oxygen tension and low pH, conditions that are present in tissue infections. If the neonate is a small premature infant or has a central vascular catheter, the possibility of nosocomial bacteria *(Pseudomonas aeruginosa* or coagulase-negative staphylococci) or fungi *(Candida)* should be considered.

In infants and children younger than 5 yr of age, the principal pathogens are *S. aureus*, streptococcus, and *H. influenzae* type b in children who have been vaccinated. Cefuroxime (200–300?mg/kg/24?hr divided q8h IV) provides coverage against these causes. After 5 yr of age and in the absence of special circumstances, virtually all cases of osteomyelitis are caused by gram-positive cocci; an antistaphylococcal antibiotic such as nafcillin (150–200?mg/kg/24?hr divided q6h) or cefazolin (100–150?mg/kg/24?hr divided q8h IV) can be used. In children older than 5 yr of age with suppurative arthritis, the bacterial causes are more varied and broader-spectrum drugs (a third-generation cephalosporin) are generally administered unless gram-positive cocci are seen in the Gram stain of synovial fluid.

Special situations dictate deviations from the usual empirical antibiotic selection. In patients with sickle cell disease with osteomyelitis, gram-negative enteric bacteria are common pathogens; a broad-spectrum cephalosporin such as cefotaxime or ceftriaxone is used in addition to an antistaphylococcal drug. Clindamycin (30–40?mg/kg/24?hr divided q6h IV) is a useful alternative drug for patients allergic to ß-lactam drugs. In addition to good antistaphylococcal activity, clindamycin has broad activity against anaerobes and is useful for the treatment of infections secondary to penetrating injuries or compound fractures. Clindamycin and vancomycin (40?mg/kg/24?hr divided q6h IV) are alternatives when treating methicillin-resistant *S. aureus* infections. For immunocompromised patients, combination therapy is usually initiated, such as with vancomycin and ceftazidime, or with piperacillin-clavulanate and an aminoglycoside.

When the pathogen is identified, appropriate adjustments in antibiotics are made, if necessary. If a pathogen is not identified and a patient's condition is improving, therapy is continued with the antibiotic selected initially. If a pathogen is not identified and a patient's condition is not improving, re-aspiration or biopsy and the possibility of a noninfectious condition should be considered.

Duration of antibiotic therapy is individualized depending on organism isolated and clinical course. For infections caused by *S. aureus* or gram-negative bacillary infections, the minimum duration of antibiotics is 21 days, provided that (1) the patient shows prompt resolution of signs and symptoms (within 5–7 days) and (2) the ESR has normalized; a total of 4–6 wk of therapy may be required. For group A streptococcus, *S. pneumoniae*, or *H. influenzae* type b, antibiotics are given for a minimum of 10–14 days, using the same criteria. A total of 7 postoperative days of treatment is adequate for *Pseudomonas* osteochondritis when thorough curettage of infected tissue has been performed. Immunocompromised patients generally require prolonged courses of therapy, as do patients with mycobacterial or fungal infection.

Changing antibiotics from the intravenous route to oral administration when a patient's condition has stabilized, generally after 1 wk of intravenous therapy, may be considered. For the oral antibiotic regimen with ß-lactam drugs for staphylococcal or streptococcal infection, a dosage two to three times that used for other infections is prescribed. The adequacy of the dose may be assessed by peak **serum bactericidal titers,** or **Schlichter titers,** 45–60?min after a dose of suspension or 60–90?min after a capsule or tablet. A serum bactericidal titer of 1:8 or more is considered desirable. The oral regimen decreases the risk of nosocomial infections related to prolonged intravenous therapy, is more comfortable for patients, and permits treatment outside the hospital if adherence to treatment can be assured. Alternatively, intravenous antibiotic therapy via a central venous catheter can be used for the completion of therapy at home.

SURGICAL THERAPY.

Surgical management of skeletal infections has not been subjected to randomized prospective study comparing surgical procedures. When frank pus is obtained from subperiosteal or metaphyseal aspiration, a surgical drainage procedure is usually indicated. Surgical intervention is also often indicated after a penetrating injury and when a retained foreign body is possible.

Infection of the hip is considered a surgical emergency because of the vulnerability of the blood supply to the head of the femur. For joints other than the hip, daily aspirations of synovial fluid may be required. Generally, one or two subsequent aspirations suffice. If fluid continues to accumulate after 4–5 days, arthrotomy is needed. At the time of surgery, the joint is flushed with sterile saline solution. Antibiotics are not instilled, because they are irritating to synovial tissue and adequate amounts of antibiotic are achieved in joint fluid with systemic administration.

Treatment of chronic osteomyelitis consists of surgical removal of sinus tracts and sequestrum, if present. Antibiotic therapy is continued for several months or longer until clinical and radiographic findings suggest that healing has occurred.

PHYSICAL THERAPY.

The major role of physical medicine is a preventive one. If a child is allowed to lie in bed with an extremity in flexion, limitation of extension may develop within a few days. The affected extremity should be kept in extension with sandbags, splints, or, if necessary, casts. Casts are also indicated when there is a potential for pathologic fracture. After 2–3 days, when pain is easing, passive range of motion exercises are started and continued until the child resumes normal activity. In neglected cases with flexion contractures, prolonged physical therapy is required.

Prognosis.

When pus is drained and appropriate antibiotic therapy is given, the improvement in signs and symptoms is rapid. Failure to improve or worsening by 72?hr requires review of the appropriateness of the antibiotic therapy, the need for surgical intervention, or the correctness of the diagnosis. Acute-phase reactants may be useful as monitors. The serum CRP typically normalizes within 7 days after start of treatment, whereas the ESR typically rises for 5–7 days, then falls slowly, dropping sharply after 10–14 days. Failure of either of these acute-phase reactants to follow the usual course should raise concerns about the adequacy of therapy. Recurrence of disease and development of chronic infection after treatment occur in less than 10% of patients.

Because children are in a dynamic state of growth, sequelae of skeletal infections may not become apparent for months or years; therefore, long-term follow-up is necessary with close attention to range of motion of joints and bone length. Although firm data about the impact of delayed treatment on outcome are not available, it appears that initiation of medical and surgical therapy within 1 wk of onset of symptoms provides a better prognosis than delayed treatment.

Chapter 675 - Epidemiology and Prevention of Injuries

Physical activity for youth is a national health priority. The Surgeon General's Healthy People 2010 Objectives emphasize moderate to vigorous physical activity on a regular basis for adolescents. Physical activity has favorable effects on hypertension, obesity, and serum lipid levels in youth. In adults, physical activity is associated with lower rates of cardiovascular disease, type 2 diabetes mellitus, osteoporosis, and colon and breast cancer.

Physicians should promote physical activity to their patients and make adjustments in the type of physical activity depending on their health status (Tables 675–1 (Table Not Available) through 675–3 (Table Not Available)). Extra effort is needed to try to make physical activity part of the lifestyle for those with lower rates of physical activity and sports participation, including children with special health care needs, females, and those from lower socioeconomic groups. Coincident with promoting sports participation and physical activity, physicians have the responsibility of providing medical clearance for participation in physical activity and sports and for diagnosis and rehabilitation of injuries.

Having fun during sports participation should be a priority. Athletic success and having fun can occur together yet are not synonymous. Those who have not had success or fun may conclude they are not an athlete and eliminate exercise from their lifestyle. Youth sports programs should teach skills for life. Sports participation and physical activity can be associated with improved self-esteem, improved fitness, and the satisfaction of improving skills related to the sport. These benefits are more likely to occur when the demands of the sport match the physical, cognitive, emotional, and attitudinal resources of the youth. When the demands exceed these resources, frustration and reduced self-esteem can occur. This frustration can progress to clinical problems, such as falling grades, anxiety, and/or depression. The manifestations of the anxiety and depression are myriad and include unexplained fatigue, poor athletic performance, and musculoskeletal pain with no organic etiology. The physician should (1) rule out an underlying organic etiology; (2) review the athlete's training schedule; (3) review the athlete's nutritional intake, assuring adequate calories; and (4) if the evaluation reveals no organic etiology and overtraining appears to be the problem, recommend a reduction in training. Complete rest is not recommended; for most conditions some ongoing exercise training is prescribed, as long as the symptoms improve. The reduction in training, with some guidelines for criteria

to gradually increase training if symptoms subside, gives the athlete a plan for returning to sports.

Some parents describe sports as a career pathway for their child. Playing on a Division I, select, or traveling team is in some parents' and coaches' minds a required step in the development of elite athletes who are “serious about their sport.” The notion that there is one pathway to elite athletic status and that path includes beginning at a young age with intense, year-round training is misleading. Parents and coaches may believe that a given child has talent and requires more training and commitment to

---

reach the elite status. Parents may experience achievement by proxy, with adult pride in the performance of their child. Positive, supportive behaviors include unconditional love and being an objective parent, manifest as enforcing medical recommendations, even against the will of the young athlete and the coach. Physicians' recommendations to reduce training are often challenged by young athletes, their parents, and coaches. An explanation of the diagnosis of a musculoskeletal injury, with anatomic models, to the youth and family, with the natural history of the injury if treated appropriately versus injury progression if the athlete continues with pain, is indicated. The physician can offer to talk to the coach on the athlete's behalf. The overriding principle that should guide return to play and rehabilitation recommendations is what is best for the short- and long-term health of the athlete. Behavior becomes pathologic when the parents' or coaches' goals take

priority over the health and well-being of the child. When the parents give decisions to train and participate to the coach, exploitation and abuse can occur in an attempt to further the coach's career. The suggestion that parents and coaches do not have the athlete's health and well-being as the top priority is often met with resistance.

Year-round training may increase the risk of repetitive, overuse injuries and the risk of psychological burnout. This risk exists for children with talent in other activities, such as dance, drama, or singing. The overly focused athlete may have talent in other areas but will not be given the opportunity to discover this.

Coaches often require young athletes at some large high schools and elite youth teams to declare their allegiance to one sport, to the exclusion of all others. This is counter to the need for athletes to have time away from a sport, both physically and psychologically. There should not be an age at which the young athlete must declare his or her commitment to one sport.

In 2001, 65% of high school students participated in vigorous physical activity for 20?min or more on at least 3 of the previous 7 days. Fifty-five per cent of high school students played on school sports team in 2001, with 38% playing on teams outside of school. Approximately 30 million children and adolescents participate in organized sports in the United States. Approximately 3 million injuries occur annually if injury is defined as time lost from the sport. Deaths in sports are rare, with the majority of nontraumatic deaths caused by cardiac diseases (see Chapter 428.6). There are three times more nontraumatic than traumatic deaths. The majority of traumatic deaths are caused by head and neck injuries. Within the same sport, injury rates for males and females are similar, with the exception of anterior cruciate ligament injuries, which are higher in females. The majority of sports injuries are sprains, strains, overuse injuries, contusions and, least of all, fractures. The potential for growth plate injury is a complication of appendicular trauma that distinguishes young athletes from adult athletes. An injury that might cause a ligament sprain in adults could cause a growth plate injury in a young athlete, because the growth plate is weaker than the ligament. A fracture of the growth plate (i.e., Salter-Harris type I injury) should be considered when there is point tenderness at the growth plate and the initial radiographic findings are normal (see Chapter 673). In addition, fracture rates in adolescence peak approximately 6 mo before peak height velocity in males and females. Peak accretion of bone mineral occurs approximately 6 mo after peak height velocity, suggesting that the increased fracture rate during early and mid adolescence may be related to a relative porosity of bone because bone mineralization, and presumably bone strength, may lag behind long bone growth, making long bones more susceptible to fracture. Overall, injury rates and injury severity in sports increase with age and pubertal development, related to the greater speed, strength, and intensity of competition.

Recognizing mechanisms of injury and enforcing rules that reduced the likelihood of that mechanism of injury, including penalizing dangerous play, have reduced catastrophic injury rates. Injury rates have also been reduced by removing environmental hazards, such as trampolines in gymnastics and stationary (vs breakaway) bases in softball, and by modifying heat injury rates in soccer tournaments by adding water breaks and reducing the playing time. Wearing equipment such as mouthguards can reduce dental injuries, yet they are not worn

routinely by athletes in any sport except football. A common reason for re-injury is lack of rehabilitation of old injuries; appropriate rehabilitation reduces injury rates. Preseason training for high school athletes, with an emphasis on speed, agility, jump training, and flexibility is associated with lower injury rates in soccer and serious knee injuries in female athletes. Limited data and experience in implementing preseason programs exist to recommend broad implementation to prevent injuries. Pre-exercise stretching, alone, in otherwise healthy individuals, does not prevent injuries. One setting for implementing some of these prevention strategies and for detecting unrehabilitated injuries and medical problems that could impact participation in sports is the preparticipation sports examination (PSE).

Preparticipation Sports Examination.

The PSE is performed with a directed history and a directed physical examination, including a screening musculoskeletal examination. It identifies possible problems in 1–8% of athletes and excludes less than 1% from participation. The PSE is not a substitute for the recommended comprehensive annual evaluation, which looks at behaviors that are potentially harmful to teens, such as sexual activity, drug use, suicide, and violence. The purposes of the PSE include detecting medical conditions that delay or disqualify athletic participation owing to a risk of injury or death; detecting previously undiagnosed medical conditions; detecting medical conditions that need further evaluation or rehabilitation before participation; providing guidance for sports participation for patients with health conditions; and meeting legal and insurance obligations. If possible, the PSE should be combined with the comprehensive annual health visit with emphasis on preventive health care (see Chapters 14 and 100). Another option is to perform the PSE and have the athlete complete a comprehensive screening questionnaire, such as the Guidelines for Adolescent Preventive Care (GAPS) form published by the American Medical Association (AMA). If problems are detected on the screening questionnaire, then a follow-up visit can be scheduled. This is less optimal because it relies on the sensitivity of a questionnaire, without an interview to detect health risk behaviors.

TABLE 675-3 -- **Classification of Sports by Strenuousness**
(Not Available)
From the American Academy of Pediatrics, Committee on Sports Medicine and Fitness: Medical conditions affecting sports participation. Pediatrics 2001;107:1208.

State requirements for how often a youth needs a PSE differ, ranging from annually to entry to a new school level (junior high, senior high, college). At a minimum, a focused, annual interim evaluation should be done on an otherwise healthy young athlete. The PSE is optimally performed 3–6 wk before the start of practice so that rehabilitation of old injuries and evaluation of potential health problems can be

completed to minimize absence from practices or games.

HISTORY AND PHYSICAL EXAMINATION.

The essential components of the PSE are the history and focused medical and musculoskeletal screening examinations. Identified problems require more investigation (Table 675–4). In the absence of symptoms, no screening laboratory tests are required.

Seventy-five per cent of significant findings are identified by the history; a standardized questionnaire given to the parent and athlete is important because the young athlete may not know or may forget important aspects of their history. The questionnaire should include questions about previous medical, surgical, cardiac, pulmonary, neurologic, dermatologic, visual, psychologic, musculoskeletal, and menstrual problems, as well as about heat illness, medications, allergies, immunizations, and diet. The most common identified problems are unrehabilitated injuries. An investigation of previous injuries including diagnostic tests, treatment, and present functional status is indicated. The most common musculoskeletal injuries identified are of the knee and ankle.

Sudden death during sports may result from undetected cardiac disease such as hypertrophic or other cardiomyopathies, anomalous coronary vessels, or a ruptured aorta in Marfan syndrome (see Chapter 690). In many cases the underlying heart disease is not suspected, and death is the first sign of heart disease (see Chapter 428.6). Chest radiographs, electrocardiograms (ECGs), and echocardiograms (ECHOs) are not recommended as screening tests. If there is a suspicion of heart disease, such as a history of syncope, presyncope, palpitations, excessive dyspnea with exercise, or a family history of a condition such as hypertrophic cardiomyopathy or prolonged QT or Marfan syndromes, then the evaluation should be complete and include a 12-lead ECG, an ECHO, a Holter or event capture monitor, and a stress test with ECG monitoring. Recommendations for participation with identified cardiac disease should be done in consultation with a cardiologist.

Disqualification and limitations for sports participation among various medical conditions are noted in Table 675–2 (Table Not Available) . Classification of sports activities by type of demand is delineated in Table 675–3 (Table Not Available) . Athletes may seek to participate in sports against medical advice and have done so successfully for professional sports. Section 504(a) of the Rehabilitation Act of 1973 prohibits discrimination against disabled athletes if they have capabilities/skills required to play a competitive sport. This was reinforced through the Americans with Disabilities Act of 1990. An amateur athlete has no absolute right to decide whether to participate in competitive

TABLE 675-4 -- **Preparticipation Sports Examination**

Component of the Physical Examination	**Condition to be Detected**
Vital signs	Hypertension, cardiac disease, brady/tachycardia
Height and weight	Obesity, eating disorders
Vision and pupil size	Legal blindness, absent eye, anisocoria
Lymph node	Infectious diseases, malignancy
Cardiac (performed standing and supine)	Heart murmur, prior surgery, rhythm
Pulmonary	Recurrent and exercise-induced bronchospasm, chronic lung disease
Abdominal	Organomegaly, abdominal mass
Skin	Contagious diseases (impetigo, herpes, staphylococcal, streptococcal)
Genitourinary	Varicocele, undescended testes, tumor
Musculoskeletal	Acute and chronic injuries, physical anomalies (scoliosis)

sports. Participation in competitive sports is considered a privilege, not a right. *Knapp v. Northwestern University* established that “difficult medical decisions involving complex medical problems can be made by responsible physicians exercising prudent judgment (which will be necessarily conservative when definitive scientific evidence is lacking or conflicting) and relying on the recommendations of specialist consultants or guidelines established by a panel of experts.”

Chapter 676 - Management of Musculoskeletal Injury

MECHANISM OF INJURY

Acute Injuries.

The majority of musculoskeletal injuries are sprains, strains, and contusions. Often, the history of the injury is unclear and it is harder to evaluate the injury. More severe injuries, indicative of structural derangement, may have acute signs and symptoms such as immediate swelling, deformity, numbness or weakness, inability to continue playing, inability to walk without a limp, a loud painful pop, mechanical locking of the joint, or the sensation of instability when the athlete describes that at the time of the injury it felt like the bones moved in the wrong direction.

Overuse Injuries.

Overuse injuries are caused by repetitive microtrauma that exceeds the body's rate of repair. This occurs in muscles, tendons, bone, bursas, cartilage, and nerves. Overuse injuries occur in all sports but more frequently in sports emphasizing repetitive motion (e.g., swimming, running, tennis, gymnastics). Parents' and coaches' excessively high expectations may add to the risk of an overuse injury in a young, eager-to-please athlete. Possible risks for or indicators of overuse or burnout include early specialization in a single sport, playing on a “select traveling team,” practicing most days of the week without sufficient recovery period, loss of enjoyment, decreased performance, vague muscle soreness/stiffness, fatigue, dysphoria, and sleep disturbances. Factors can be categorized into extrinsic (training errors, poor equipment or workout surface) and intrinsic. Training error is the most frequently identified factor. At the beginning of the workout program, athletes may violate the “10% rule”: Do not increase the duration or intensity of workouts more than 10% per week. Intrinsic factors include abnormal biomechanics (e.g., leg-length discrepancy, pes planus, pes cavus, tarsal coalition, valgus heel, external tibial torsion, femoral anteversion), muscle imbalance, inflexibility, and medical conditions (deconditioning, nutritional deficits, amenorrhea, obesity). The athlete should be asked about the specifics of his or her training. For example, runners should be asked about their shoes, orthotics or braces, running surface, pace, weekly mileage or time spent running per week, speed or hill workouts, duration of the current regimen, and previous injuries and rehabilitation. When causative factors are identified, they can be eliminated or modified so that after rehabilitation the athlete does not return to the same regimen and suffer re-injury.

For athletes engaged in excessive training that causes an overuse injury, curtailing all sports is not always feasible. A rehabilitation program designed to return athletes

to their sport as soon as possible while minimizing exposure to re-injury is indicated. Early identification of an overuse injury requires less alteration of the workout regimen.

The *inflammatory response after injury* is manifested as pain, spasm, edema, and, if unabated, scarring. Pain and spasm cause decreased use of the affected area. Although reduced use may protect the area, continued nonuse causes atrophy and decreased flexibility, strength, endurance, and proprioception. Stiff, weak structures with poor proprioception do not function normally and are vulnerable to re-injury. The goals of treatment are to control pain and spasm to rehabilitate flexibility, strength, endurance, and proprioceptive deficits (Table 676–1).

INITIAL EVALUATION OF THE INJURED EXTREMITY

Initially, the examiner should determine the quality of the peripheral pulses and capillary refill rate as well as the gross motor and sensory function to assess for neurovascular injury. The first priorities are to maintain vascular and skeletal stability.

Criteria for immediate attention and rapid orthopedic consultation include vascular compromise (blood flow may be obstructed by a dislocated structure, so a skilled physician should reduce any obstructing dislocated joint); nerve compromise (peripheral nerve damage can be repaired after vascular and skeletal stability have been achieved); and open fracture (an open fracture should not be reduced immediately because of the risk of further contamination). The exposed wound should be covered with sterile saline-soaked gauze, and the injured limb should be padded and splinted. Pressure should be applied to any site of bleeding. Additional criteria include deep laceration over a joint, unreducible dislocation, grade III (complete) tear of a muscle-tendon unit, and displaced, significantly angulated fractures (depends on the bone involved, the degree of displacement and angulation, and neurovascular status of the extremity). After the neurovascular assessment, the management of acute musculoskeletal trauma should follow the RICE (rest, ice, compression, elevation) guidelines.

THE TRANSITION FROM IMMEDIATE MANAGEMENT TO RETURN TO PLAY

Rehabilitation of a musculoskeletal injury should begin on the day of the injury.

Phase 1: Limit further injury, control swelling and pain, and minimize strength and flexibility losses. This requires the use of an

TABLE 676-1 -- **Staging of Overuse Injuries**

Grade	Grading Symptoms	Treatment
I	Pain only after activity Does not interfere with performance or intensity Generalized tenderness Disappears before next session	Modification of activity, consider cross-training, home rehabilitation program
II	Minimal pain with activity Does not interfere with performance More localized tenderness	Modification of activity, cross-training, consider NSAIDs, home rehabilitation program
III	Pain interferes with activity and performance Definite area of tenderness Usually disappears between sessions	Significant modification of activity, strongly encourage cross-training, NSAIDs, home rehabilitation program, and outpatient physical therapy
IV	Pain with activities of daily living Pain does not disappear between sessions Marked interference with performance and training intensity	Discontinue activity temporarily, cross-training only, NSAIDs, home rehabilitation program and intensive outpatient physical therapy
V	Pain interferes with activities of daily living Signs of tissue injury (e.g., edema) Chronic or recurrent symptoms	Prolonged discontinuation of activity, cross-training only, NSAIDs, home rehabilitation program, and intensive outpatient physical therapy

fNSAIDs = nonsteroidal anti-inflammatory drugs.

appropriate device such as crutches or a sling, ice, compression, elevation, and analgesia. Crutches, air stirrups for ankle sprains, slings for arm injuries, and elastic wraps (4 to 8?in) for compression are a reasonable inventory of office supplies. Ice in a plastic bag is placed directly on the skin for 20?min continuously, three to four times per day until the swelling resolves. Compression limits further bleeding and swelling but should not be so tight that it limits perfusion. Elevation of the extremity promotes venous return and limits swelling. Nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen is indicated for analgesia.

Pain-free isometric strengthening and range of motion should be initiated as soon as possible. Pain inhibits full muscle contraction; deconditioning results if the pain and resultant nonuse persist for days to weeks, thus delaying recovery. Education about the nature of the injury and the specifics of rehabilitation exercises including handouts with written instructions and drawings demonstrating the exercises are helpful.

Phase 2: Improve strength and range of motion (i.e., flexibility) while allowing the injured structures to heal. Protective devices are removed when the patient's strength and flexibility improve and activities of daily living are pain free. Flexibility can then be improved by a program of specific stretches, held for 15–20?sec for 3 to

5 repetitions, once or twice daily. A physical therapist or athletic trainer is invaluable in this treatment. Protective devices may need to be used for months during sports participation. Swimming, water jogging, and stationary cycling are good aerobic exercises that can allow the injured extremity to be rested or used pain free while maintaining cardiovascular fitness.

Phase 3: Achieve near normal strength and flexibility of the injured structures and further improve or maintain cardiovascular fitness. Strength and endurance are improved under controlled conditions using elastic bands and eventually free weights or exercise equipment. Proprioceptive training allows the athlete to redevelop a kinesthetic sense, which is critical to joint function and stability.

Phase 4: Return to exercise or competition without restriction. When the athlete has reached nearly normal flexibility, strength, proprioception, and endurance, he or she can start sports-specific exercises. The athlete will make the transition from the rehabilitation program to functional rehabilitation appropriate for the sport. Substituting sports participation for rehabilitation is inappropriate; rather, there should be progressive stepwise functional return to a full activity/play program. For instance, a basketball player recovering from an ankle injury might begin a walk-run-sprint-cut program before returning to competition. At any point in this progression if pain is experienced, the athlete needs to stop, apply ice, avoid running for 1–2 days, continue to do ankle exercises, and then resume running at a lower intensity and progress accordingly.

Relative Rest and Return-to-Play Guidelines.

Relative rest means that the athlete can do whatever he or she wants as long as the injured structures do not hurt during or within 24?hr of the activity. Going beyond relative rest delays recovery.

DIFFERENTIAL DIAGNOSES OF MUSCULOSKELETAL PAIN

The presenting complaint of musculoskeletal pain can be caused by traumatic, rheumatologic, infectious, hematologic, psychologic, and oncologic processes. Symptoms such as fatigue, weight loss, rash, multiple joint complaints, fever, chronic or recent illness, and persistence of pain suggest diagnoses other than sports-related trauma. Incongruity between the patient's history and physical examination findings should lead to further evaluation. A normal review of systems with an injury history consistent with the physical findings suggests a sports-related etiology. Nonorganic causes are to be considered when the evaluation indicates the absence of identifiable organic disease yet the symptoms persist.

676.1 Growth Plate Injuries

Twenty per cent of pediatric sports injuries seen in the emergency department are fractures. Twenty-five per cent of those fractures involve an epiphysis (see Chapter 673). Growth in long bones occurs in three areas: the epiphyseal, or growth, plate, the articular surface (the cartilaginous covering of the bones), and the apophysis (the growth cartilage where major tendons attach to the bone). The growth plate can be acutely injured at the epiphysis (Salter-Harris fractures), the articular surface (osteochondritis dissecans), or the apophysis (avulsion fractures). Boys suffer about twice as many epiphyseal fractures as girls; the peak incidence of fracture is during peak height velocity (girls, 12 ± 2.5 yr; boys, 14 ± 2 yr).

The most common *epiphyseal injuries* are to the distal radius, followed by phalangeal and distal tibial fractures. Physeal injuries at the knee (distal femur and proximal tibia) are rare. Growth disturbance following a growth plate injury is a function of location, the part of the epiphysis fractured, and the vascular communication between the epiphysis and metaphysis. These factors influence the probability of physeal bar formation resulting in growth arrest at that growth plate. The areas making the largest contribution to longitudinal growth in the upper extremities are the proximal humerus and distal radius/ulna; in the lower extremities, they are the distal femur and the proximal tibia/fibula. Injuries to these areas are more likely to cause growth disturbance compared with epiphyseal injuries at the other end of these long bones. The part of the epiphysis fractured is described by the Salter-Harris classification system (see Fig. 673–2 (Figure Not Available)).

Osteochondritis dissecans (OCD) is avascular necrosis of the bone underlying the articular cartilage. The articular cartilage may flatten, soften, or break off. Some OCD lesions are asymptomatic (diagnosed on “routine” radiographs), whereas others are manifested as edema, pain, decreased range of motion, and mechanical symptoms (locking, popping, crepitus). Seventy-five per cent of OCD lesions are located on the medial side of the femoral notch on a non–weight-bearing surface and therefore may have minimal symptoms. Other joints where OCD lesions are identified are the ankle (talus) and elbow, usually involving the medial humeral epiphysis, capitellum, or radial head. OCD classically affects athletes in their second decade. The severity of the lesion is graded as follows: I—compression of the bone, cartilage intact; II—partial separation; III—loose fragment but still in place; and IV—loose fragment detached. Most grade I and II lesions heal spontaneously with protection of the injured joint from loading and torquing actions. If the lesion loosens, internal fixation or debridement may be required. The key to preventing complications is early diagnosis and treatment including no weight bearing or no traumatic activity until healing has occurred. Patients with OCD should be referred to an orthopedic surgeon.

Avulsion fractures occur when a forceful muscle contraction dislodges the apophysis from the bone. They occur most frequently around the hip, elbow, and ankle. Chronically increased traction at the muscle-apophysis attachment can lead to repetitive microtrauma, inflammation, and pain at the apophysis. The most common areas affected are the knee (*Osgood-Schlatter* and *Sindig-Larsen-Johannson disease*), the ankle **(Sever disease),** and the medial epicondyle **(Little League elbow).** Traction apophysitis of the knee and ankle can be potentially treated in a primary care setting, following the principles discussed under rehabilitation. The main goal of treatment is to minimize the intensity and frequency of pain and disability. Exercises that increase the strength, flexibility, and endurance of the muscles attached at the apophysis, using the relative rest principle, are appropriate. Symptoms can last for 12–24 mo if untreated. As growth slows, symptoms abate. Traction apophysitis of the elbow should be referred to a pediatric orthopedic surgeon.

676.2 Shoulder Injuries

An acute shoulder injury characterized by radiating symptoms down the arm should suggest the possibility that a coexisting neck injury has occurred. Neck pain and tenderness or limitation of cervical range of motion requires that the cervical spine be immobilized and that the athlete be transferred for further evaluation. If there is no neck pain or tenderness or limitation of motion of the cervical spine, then the shoulder is the site of the primary injury.

Acromioclavicular (AC) Separation.

This injury most commonly occurs when an athlete falls or collides with another player or object and the point of contact is the distal clavicle. Patients have discrete tenderness at the AC joint and may have an apparent step-off between the distal clavicle and the acromion. If a humeral fracture is present, point tenderness is noted over the fracture. If a patient has crepitance, the arm should be immobilized in a sling and the patient transferred to the emergency department. AC separations in skeletally immature patients should be immobilized in a sling, and patients should be sent for radiographs because a Salter fracture of the distal clavicle may have occurred rather than an AC separation. Older (skeletally mature) athletes may not require radiography to evaluate a mild separation if the tenderness is discrete and over the AC joint. Salter fractures require consultation with an orthopedic surgeon. Assuming the radiographic results are negative, icing and pain-free range of motion exercises should be started. As the pain-free range improves, strengthening of the rotator cuff, deltoid, and trapezius muscles can start. When the AC joint is nontender and patients have sufficient strength to be functionally protected from a collision or fall and perform the maneuvers required for the sport, they can return to their sport. Surgery is not indicated for the majority of AC separations. Approximately 5% of AC separations are complicated by distal clavicular osteolysis, manifested as persistent pain for months and evidence of osteolysis radiographically. Distal claviculectomy is associated with alleviation of this persistent pain and full functional recovery.

Anterior Dislocation.

The common mechanisms of injury are falling onto an outstretched hand with a straight arm or making contact with another player with the shoulder abducted to 90 degrees and forcefully rotated externally. An example of the latter is football players' tackling another player only with their arm. Patients complain of severe pain and that their shoulder “popped out of place” or “shifted.” Patients with an unreduced anterior dislocation have a hollow region inferior to the acromion and a bulge in the anterior portion of the shoulder caused by anterior displacement of the humeral head. This differentiates it from a brachial plexus injury, but anterior dislocation can be complicated by injury to the brachial plexus manifest as a “stinger or burner” (see Head and Neck Injuries, later). Abnormal sensation of the lateral deltoid region (axillary nerve) and the extensor surface of the proximal forearm (musculocutaneous nerve) and the ability to contract the middle deltoid (resisted abduction) and biceps isometrically should be noted. An attempt to reduce the anterior dislocation is indicated, assuming no crepitance is present. Once the dislocation is reduced and radiographs (anteroposterior and West Point views) show a normal position, rehabilitation begins with isometric internal rotator strengthening. This can progress to elastic band exercises. The rotator cuff muscles are dynamic stabilizers of the shoulder anteriorly, and prevention of future anterior dislocations requires that their strength be restored. For 3 wk, no abduction beyond 10 degrees or external rotation beyond 90 degrees is allowed to permit anterior capsule healing. After 3 wk, as the internal rotator muscles strengthen, progressive strengthening of the rotator cuff muscles begins at greater degrees of abduction and external rotation. Patients can return to play when their strength, flexibility, and proprioception are equal to that of the uninvolved side so that they can protect the shoulder and perform the sports-specific activities pain free. Surgery is not recommended unless the shoulder has been dislocated at least three times and the patient has normal elasticity.

Patients with chronic shoulder pain may have symptoms due to repetitive stress, with some degree of *glenohumeral instability* causing inflammation in rotator cuff muscles and surrounding structures. Patients may have limitation of pain-free range of motion, a positive impingement sign, and reproduction of pain with resisted rotator cuff muscle testing. Rehabilitation consists of relative rest (including no throwing or whatever the causative activity is), icing, pain-free range of motion exercises, strengthening the rotator cuff muscles, and use of NSAIDs. Strengthening the rotator cuff muscles is critical because they are the dynamic stabilizers of the glenohumeral joint as the shoulder goes through a wide range of motion. As patients become pain free and range of motion and strength approach that of the uninvolved shoulder, they can begin functional rehabilitation, such as gently throwing a ball or swinging a racquet. If a patient continues to have pain despite these measures, another diagnosis should be considered, including a stress fracture of the proximal humerus (see later). More often, however, the athlete is not compliant with the treatment program and is exceeding the relative rest guideline. Weeks to months may often be required for an athlete to become pain free, with the length of recovery related to the duration of symptoms before starting on an appropriate rehabilitation program.

Proximal humeral stress fracture (epiphysiolysis) is a rare cause of proximal shoulder pain and is suspected when shoulder pain does not respond to routine measures. Gradual onset of deep shoulder pain occurs in a young (open epiphyseal plates) athlete involved in repetitive overhead motion, such as in baseball, tennis, or swimming, but with no history of trauma. Tenderness is noted over the proximal humerus; the diagnosis is confirmed by detecting a widened epiphyseal plate on plain radiographs or increased uptake on nuclear scan.

676.3 Elbow Injuries

Acute Injuries.

The most common elbow dislocation is a posterior dislocation. The mechanism of injury is falling backward onto the outstretched arm with the elbow extended. Dislocation potentially compromises the brachial artery; rich collateral circulation makes distal arterial insufficiency unlikely. Intact radial and ulnar pulses are the best indicators of vascular integrity of the distal upper extremity. An obvious deformity is noted, with the olecranon process displaced prominently behind the distal humerus. Reduction is performed by gently applying longitudinal traction to the forearm with gentle upward pressure on the distal humerus. If reduction is not possible, the arm should be padded and placed in a sling and the patient transferred to the emergency

department. Elbow injuries can compromise the radial, median, and ulnar nerves.

Supracondylar humeral fractures can result from the same mechanism of injury as elbow dislocations and can be complicated by coexisting injury to the brachial artery and, to a lesser extent, the median, radial, and ulnar nerves. A compartment syndrome may develop.

Chronic Injuries.

Overuse injuries occur primarily in throwing sports and sports that require repetitive wrist flexion or extension or demand weight bearing on hands (gymnastics). "Little League elbow" is a broad term for several different elbow problems.

Overuse, poor technique, unrehabilitated injuries, and poor overall conditioning can lead to injury at the elbow and shoulder. In throwing overhand, medial stretching and lateral compressive

---

forces are placed on the elbow. Repetitive stress is also placed on the flexor and extensor muscle groups' insertions located on the medial and lateral epicondyles, respectively.

Medial elbow pain is a common complaint of young throwers. The stage of bone maturation assists in formulation of the diagnosis. In preadolescents, who still have maturing secondary ossification centers, *traction apophysitis of the medial epicondyle* is likely. Patients have tenderness along the medial epicondyle; this is exacerbated by valgus stress or resisted wrist flexion. Treatment includes no throwing for 4–6 wk, pain-free strengthening, and stretching of the flexor/pronator group, followed by 1–2 wk of a progressive functional throwing program with accelerated rehabilitation. In adolescents, who have secondary ossification centers and whose epiphyseal plates have not fused, *avulsion fracture of the medial epicondyle* must be considered. In young adults, with fused epiphyses, the vulnerable structure is the *ulnar collateral ligament* (UCL). UCL tears are managed conservatively but may require surgery if the joint is unstable. Finally, *medial epicondylitis* is caused by overuse of the flexor-pronator muscle groups at their origin, the medial epicondyle, and occurs in sports requiring repetitive wrist flexion. Tenderness is felt over the medial epicondyle exacerbated by passive wrist extension or resisted wrist flexion. Treatment includes relative rest, analgesics, warm and cold modalities, stretching and strengthening wrist flexors, and counterforce bracing.

Lateral elbow compression during the throwing motion can cause problems at the radiocapitellar joint. *Panner disease* is osteochondrosis of the capitellum that presents between age 7–12 yr. *OCD* of the capitellum presents at age 13–16 yr. Although patients with both conditions present with insidious onset of lateral elbow pain exacerbated by throwing, patients with OCD have mechanical symptoms (popping and locking) and, more frequently, decreased range of motion. Patients with Panner disease have no mechanical symptoms and often have normal range of motion. The prognosis of Panner disease is excellent, and treatment consists of relative rest (no throwing), brief immobilization, and repeat radiographs in 6–12 wk to assess bone remodeling.

Lateral epicondylitis, or "tennis elbow," is caused by repetitive contraction of the extensor muscles at their origin on the lateral epicondyle. Tenderness is elicited over the lateral epicondyle, and pain is felt with passive wrist flexion and resisted wrist extension. Treatment includes relative rest. This injury may require a wrist splint worn during daily activity and at night. Treatment also includes analgesic medication, warm and cold modalities, stretching and strengthening wrist extensors, and counterforce bracing. Steroid injections help acutely, but, in the long-term, physiotherapy has the best results for healing. Functional rehabilitation, such as returning to playing tennis, should be gradual and progressive.

Other less common problems that cause elbow pain are ulnar neuropathy, triceps tendinitis and olecranon apophysitis, and loose bodies.

676.4 Back Injuries

Spondylolysis, a common cause of pain in athletes, is a stress fracture of the pars interarticularis (see Chapter 669.6). It can occur at any vertebral level but is most likely in the lower lumbar area. Besides direct trauma that causes an acute fracture, the mechanism of injury is either a congenital defect, which is exacerbated by lumbar extension loading, or a stress fracture due to repetitive extension loading. Ballet, weightlifting, gymnastics, and football are examples of sports in which repetitive extension loading of the lumbar spine occurs; however, it occurs in any activity where there is repetitive extension loading, including swimming. Patients often present with pain without a single precipitating event. However, there may be a precipitating injury. The diagnosis is often delayed. The pain is reproduced with lumbar extension while standing. The diagnosis is confirmed by finding a pars defect on an oblique lumbar spine radiograph. The defect is not easily seen on anteroposterior and lateral views. The diagnosis is established by single-photon emission CT or a traditional two-dimensional nuclear scan, the former being more sensitive. A plain CT scan can help in the identification of degree of bony involvement. *Spondylolisthesis* results from anterior displacement of the vertebral body. This is a known complication of untreated spondylolysis and is diagnosed by a lateral lumbar radiograph.

Facet syndrome has a similar history and physical examination findings as spondylolysis. It is caused by instability in the facet joint, posterior to the pars interarticularis and at the interface of the inferior and superior articulating processes. Facet syndrome can be established by identifying facet abnormalities on CT or by exclusion, requiring a nondiagnostic radiograph and nuclear scan to rule out spondylolysis.

Spondylolysis, spondylolisthesis, and facet syndrome are injuries posterior to vertebral bodies. Treatment of posterior element injuries is conservative, directed at reducing the extension loading activity, often for 6–12 mo. Extension loading activities include jogging, overhead weightlifting, landing from the vault in gymnastics, and ballet. Walking and cycling are appropriate exercises during rehabilitation. Bracing to reduce lordosis is advocated by some. Surgery is rarely required for spondylolisthesis. Increased emphasis is being placed on core strengthening exercises, first, then moving to exercises that attempt to increase the

strength of the abdominal musculature and the flexibility of the lumbar extensor, hamstring, and quadriceps muscles.

Sciatica may be due to lumbar disk herniation or piriformis syndrome. It is unusual in early and middle pubertal athletes, yet not in older adolescent athletes. **Lumbar disk herniation** presents as back pain radiating to the buttocks or down the leg (often below the knee) (see Chapter 669.8). Physical examination findings include positive results of a straight-leg raising test, sciatica that worsens when the patient bends forward (i.e., lumbar flexion), and possibly reduced strength, sensation, or deep tendon reflexes in the leg. MRI has a 30% false-positive rate in diagnosing disk protrusion in adults; MRI confirms the clinical diagnosis. Assuming the herniation is not large, the pain is not intractable, and the neurologic deficit improves with therapy, the treatment of choice is analgesia, anti-inflammatory medication, and physical therapy. Bed rest or surgery is rarely necessary. Acute lumbar strain or contusion presents after a precipitating event, and the pain ranges from mild to disabling. Treatment includes analgesia, ultrasound with massage, and physical therapy, as tolerated. The natural history of acute back strain in adults is that 50% are better in 1 wk, 80% in 1 mo, and 90% in 2 mo, regardless of therapy. Treatment is as for disk herniation.

The **piriformis syndrome** is manifested as sciatica because the sciatic nerve passes through the piriformis muscle in 25% of individuals, and in the remainder it courses along the piriformis muscle. If the piriformis muscle is injured, the sciatic nerve can be secondarily involved and sciatica ensues. Patients may have some reproduction of sciatica with the straight-leg raising maneuver, but the pain is provoked with maneuvers that stretch or resist the piriformis muscle. The piriformis muscle is an external rotator of the hip. The “figure-of-four” test is done by externally rotating the ipsilateral hip by placing the foot on the contralateral quadriceps with the patient supine and then by bending the contralateral knee, causing stretch of the piriformis muscle. Pain would support the diagnosis of piriformis strain.

Sacroiliitis presents as lumbar pain that is usually chronic and without a history of trauma. Patients have a positive result of a **Patrick test,** which includes external rotation of the ipsilateral hip by placing the foot on the contralateral quadriceps with the

patient in the supine position, placing one hand on the contralateral anterior-superior iliac spine, and then passively flexing the ipsilateral hip. A radiograph of the sacroiliac joints is indicated, and if results are positive, exploration for a rheumatologic disease (ankylosing spondylitis, juvenile rheumatoid arthritis, ulcerative colitis) is warranted. Treatment is with relative rest, nonsteroidal anti-inflammatory drugs, and physical therapy. Ankylosing spondylitis is more likely if the onset of lower back pain is before age 40 years, if there is morning stiffness that is associated with improvement with activity, and if the pain has a gradual onset and has lasted more than 3 months. Chronic back pain associated with stress can manifest as marked and widespread tenderness with superficial palpation, provoked by maneuvers such as pressure on the top of the head or allowing rotation of the spine and pelvis together; inconsistent performance on various tests; and loss of strength and sensation that do not fit a dermatomal pattern.

Less likely causes of sciatica are polyneuropathies and mass lesions that impinge on the sciatic nerve. Nerve conduction studies should be considered in these cases to establish the site of the nerve impingement and the site for further radiologic testing and other diagnostic tests. Other causes of lower back pain include infection (osteomyelitis, diskitis) and neoplasia (see Chapter 669). These should be considered in patients with fever, other constitutional signs, or lack of response to initial therapy. Osteomyelitis of the lower back is often, but not always, associated with fever. Suppurative organisms, for instance, are more likely to cause fever. Infection with *Mycobacterium tuberculosis* may present as lower back pain without fever. An epidural abscess is most likely to be associated with fever.

676.5 Hip and Pelvis Injuries

Hip and pelvis injuries represent a small percentage of sports injuries, but they are potentially severe and require prompt diagnosis. Hip pathology can present as knee pain and normal findings on knee examination.

Slipped capital femoral epiphysis (SCFE) usually presents in the 11–15 yr age range during the time of rapid linear bone growth (see Chapter 668.4). There is a higher incidence in males (4:1), in African-Americans, and obesity. Twenty-five per cent are bilateral but may not present synchronously. Pain and limitation of range of motion (especially internal hip rotation) are hallmarks. Radiographic examination shows the epiphysis displaced off the femur, which is described radiographically as “ice cream falling off the cone.” If the condition is detected early, the epiphysis may show only slight widening. A bone scan or MRI may be required to diagnose an early or “preslip” SCFE. Non-weight bearing and urgent orthopedic referral are necessary.

Avulsion fractures occur in adolescents playing sports requiring sudden, explosive bursts of speed. Large muscles contract and create force greater than the strength of the attachment of the muscle to the apophysis. The most common sites of avulsion fractures (and the muscles that attach there) are the iliac crest (abdominal muscles), anterior superior iliac spine (sartorius), anterior inferior iliac spine (rectus femoris), lesser femoral trochanter (iliopsoas), and ischial tuberosity (hamstrings). Bilateral radiographs are required. When these fractures are nondisplaced or minimally displaced, healing occurs with conservative management in 4–12 wk. Surgery is reserved for displaced, large fracture fragments or failure of conservative management. Re-injury can occur with premature return to competition. Contact to the bone around the hip and pelvis causes exquisitely tender subperiosteal hematomas called *hip pointers.* Symptomatic care includes rest, ice, analgesia, and protection from re-injury.

A *stress fracture* may present as vague hip pain. If radiographs do not demonstrate a periosteal reaction consistent with a stress fracture, a bone scan or MRI may be required. Orthopedic consultation is necessary in femoral neck stress fractures because of their predisposition to nonunion. *Osteitis pubis* is an inflammation at the pubic symphysis that may be caused by excessive side-to-side rocking of the pelvis (hockey, roller-blading). Radiographic evidence (irregularity, sclerosis, widening of the pubic symphysis with osteolysis) may not be present until symptoms are present for 6–8 wk; bone scan and MRI are more sensitive to early changes. Relative rest for 6–12 wk may be required. *Legg-Calvé-Perthes disease* (avascular necrosis of the

femoral head) also presents in childhood with insidious onset of limp and hip pain (see Chapter 668.3). Treatment allows remodeling of the femoral head by containing it within the acetabulum. Containment may necessitate the use of a brace or surgery.

676.6 Knee Injuries

The knee is the most common musculoskeletal site at which adolescents have complaints. Acute knee injuries that cause immediate disability are likely to be due to fracture, patellar dislocation, “internal derangement,” or OCD. *Internal derangement* is a nonspecific term and includes injury to the cruciate and collateral ligaments, menisci (cartilage), fracture, or chondral lesions (see Chapter 667). The mechanism of injury is usually a weight-bearing event. After injury, if a player cannot bear weight within a few minutes, a fracture or internal derangement is more likely. If a player is able to bear weight and return to play after the injury, a serious injury is unlikely to have occurred.

Anterior cruciate ligament sprains occur from being hit directly, landing off balance from a jump, or quickly changing direction while running. *Posterior cruciate ligament sprains* occur from a direct blow to the region of the proximal tibia, such as might occur with a kick in martial arts or a dashboard injury. *Medial collateral ligament sprains* result from a valgus blow (directed inward) to the outside of the knee. *Lateral collateral ligament sprains* are unusual as isolated injuries. *Meniscal tears* occur by the same mechanisms as the anterior cruciate ligament sprains.

Patellar dislocations occur most often as a noncontact injury when the quadriceps muscles forcefully contract to extend the knee while the lower leg is externally rotated. The patella is almost always dislocated laterally, and this motion tears the medial patellar stabilizers, causing a rapidly enlarging medial hematoma. If a patient continually subluxates the patella or has hypermobile joints, little bleeding may ensue after a dislocation. Patellar dislocation is a great imitator of knee pathology and can present in a fashion similar to the causes of internal derangement mentioned earlier.

Physical Examination.

The physician should inspect for hemarthrosis and obvious deformities; if these are present, the physician should assess neurovascular status and transfer the patient for emergency care. If no gross deformities are present and neurovascular integrity is intact, initial maneuvers include full passive extension and gentle valgus stress to the knee while the knee is in extension. The patient's ability to contract the vastus medialis obliques should be noted. Point tenderness is consistent with fracture or injury to the underlying structure; a medial meniscal tear may be manifest as tenderness along the medial joint line, however medial joint line tenderness is not specific for a medial meniscus tear. Presence of swelling in the first 24?hr is diagnostic of internal derangement. Limitation in either passive flexion or extension while rotating the tibia (the McMurray or modified McMurray tests) implies a meniscal injury, as do other maneuvers (Fig. 676–1 (Figure Not Available)). Ligament injury is manifested as pain or laxity with

Figure 676.6-1 (Figure Not Available) Examination maneuvers. Right knee shown. Examination maneuvers include the Lachman, anterior drawer, lateral pivot shift, Apley compression, and McMurray tests. The Lachman test, performed to detect anterior cruciate ligament (ACL) injuries, is conducted with the patient supine and the knee flexed 20–30 degrees. The anterior drawer test detects ACL injuries and is performed with the patient supine and the knee in 90 degrees of flexion. The lateral pivot shift test is performed with the patient supine, the hip flexed 45 degrees, and the knee in full extension. Internal rotation is applied to the tibia while the knee is flexed to 40 degrees under a valgus stress (pushing the outside of the knee medially). The Apley compression test, used to assess meniscal integrity, is performed with the patient prone and the examiner's knee over the patient's posterior thigh. The tibia is externally rotated while a downward compressive force is applied over the tibia. The McMurray test, used to assess meniscal integrity, is performed with the patient supine and the examiner standing on the side of the affected knee. (From Solomon DH, Simel DL, Bates DW, et al: Does this patient have a torn meniscus or ligament of the knee? *JAMA* 2001;286:1610.)

the appropriate maneuver. Gross laxity with passive maneuvers implies fracture. Patients with patellar dislocation have pain and apprehension when the examiner gently tries to push the patella laterally (the “apprehension sign”). If the patella is dislocated, reduction is indicated.

Initial Treatment of Acute Knee Injuries.

If a patient cannot bear weight pain free or has clinical signs of instability, the knee should be immobilized, crutches given, and plain radiographs obtained. Straight-leg immobilizers offer no structural support. If any brace is used, a hinged brace is indicated. A brace with a lateral buttress is indicated for patients with acute patellar dislocation. Performing isometric quadriceps contractions pain free is necessary to maintain quadriceps strength and requires physical therapy. An elastic wrap or tubular stockinette can be applied for compression and the knee elevated throughout the day. Rehabilitation is indicated through a physical therapist or athletic trainer.

Treatment of Chronic Injuries.

Patellofemoral pain syndrome (PFPS) is the most common cause of chronic anterior knee pain. It is worse going up stairs, after sitting for prolonged periods, or after squatting or running. The knee is usually stable, although the patient may complain of “giving way.” In contrast to giving way from mechanical instability, such as with an ACL or meniscal tear in which the patient may fall to the ground, have immediate pain, and develop effusion, the “giving way” of PFPS is usually due to quadriceps insufficiency or a transient pain causing the extensor mechanism to momentarily fail, yet the just-mentioned symptoms (e.g., falling to the ground) do not occur. The mechanism of PFPS includes a relatively weak vastus medialis muscle with hamstring and quadriceps muscle inflexibility and reduced endurance. The most common mechanism of injury is overuse. The diagnosis is confirmed with peripatellar tenderness.

Osgood-Schlatter disease is a traction apophysitis that is a variant of PFPS, with the injury occurring at the insertion of the patellar tendon on the tibial tuberosity. Osgood-Schlatter disease is treated like patellofemoral syndrome, with the addition of a protective Osgood-Schlatter pad, which protects the tibial tubercle from direct

trauma. Patients should miss little if any time from sports. *Iliotibial band tendinitis* is the most common cause of chronic lateral knee pain. Generally it is not associated with swelling and instability. Tenderness should be elicited along the iliotibial band as it courses over the lateral femoral condyle or at its insertion at the Gerdy tubercle, along the lateral tibial plateau; tightness of the iliotibial band is also noted using the Ober test. Treatment principles follow those for patellofemoral syndrome, except the emphasis is on improving strength, flexibility, and endurance of the iliotibial band. As with any overuse injury, it is important to consider the kinetic chain and training

errors in treating these conditions. If these are not corrected, it is likely that the condition will recur.

676.7 Shin Splints and Stress Fractures of the Lower Leg

Shin splints, presenting with pain along the medial tibia, is an overuse injury of the lower leg. The pain initially appears toward the end of exercise, and if exercise continues without rehabilitation, the pain worsens, occurs earlier in the exercise period, and lasts longer after exercise. Tenderness is elicited over a 5–15-cm area of the posterior tibialis muscle body (just medial to the tibia) but not over the bone. This is to be distinguished from a *tibial stress fracture,* in which the tenderness is more discrete (2–5?cm) over the tibia. The tenderness is worse with a stress fracture.

The diagnosis can be made by history and physical examination. Findings on plain radiographs of the tibia are normal with shin splints and in tibial stress fractures within the first few weeks of the injury. Afterward, the radiograph may demonstrate periosteal reaction if a stress fracture is present. A bone scan is the most sensitive test to diagnose stress fractures; it demonstrates discrete tracer uptake at the site(s) of the stress fracture. Increased uptake may be noted in the presence of shin splints but in a fusiform pattern along the periosteal surface. If results of the bone scan are normal, the diagnosis is likely to be shin splints.

The treatment of shin splints and tibial stress fractures is similar, involving relative rest, correcting training errors and kinetic chain dysfunction, and, possibly the use of appropriate running shoes (see Running, later). Fitness can be maintained with swimming, cycling, and water jogging, while following the relative rest guideline. After 7–10 days, patients can start on the walk-run program. If pain worsens, 2–3 pain-free days are required before resuming the walk-jog program. Ice should be used daily. Orthotics may be useful in patients who pronate. Stretching and strengthening the ankle dorsiflexors, plantarflexors, and everters can be useful. Analgesic medication can be used for shin splints but not routinely for stress fractures. Being pain free for 7–10 days is recommended before exercise walking is commenced; analgesics may mask the pain.

Stress fractures can occur in any bone in the lower extremity and are most common in the tibia and metatarsals. Stress fractures of the tarsal navicular, talus, proximal anterior third of the tibia, and femoral neck require consultation with an orthopedic surgeon.

676.8 Ankle Injuries

Ankle injuries are the most common acute athletic injury. Eighty-five per cent of ankle injuries are sprains, and 85% of those are inversion (foot planted with the lateral fibula moving toward the ground) injuries, 5% are eversion (foot planted with the medial malleolus moving toward the ground) injuries, and 10% are combined.

Examination and Injury Grading Scale.

In obvious cases of fracture or dislocation, evaluating neurovascular status with as little movement as possible is the priority (Table 676–2). If no deformity is obvious, the next step is inspection for edema, ecchymosis, and anatomic variants. Key sites to palpate are the entire length of the fibula; the medial and lateral malleoli; the base of the fifth metatarsal; the anterior, medial, and lateral joint lines; and the navicular and the Achilles tendon complex. Assessment of active range of motion (patient alone) in dorsiflexion, plantarflexion, inversion, and eversion and of resisted range of motion is indicated. Passive movement in a pain-free range is seldom useful in the acute injury. The peroneal muscles are the

TABLE 676.8-2 -- **Scheme for Grading Ankle Injuries**

Severity	Signs and Symptoms	Disability
Grade I (mild)	Minimal swelling (clear definition of Achilles tendon), small area of tenderness, little or no hemorrhage, minimal decreased range of motion	Little or no limp with walking, minimal difficulty hopping (7–10 days' rest with optimal rehabilitation)
Grade II (moderate)	Moderate swelling (margin of Achilles tendon less defined), more generalized tenderness, some hemorrhage, decreased range of motion	Obvious limping with walking, unable to run, unable to hop, unable to do toe raise (2–4 wk rest with optimal rehabilitation)
Grade III (severe)	Diffuse swelling (no clear margins of Achilles tendon), widespread tenderness, hemorrhage evident, pronounced decreased range of motion	Unable to bear weight, involuntary guarding with examination (5–10 wk rest with optimal rehabilitation)

most often injured and best assessed in the plantarflexed foot with resisted eversion.

Provocative testing attempts to evaluate the integrity of the ligaments. In a patient with a markedly swollen, painful ankle, provocative testing is not helpful because of muscle spasm and involuntary guarding. The anterior drawer test assesses for anterior translation of the talus and competence of the anterior talofibular ligament (ATFL). The inversion stress test examines the competence of the ATFL and calcaneofibular ligament (Fig. 676–2). In the acute setting, the integrity of the tibiofibular ligaments and syndesmosis is examined by the syndesmosis squeeze test. The peroneal subluxation test applies pressure from behind the peroneal tendon with resisting eversion while plantar flexed. If results of either of these tests are

abnormal, orthopedic consultation should be sought.

RADIOGRAPHS.

Anteroposterior, lateral, and mortise views of the ankle are obtained when patients have pain in the area of the malleoli, are unable to bear weight, or have bone tenderness over the posterior distal tibia or fibula (Ottawa rules). A foot series should be obtained when patients have pain in the area of the midfoot, are unable to bear weight, or have bone tenderness over the navicular or fifth metatarsal. It is important to differentiate an avulsion fracture of the proximal fifth metatarsal from the Jones fracture of the more distal portion of the proximal fifth metatarsal. The former is treated as an ankle sprain; the latter fracture has an increased risk of nonunion and requires orthopedic consultation. The *talar dome fractures* are manifested as an

Figure 676.8-2 Inversion stress tilt test for ankle instability. (From Hergenroeder AC: Diagnosis and treatment of ankle sprains: A review. *Am J Dis Child* 1990;144:809.)

ankle sprain that does not improve. Radiographs on initial presentation may have subtle abnormalities. Inability to evert the ankle actively and pain over the peroneal retinaculum may indicate a *peroneal rupture or dislocation.* Children with signs restricted to the distal fibula are unlikely to have high risk fractures, which include all fractures except avulsion, buckle, and nondisplaced Salter-Harris I and II fractures of the distal fibula.

Rehabilitation.

This should begin the day of injury; for those with pain with movement, isometric strengthening can be started. Important deficits to correct include loss of dorsiflexion, peroneal muscle weakness, and decreased proprioception. Until these deficits are restored, the ankle is vulnerable to re-injury. While standing on the uninjured side only, the athlete is instructed to hop five times as high as possible (“the five hop test”). When athletes are able to hop as high on the injured side without pain, they can return to sports.

Recurrent ankle injuries are more likely in patients who have not undergone complete rehabilitation. Ankle sprains are less likely in players wearing high-top shoes. Taping the ankle with adhesive tape provides no functional support. If functional support is needed, an ankle brace such as an air stirrup or canvas brace is indicated. Ankle sprains with residual functional instability after 9–12 mo of adequate rehabilitation may require surgery.

676.9 Foot Injuries

Sever disease (calcaneal apophysitis) occurs at the insertion of the Achilles tendon on the calcaneus. It is more common in boys (2:1); bilateral involvement occurs in 30%. Presentation is between age 8–13 yr. The chief complaint is activity-related heel pain. Tenderness is elicited at the insertion of the Achilles tendon into the calcaneus, and heel cords are tight. Treatment includes relative rest, ice, massage, stretching and strengthening of the Achilles' tendon, heel lifts (e.g., heel cups), and correcting abnormal foot morphology with orthotics or arch supports. With optimal management, symptoms improve in 4–8 wk. If there is no improvement, consideration should be given to less common causes of foot pain, including plantar fasciitis, tarsal coalitions, Achilles tendinitis, stress fractures, and OCD.

Chapter 677 - Head and Neck Injuries

Head and neck injuries account for 90% of traumatic deaths and are the leading cause of permanent disability resulting from sports participation. The incidence of catastrophic neck injuries associated with incomplete neurologic recovery is less than 1/100,000. The incidence of sports-related catastrophic head and neck injuries has decreased secondary to improved equipment standards for helmets and enforcing rules to prohibit the use of the head as the point of initial contact when tackling.

Head Injury.

Sixty-three per cent of mild traumatic head injuries in high school sports occur in football. The rate of mild traumatic brain injuries in the 10 most popular high school sports is (denominator = 100 player-seasons): football—3.7; wrestling—1.6; about 1.0 in girls and boys soccer and boys and girls basketball; 0.5 in softball and field hockey; 0.2 in baseball; and 0.1 in volleyball. The most common sequela of mild head injury is the *concussion,* a traumatically induced alteration of mental status not necessarily resulting in loss of consciousness. The constellation of complaints includes disturbance of vision and equilibrium, amnesia and other cognitive dysfunction, and headache (also see Chapter 57.7). Multiple concussions can cause cognitive impairment, including impaired memory, attention, and planning activities and emotional lability and fatigue. Because of these potential problems, it is recommended that athletes with concussions avoid contact sports, the duration of this restriction depending on the number and severity of the concussions. Return to play guidelines after a concussion are given in Table 677–1 .

An *epidural hematoma* is a rapidly accumulating hematoma between the dura and the cranium. Eighty-five per cent are associated with a skull fracture, and the most serious lacerate the middle meningeal artery. Most victims suffer loss of consciousness followed by a lucid, awake interval often associated with a severe headache. If untreated, this abruptly evolves to deterioration and death within 15–30?min. If treated appropriately, the outcome is generally excellent. A *subdural hematoma* occurs when an artery or bridging vein is torn between the dura and the brain parenchyma. It is the most frequent, identifiable

TABLE 677-1 -- **Concussion Guidelines and Recommendations**

Acute head injuries are usually divided into two categories:

1. Diffuse brain injuries—concussion and diffuse axonal injuries.
2. Focal brain injuries—all fractures and intracranial injuries.

It is not necessary to have loss of consciousness to have a concussion.[*] Several severity grading scales for concussion exist; one that is commonly used is the following:

Colorado Medical Society Guidelines

Grade	*Confusion*	*Amnesia*	*Loss of Consciousness*
I	+	–	–
II	+	+	–
III	+	+	+

Return-to-Play Criteria

Return-to-play criteria are based on prevention of the *second impact syndrome*. This syndrome is characterized by a loss of autoregulation of cerebral blood flow, manifest as a rapid increased intracranial pressure after a second head injury before full recovery from the initial head injury has occurred. Return to contact sports is based on the grade of the injury.

Recommendations for Return to Contact Sports Following a Concussion[†]

Grade	*Minimum Time to Return*	*Time Asymptomatic[‡]*
I	20 min	when examined
II	1 wk	1 wk
III	1 mo	1 wk

Recommendations for Return to Contact Sports After Repeated Concussions

Grade	*Minimum Time to Return*	*Time Asymptomatic[‡]*

I (2nd time)	2 wk		1 wk
II (2nd time)	1 mo		1 wk
I (× 3), II (× 2), III (× 2)	Season over		1 wk

**In animal studies, there is evidence that there are microscopic changes in the brain after a concussion. These may not be evident in imaging studies, so the clinician must rely on history and neuropsychologic examination to follow a patient's progress. In college football players who experienced their first concussion, the neuropsychologic testing normalized in 5 days and symptoms of headache and memory resolved in 10 days.*
The chronic effects of repetitive boxing injuries include cortical atrophy and a cavum septum pellucidum (identified radiographically). Whether this occurs in other sports in which head injuries are common (football, ice hockey, wrestling) or in which the head is used as part of the game (soccer) is debatable. However, there appears to be no danger in the young soccer player occasionally heading the ball.
†Contact sports means any situation in which contact is possible, including practice.
‡A symptomatic athlete should not return to contact sports regardless of the initial diagnosis. Athletes with focal brain injuries are excluded from contact sports indefinitely. Patients with a neck injury can return to contact sports when they have full, pain-free range of motion, strength and sensation, and normal lordosis of the cervical spine.

focal brain injury in sports and the most common cause of death in sports-related head injuries because it is also associated with cerebral contusion and edema. Patients may lose consciousness at the time of injury but recover in the acute setting. A *cerebral contusion,* bruising of the brain parenchyma, can present as focal symptoms at the site of injury (coup) or on the area opposite to the injury (contracoup). Cerebral contusions are often associated with skull fractures (see Chapter 57.7). Intracerebral hematoma is generally associated with severe head trauma and characterized by loss of consciousness and severe headache, if they regain consciousness. A subarachnoid hemorrhage is generally associated with loss of consciousness, severe headache, and rapidly deteriorating mental status. The latter has been associated with congenital arteriovenous malformations.

Neck Injuries.

Fracture with or without dislocation is considered when a player has any head or neck injury or loss of consciousness and, more specifically, when the athlete has midline cervical pain, painful range of motion, or peripheral neurologic signs or symptoms after neck trauma. Patients should be immobilized and should have a full radiographic evaluation with anteroposterior, lateral, oblique, and open-mouth views before removing the neck immobilizer. If the radiographs are normal, patients should have flexion and extension radiographs to evaluate for ligamentous instability. If the patient cannot actively flex or extend the cervical spine, then CT is indicated. If patients have bilateral symptoms but normal findings on radiographs, a lesion impinging on the spinal cord, cord hematoma or edema, or stenotic cervical canal is possible and a non–contrast-enhanced MRI of the cervical spine is indicated. In adults following blunt trauma, a lower probability of cervical spine injury is associated with no midline cervical tenderness, no focal neurologic deficits, normal level of consciousness, no drugs or intoxicants, and no distracting painful injury elsewhere.

Transient quadriplegia (<36?hr) is manifested as sensory changes that may be associated with motor paresis involving both arms, both legs, or all four extremities. Functional spinal narrowing caused by congenital spinal stenosis, fused vertebrae, or a structural lesion that narrows the canal, such as disk herniation, is possible. These diagnoses are made by MRI. Players who have had a neck injury and functional spinal stenosis are at increased risk of permanent disability if they play contact sports. They must be excluded from contact sports.

Patients with a neck injury and an otherwise normal radiographic examination can return to contact sports when they have full, pain-free range of motion, strength and sensation, and normal lordosis of their cervical spine.

Brachial Plexus Injuries.

The brachial plexus includes nerves originating from C5-T1 and emerging from the spinal column in the deep triangle of the neck. The upper trunk (C5-C6) can be contused or stretched during football when tackling with the shoulder or having the head forcefully flexed laterally. Manifestations include unilateral burning (known as a “burner” or “stinger”), paresthesia, and weakness in the arm, usually in a C5-C6 distribution manifested as the inability to forward flex or abduct the shoulder. These symptoms often resolve spontaneously within minutes. Bilateral symptoms, such as transient quadriplegia, are an indication to curtail participation until the patient is evaluated by MRI. If a player has recurrent “stingers,” an MRI study of the cervical spine is indicated. Fifteen per cent of patients younger than age 21 yr with Down syndrome have atlantoaxial instability (AAI). Asymptomatic AAI has not been demonstrated to be a risk factor for symptomatic AAI, which is a rare condition in patients with Down syndrome. Special Olympics still require these radiographs in asymptomatic individuals with Down syndrome. All symptomatic patients, such as with evidence of upper motor neuron or posterior column dysfunction, need these radiographs.

Treatment.

In the acute management of head and neck injuries, the principles of advanced life support are followed. Airway, breathing, circulation, and other painful injuries/disability are the initial concerns (see Chapter 57.1). Other management principles include the following:

1. Assume a neck injury is present in an unconscious athlete and immobilize the cervical spine. Do not remove the helmet of an injured player with a suspected neck injury.
2. If access to a compromised airway is required, remove the face mask.
3. Do not use ammonia smelling salts. The noxious stimulant causes involuntary withdrawal, which may cause secondary injury to an unstable cervical spine.
4. Perform serial neurologic examinations. If the athlete is lucid, look for the signs indicative of a neck injury before the athlete is permitted to move. These

include neck pain, painful range of motion, or bilateral neurologic signs.

Athletes with a suspected skull fracture, deteriorating mental status or worsening headache, focal neurologic deficits or seizure, loss of consciousness for more than 5?min, confusion lasting longer than 30?min, persistent emesis, more than one concussion in a practice/game, or inadequate postinjury supervision require transfer to an emergency department for evaluation and observation.

Chapter 678 - Heat Injuries

After heart disease, the second most common cause of nontraumatic death is heat illness. One to two athletes per year in the United States die of this preventable form of sudden death. Heat illness is a continuum of clinical signs and symptoms that can be mild (heat stress) to fatal (heatstroke).

Seventy-five per cent of the energy produced by muscular contraction is manifest as heat, whereas 25% is converted into muscle work. Without proper heat dissipation mechanisms, intense exercise would elevate core body temperature by 1°C every 5?min and would approach heat stroke within 15–20?min of intense exercise. The body dissipates heat by radiation (60% heat transfer to the air), evaporation (20–25%), and convection (15%). With repeated exposure to heat for 8–12 days, the body acclimatizes. Children's ability to tolerate heat stress is not as effective as that of adults. Children have a lower sweat rate and slower acclimatization process, absorb greater ambient heat secondary to their higher surface area to body mass ratio, and produce more metabolic heat per mass unit.

Heat cramps, the most common heat injury, usually affect the calf and hamstring muscles. They respond to oral rehydration with electrolyte solution and with gentle stretching. *Heat syncope* is fainting after prolonged exercise attributed to poor vasomotor tone and depleted intravascular volume, and it responds to fluids, cooling, and supine positioning. *Heat edema* is mild edema of the hands and feet during initial exposure to heat; it resolves with acclimatization. *Heat tetany* is carpopedal tingling or spasms caused by heat-related hyperventilation. It responds to moving to a cooler environment and decreasing respiratory rate (or rebreathing by breathing into a bag).

Moderate heat injury is characterized by body temperature from 99–104°F. *Heat exhaustion* is manifested as headache, nausea, vomiting, dizziness, orthostasis, weakness, piloerection, and possibly syncope. The latter complaint should also suggest head trauma and cardiac conditions. Patients with moderate heat injury do not have serious central nervous system (CNS) dysfunction. *Treatment* includes moving to a cool environment, cooling the body with fans, removing excess clothing, and placing ice

---

over the groin and axilla. If a patient is not able to tolerate oral rehydration, intravenous fluids are indicated. Patients should be monitored, including rectal temperature, for signs of heatstroke.

Severe heat injury is characterized by body temperature greater than 104°F and altered mental status. *Heatstroke* is a medical emergency; the mortality rate is 50%. Sports-related heatstroke is characterized by profuse sweating and is related to intense exertion, whereas "classic" heatstroke with dry, hot skin is of slower onset (days) in elderly or chronically ill persons exposed to summer heat waves. The physical response of a dehydrated athlete is to attempt to maintain the blood pressure by vasoconstriction, which makes it difficult to transfer heat peripherally. *Treatment* starts by addressing the airway, breathing, and circulation and proceeds to aggressive cooling using ice water baths, cooling fans, and removal of excess clothing. Intravenous fluid at a rate of 800?mL/m^2 in the first hour with dextrose/saline solution improves intravascular volume and the body's ability to dissipate heat. In a previously healthy individual, the risk of pulmonary and cerebral edema is minimal compared with the risk of uncorrected hypovolemia.

Heat-related illness can be prevented. The preparticipation sports examination should include screening questions to identify predisposing risk factors such as obesity, lack of physical conditioning, lack of acclimatization (usually requiring 8–10 exposures to the heat for 30–45 minutes), drugs/medications (amphetamines, LSD, alcohol, thyroid hormone, antihistamines, anticholinergics, haloperidol, phenothiazines, diuretics, laxatives, monoamine oxidase inhibitors, tricyclic antidepressants), excessive fluid/sweat loss (febrile illness, diarrhea, diabetes mellitus and insipidus, cystic fibrosis, dermatologic disorders with sweat gland dysfunction, some cyanotic congenital heart defects), inadequate intake (CNS disorder, mental retardation, or young age), or hypothalamic thermoregulatory dysfunction (malnutrition and eating disorders, prior heat injury).

Dehydration is common to all heat illness; therefore, measures to prevent dehydration may also prevent heat illness. Mild dehydration (2%) can decrease athletic performance and decrease normal thermoregulation. Thirst is not an adequate indicator of hydration status because it is initiated at 2–3% dehydration. Athletes are advised to be well hydrated before exercise and should drink every 20?min during exercise (5?oz for those weighing less than 40?kg, 9?oz for 60?kg, and 10–12?oz for those larger

TABLE 678-1 -- **Restraints on Activities at Different Levels of Heat Stress**

(Not Available)
From the American Academy of Pediatrics, Committee on Sports Medicine and Fitness: Climatic heat stress and the exercising child and adolescent. Pediatrics2000; 106:159.

than 60?kg). Free access to cold water, which is more efficiently absorbed than warm water, is effective and should be advocated to coaches. Scheduled breaks every 20–30?min with helmets off to get out of the heat can decrease the cumulative amount of heat exposure. Practices and competition should be scheduled in the early morning or late afternoon to avoid the hottest part of the day. Guidelines have been published about modification of activity related to the wet bulb temperature (Table 678–1 (Table Not Available)). Proper clothing such as shorts and T-shirts without helmets can improve heat dissipation. Proper supervision by an individual who can recognize and treat early heat illness can prevent progression to more severe injury. Prepractice and postpractice weight can be helpful in determining the amount of fluid needed to be replaced (16?oz or ½?L/lb weight loss).

Water is adequate for exercise lasting less than 1?hr. Fluids with electrolyte and carbohydrate should be reserved for exercise lasting for more than 1?hr. However, if these drinks are not available, water intake should continue. Most commercially available sports drinks have 6–8% carbohydrate; experimenting with different drinks or diluting standard sports drinks can decrease the side effects of nausea, bloating, and abdominal pain. Salt pills should not be used because of their risk of causing hypernatremia and delayed gastric emptying.

Chapter 679 - Female Athletes: Menstrual Problems and the Risk for Osteopenia

Special concerns are related to overtraining in young women and its effect on reproductive function and bone mineral status (see Chapter 107).

The majority of bone mass is acquired by the end of the 2nd decade. Sixty to 70% of adult bone mass is genetically determined, and the remaining is influenced by three controllable factors: exercise, calcium intake, and sex steroids, primarily estrogen. In general, exercise promotes bone mineralization in the majority of young women and is to be encouraged. In females with eating disorders and those who exercise to the point of excessive weight loss with amenorrhea or oligomenorrhea, exercise can be detrimental to bone mineral acquisition, resulting in reduced bone mineral content, or *osteopenia*.

Menstrual dysfunction, including amenorrhea or oligomenorrhea, can occur in women participating in any sport. The cause of the amenorrhea (amenorrhea will be used to refer to amenorrhea/oligomenorrhea here) must be established as for any other patient (see Chapter 107). In the absence of a pathologic cause, the diagnosis of hypothalamic amenorrhea is established by exclusion. It is characterized by reduced hypothalamic pulsatile release of gonadotropin-releasing hormone (GnRH) and, consequently, reduced serum gonadotropin concentrations. Athletes with amenorrhea have an increased risk of osteopenia and are at risk for stress fractures compared with their eumenorrheic athletic peers. This osteopenia is persistent, increasing their long-term risk for osteoporosis.

Young athletes with hypothalamic amenorrhea and without an eating disorder appear fit, typically have an estimated ideal body weight (eIBW) greater than 85%, and have training bradycardia (resting pulse in the range of 40–60 beats/min). There are three eating disorders that can present in the context of hypothalamic amenorrhea: (1) anorexia nervosa, manifest as weight less than 85% of eIBW with evidence of starvation

manifest as bradycardia, hypothermia, and orthostatic hypotension or orthostatic tachycardia; (2) bulimia nervosa, manifest as reduced or normal weight, with wider fluctuations of weight than would be expected based on their reported caloric intake and exercise; and (3) eating disorder not otherwise specified (EDNOS), with some of the features of either anorexia or bulimia nervosa, yet not meeting all criteria from the *Diagnostic and Statistical Manual for Mental Disorders,* 4th edition, for diagnosis of either (see Chapter 104).

The *treatment* of hypothalamic amenorrhea in the athlete involves lifestyle changes that result in reduced energy expenditure (i.e., exercise) and increased energy intake. The degree of recommended exercise reduction and increased caloric intake depends on the percent of eIBW. For example, if an athlete weighs 85–90% of eIBW and is exercising daily, then a reduction in exercise to 3 days a week and adding one or two dietary supplemental drinks (~250?kcal apiece) or snacks per day might be recommended. Generally, exercise is not recommend if the body weight is less than 85% of eIBW, although there are exceptions, especially if the athlete is eumenorrheic. Amenorrheic athletes who gain weight through reduced training and improved diet can resume menses spontaneously and increase their bone density. Gradually, their training is increased and their menstrual and nutritional status monitored. If the athlete is unable to gain weight with nutrition and medical counseling alone, then psychological consultation is sought. Estrogen replacement, usually in the form of low dose oral contraceptive pills, is recommended if the amenorrhea persists for 6 mo or more (see Chapter 108). Measuring bone mineral can help with the patient's decision if osteopenia is identified. If amenorrhea persists beyond 12 mo regardless of the bone density measurement, treatment with estrogen/progestin pills may be recommended (see Chapter 108). In making the decision to recommend estrogen/progestin pills in young women with hypothalamic amenorrhea one must consider (1) young women with anorexia nervosa and secondary amenorrhea have mean serum estradiol levels that approximate those of postmenopausal women and (2) osteopenia/osteoporosis is one of the more serious, long-term consequences of prolonged amenorrhea in adolescent athletes. The American Academy of Pediatrics Committee on Sports Medicine and Fitness recommends not providing estrogen replacement until age 16 yr. Premature use of estrogen could, theoretically, compromise adult height. There is a risk to delaying the start of estrogen/progestin therapy until epiphyseal growth is complete. The onset of anorexia nervosa before age 15 yr may affect bone size and density more than in those persons with onset after age 15 yr. Bone fragility is a function of bone size and density, which are both undergoing significant increases during puberty. A 15-yr-old with a bone age of 13 yr has achieved 96.4% of her adult height; one with a bone age of 14 yr has achieved 98.3% of her adult height; and one with a bone age of 15 yr has achieved 99% of her adult height. The mean height of females in North America is 163?cm at 15 yr of age. If estrogen therapy completely arrested height gain with the onset of therapy, then the female with a bone age of 15yr at age 15 yr could potentially lose, on average, 1.6?cm of height if her potential adult height was 163?cm. More likely, height attainment would not be arrested and some height would still be achieved after estrogen therapy is initiated. Estrogen/progesterone replacement is recommended for females with amenorrhea at 15 yr of age and a bone age of 15 yr and considered for those with a bone age of 14 yr, depending on the degree of osteopenia and malnutrition.

Adequate calcium intake is important. The current recommended daily allowance for calcium is 1,200?mg Most adolescent females consume much less. An increase of calcium intake to 1,500?mg/day is suggested for women with amenorrhea. Increased calcium intake alone in adolescent females with anorexia nervosa may not improve bone density because of increased calcium excretion and decreased absorption.

Chapter 680 - Ergogenic Aids

Also see Chapter 105.9

Ergogenic aids are any substance used for performance enhancement beyond training alone. Most ergogenics are considered nutritional supplements and lack the regulatory supervision to ensure purity, drug interactions with prescription medications, long or short-term safety profile, a recommended therapeutic dose, or convincing research to substantiate claims.

Male and female high school students have reported lifetime prevalence use of anabolic steroids of 4.2% and 2.7%, respectively. Pediatricians should discourage this use. Anabolic steroids at supraphysiologic doses increase strength and lean muscle mass when combined with increased caloric intake and exercise. Some athletes “stack” multiple formulations at many times the therapeutic dose for presumed enhanced efficacy. Steroid “pro-hormones,” such as dehydroepiandrosterone (DHEA) and androstenedione, are converted to estradiol more than testosterone and may have many of the same side effects as anabolic steroids. Short-term side effects of anabolic steroid use include liver toxicity (cholestatic jaundice, peliosis, hepatitis), endocrine abnormalities (gynecomastia, prostatic hypertrophy, hirsutism, impotence, decreased sperm count, testicular atrophy), hematologic changes (hypercoagulability, increased low-density lipoprotein and decreased high-density lipoprotein cholesterol), musculoskeletal problems (premature epiphyseal closure, muscle and tendon rupture), oncologic disorders (progression of prostate and breast cancer), dermatologic disorders (acne), and possibly psychiatric disorders. Anabolic steroid use should be suspected in an athlete with a rapid increase in lean mass and strength that is beyond that expected in normal development. Physical findings include gynecomastia, testicular shrinkage, jaundice, acne, and marked striae.

Creatine is a naturally occurring substance in the body that at the cellular level exists as phosphocreatine and theoretically increases muscle performance by faster rephosphorylation of adenosine diphosphate to adenosine triphosphate during brief high-intensity activities and as a lactic acid buffer during anaerobic activity. Because of the potential health risks (heat injury, gastrointestinal distress, renal disease) and lack of efficacy studies in adolescents, the American College of Sports Medicine recommends that creatine supplementation is not advised for those younger than 18 years of age.

?-Hydroxybutyric acid (GHB) and its metabolites ?-butyrolactone (GBL) and 1,4-butanediol (BD) cause decreased mental status, altered sensorium, decreased respiratory drive, and coma. Although these drugs are taken primarily for recreational

purposes, they have been used in some sports supplements. GHB, GBL, and BD have been linked to 122 serious illnesses and three deaths.

Chapter 681 - Specific Sports and Associated Injuries

Gymnastics.

Competitive gymnastics for females is a sport of adolescents. Participants are beginning the sport at 5–6 yr of age and achieving the highest level of competition in the mid teens, often retiring by age 20. A similar pattern occurs in males; however, their career, facilitated by pubertal development, including increasing strength, can extend into the 20s. Males tend to have more upper extremity injuries, and females have more lower

extremity injuries. In addition to mechanical or traumatic injuries, female gymnasts tend to have delayed menarche and can have hypothalamic amenorrhea or oligomenorrhea, associated with low body weight. The typical body habitus of the elite gymnast manifest as reduced weight for height, coupled with amenorrhea or oligomenorrhea, would suggest that reduced bone density is a problem for female gymnasts. The bone density of gymnasts tends to be high. It is speculated that this is secondary to the impact forces on the lower extremities related to dismount from the vault. In spite of this increased bone density in female gymnasts, stress fractures are a significant problem. The short stature associated with male and female gymnasts is caused by selection bias and not the result of gymnastics training.

Common problems include acute, traumatic injuries, such as an ankle sprain, and chronic, overuse injuries, such as wrist and spine stress fractures. The incidence of injury increases with the level of skill and is greatest in the floor exercise. Wrist pain due to chronic upper extremity weight bearing can be caused by a distal radial stress Salter I fracture, which typically presents on the radial, dorsal aspect of the wrist, but can present on the ulnar aspect, and is worsened by passive extension and palpation. Other wrist injuries include triangular fibrocartilage complex (TFCC) tears, scaphoid fractures, dorsal ganglions, and carpal ligament injuries. Treatment in almost all cases involves immobilization for some period or time, application of ice, and administration of nonsteroidal anti-inflammatory drugs (NSAIDs). If pain persists, the correct diagnosis can be made by MRI or arthroscopic examination to rule out intra-articular tears, loose bodies, or ligamentous instability. The pediatrician should have a low threshold for referral to a hand specialist in a wrist injury that is not improving with rest. Ligamentous laxity may predispose to elbow or shoulder dislocation and ankle sprains. Spine problems include spondylolysis (pars

interarticularis stress fracture) and spondylolisthesis (see Chapter 669.6) due to repetitive extension loading and need to be treated with relative rest, stretching, and possibly a thoracolumbosacral orthosis (TLSO). Re-introduction into gymnastics for all of these injuries can gradually occur, as long as the athlete stops whenever the pain recurs.

Swimming.

Shoulder injury is the most common overuse injury of competitive swimmers. *Swimmer's shoulder* is a combination of subacromial bursitis and rotator cuff tendonitis usually of the supraspinatus and is manifested as shoulder pain and tenderness of the supraspinatus tendon. The onset may be insidious. Pain, due to subacromial bursitits, may be produced by the Hawkin impingement test, in which pain is provoked by passively forward flexing the humerus to 90 degrees and then internally rotating the humerus. Supraspinatus tendonitis produces pain with active abduction between 60 and 100 degrees and doing the “emptying the can” maneuver, in which the patient internally rotates the humerus at rest and then raises the arm in a plane halfway between forward flexion and abduction. Treatment includes ice, modification of stroke technique, rest, stretching, muscle strengthening of the rotator cuff and upper back muscles, physiotherapy, nonsteroidal anti-inflammatory agents (NSAIDs), and consideration of a subacromial bursa cortisone injection. Prevention includes avoiding overwork, proper technique, and strengthening and stretching exercises.

Baseball.

Throwing injuries of the elbow and shoulder (especially among pitchers) are the most common baseball injuries. See Chapters 676.2 and 676.3 . “Little League elbow” is due to repetitive valgus forces leading to stretching injury on the medial aspect of the elbow or compressive forces on the lateral aspect of the elbow. It has been suggested that these injuries can be prevented by preseason stretching and strengthening exercises; however, this has not been demonstrated in a prospective study. The most important consideration is limitation of the number of pitches and advising players, coaches, and athletes that they should stop immediately when they experience elbow pain and if it persists they need medical evaluation. It has been recommended that a young pitcher pitch no more than 200 pitches per week and play in no more than two games per week and that the maximum number of pitches per game be approximately six times the pitcher's age in years. Deaths in baseball are rare (4/year from 1973–1999) and are caused by chest wall trauma with the ball (commotio cordis) or head injury with the ball or bat. Protective equipment needs to be worn properly to try to prevent these injuries.

Ballet.

This very demanding activity is associated with delayed menarche and eating disorders in female dancers (see Chapter 679). Acute injuries occur, most often of the lower extremities. As with any repetitive activity, overuse injuries are likely; the key is to make the correct diagnosis and also consider the kinetic chain dysfunction that may have contributed to that injury. A dancer may have an unrehabilitated ankle sprain, causing favoring of that leg, leading to a stress fracture of the contralateral tibia. Foot problems include metatarsal stress fractures, subungual hematomas, callus and bunion formation, sesamoiditis, and plantar fasciitis. There is no perfect ballet foot, although, theoretically, if the first and second rays are of equal length (manifest as the tips of the first two toes being equal) the dancer can go en pointe and distribute the weight more evenly. Going en pointe is a question that young ballet dancers and their parents may ask. An average age to go en pointe is 12 yr; however, a function test should be part of that decision: if the child can go en pointe, holding the position and not appearing unstable and weak and without pain, then he or she is probably ready to try dancing en pointe. Ankle problems include anterior and posterior impingement syndromes because of the extremes of range of motion in grand plié and en pointe, respectively. All other acute and overuse injuries of the lower extremity occur in dancers. Hip problems include both the medial snapping hip syndrome caused by the iliopsoas tendon's riding over the anterior hip capsule and tendinitis (piriformis, iliopsoas, rectus femoris). The piriformis syndrome occurs because of the repetitive external hip rotation required in ballet and can manifest as buttock and hip pain and sciatica. Spine problems include Scheuermann disease in males, idiopathic scoliosis in females, and spondylolysis.

Wrestling.

Wrestlers have great fluctuations in weight to meet weight-matched competition standards. Such fluctuations are associated with fasting, dehydration, and then bingeing.

Wrestling holds may produce injury owing to various torques or forces applied to the extremities and spine; wrestling throws with subsequent falls may produce concussions, neck strain, or spinal cord injury. The two most common sites of injury are the shoulder and knee. “Stingers” and “burners” are due to a brachial plexopathy (see Football).

Shoulder subluxation is common. Patients are often aware of their shoulder's slipping in and out (see Chapter 676.2). Hand injuries are usually not severe and include recurrent metacarpophalangeal and proximal interphalangeal sprains. Treatment of hand injuries includes splinting and taping.

Knee injuries are common and potentially serious and include prepatellar bursitis, medial and lateral sprains, and medial and lateral meniscus tears (see Chapter 676.6). Prepatellar bursitis is caused by a traumatic impact to the mat or chronic trauma. Swelling occurs over the knee, and patients have no limitation of motion except full flexion. If the skin has been broken, a septic bursitis has to be considered. The physician must try to distinguish traumatic from infected bursitis, which may require aspiration of the bursa. Treatment of traumatic bursitis includes protective neoprene knee sleeves, NSAIDs, and bursectomy if there are several recurrences.

Dermatologic problems include herpes simplex (herpes gladiatorum), impetigo, staphylococcal furunculosis or folliculitis, superficial fungal infections, and contact dermatitis. The first two are contraindications to wrestling until the infection is noninfectious. If recurrent herpes infections occur, suppressive oral antiviral agents

should be used.

Football.

Football continues to be the sport with the highest number of injuries, the greatest number of participants (~1.5 million junior and senior high school participants and 75,000 college participants in 2001), and one of the sports with a high injury rate. In terms of the severity of injury, defined as days lost per injury, the average injury in football is less severe than many other sports. Most of the injuries are sprains, strains, and contusions that once treated appropriately result in minimal time away from football.

Although the majority of catastrophic sports injuries in the United States have occurred in football, these severe injuries are rare. (*Catastrophic* is defined as a fatal injury or a severe injury with or without permanent severe functional disability.) Between 1977 and 2001, 294 disabling injuries occurred in football, for an annual rate of 12/yr. Two hundred seventeen of these were to the cervical spine; the remainder were cerebral injuries. In 1999 there were 21 catastrophic injuries in high school and 3 in college football.

Head and neck football injuries include concussion, neck sprain, and brachial plexopathy. The latter is referred to as a “stinger” or “burner.”

Lumbar spine injury manifested as low back pain may represent spondylolysis. Shoulder trauma can cause glenohumeral dislocation, the majority of which are anterior dislocations, acromioclavicular separations, and clavicular and humeral fractures.

Contusions to the arm and thigh muscles are common and may result in large hematomas if not treated aggressively. Assuming that there is no fracture, treatment includes ice and compression during most waking hours for the first few days to limit the expansion of the hematoma and then doing pain-free strengthening and stretching exercises until baseline function is achieved. Then return to contact can be approved. When the hematoma is allowed to persist and especially if there is a second hematoma into the first, myositis ossificans may develop. This requires surgical excision if the lesion causes functional limitations.

Knee injuries are the most common musculoskeletal complaint at the time of preseason examinations. Knee injuries are discussed in Chapter 676.6 .

Ankle sprains occur, and the risk of re-injury may be reduced by rehabilitation and use of air stirrups for 6 mo. Turf toe, an injury to the first metatarsophalangeal joint, is caused by forceful dorsiflexion while playing on artificial turf in soft, lightweight, flexible shoes. Treatment of turf toe includes ice, NSAIDs, an orthotic to limit extension of the great toe, and rest. Corticosteroid injections are not beneficial. Turf toe can be a season- or career-limiting injury.

Hockey.

Hockey is a collision sport associated with injuries caused by the puck or the stick hitting the player or by body contact with other players, the ice, or the boards, producing contusions, lacerations, fractures, sprains, or concussions. The risk for injury is reduced by proper equipment (helmets with face masks) and rules regarding dangerous body contact (checking from behind, high sticking, slashing, and fighting).

Specific hockey injuries include ankle sprains (dorsiflexion, eversion, and external rotation in contrast to the usual sprain of inversion in other sports), hip adductor strain, osteitis pubis, and various shoulder injuries from body contact. The latter include acromioclavicular sprain, dislocation, and clavicular fractures. The most serious injuries are to the head and neck.

Basketball and Volleyball.

Common maneuvers of these two sports include using a ball with your hand, jumping, pivoting, running, and sudden stopping, which increase the risks for ankle, knee, and finger injury.

Knee overuse injuries include patellar tendonitis (“jumper's knee”) and traction apophysitis (Osgood-Schlatter disease). As with other jumping sports, acute ligament sprains (medial collateral with or without anterior cruciate ligaments) can occur.

Ankle sprain is the most common injury and is usually caused by inversion with plantarflexion, placing the lateral ligaments at high tension. An avulsion fracture of the base of the fifth metatarsal at the insertion of the peroneus brevis tendon is another sequela of inversion ankle injuries. Achilles tendonitis is an overuse injury that may be exacerbated by rubbing of the tendon over high-top shoes. Foot pain may be due to retrocalcaneal bursitis, posterior tibial tendonitis, accessory tarsal navicular, calcaneal periostitis, plantar fasciitis, stress fracture of the tarsal navicular, Jones stress fracture of the fifth metatarsal, sesamoiditis, blisters, subungual hematoma, and paronychia.

Running.

Running problems are due to an overuse (chronic repetitive motion) injury exacerbated by muscle imbalance, a minor skeletal deformity, or poor flexibility, strength or endurance, or proprioception. With each step while running, the foot impact ranges from three to eight times the athlete's body weight. Most problems ensue as the runner increases the distance or intensity of training. Minor variations (e.g., malalignment) in anatomy, which do not cause problems at rest, may predispose to injury at specific sites (patellofemoral stress, overpronation). Muscle fatigue, environmental temperature, and running surface (grass vs. unyielding concrete) also contribute to injuries. Prevention of injuries is possible by stretching and muscle-strengthening exercises for previous injuries and cross-training (bicycling, swimming) and adequate rest. Using good-quality running shoes that match an athlete's foot type is an essential first step. Gender-specific shoes are important because girls generally have a narrower rearfoot. Those who severely overpronate need a *motion control shoe* for maximum rearfoot and arch support in the midsole. Those who mildly overpronate need a *stability* shoe that has extra support in the medial midsole and some midsole cushion. Those who supinate need a *cushioned* shoe with more shock absorption in the midsole, more curved last, and

minimal arch support.

Stress fractures of the femoral neck, inferior pubic rami, subtrochanteric area, proximal femoral shaft, proximal tibia, fibula, navicular, metatarsal, sesamoid, and calcaneal apophysis may occur. Stress fractures of all bones of the lower extremity can occur in runners. The most common are in the metatarsals, the tibia, and the fibula. Those that are the most worrisome in terms of risk of nonunion are in the anterior proximal tibia, the femoral neck, and the talus. Muscle strains frequently affect the hamstrings, followed by the quadriceps, hip adductors, soleus, and gastrocnemius muscles. Tendonitis involving the tendon and its sheath is common in the Achilles tendon, followed by the posterior tibial, peroneal, iliopsoas, and proximal hamstring tendons. Achilles tendonitis develops chronically, initially may get better during a run, is characterized by tenderness and crepitance if acute and nodularity if chronic, and must be distinguished from a retrocalcaneal bursitis. Treatment includes identification of underlying cause and temporary abstinence from running (begin cross-training), a ½-inch heel lift, heel cord stretching, and NSAIDs. Corticosteroid injection is not indicated.

Anterior knee pain is usually due to patellofemoral stress syndrome (runner's knee), which results from excessive dynamic, usually lateral, motion of the patellar tendon in relationship to the femoral intracondylar groove. Treatment includes stretching of the quadriceps and hamstring muscles and possibly the iliotibial band, quadriceps-strengthening exercises, ice, and relative

rest. Foot orthotics may be indicated if there is no improvement with the aforementioned treatment. Posterior knee pain can be caused by gastrocnemius strain, whereas posteromedial pain may be due to proximal tibial stress fractures or semimembranosus or semitendinosus tendonitis and lateral knee pain may be due to iliotibial band syndrome and popliteus tendonitis. Iliotibial band syndrome may be a combination of a bursitis and tendonitis owing to mechanical friction of the band (an extension of the tensor fasciae latae) over the lateral femoral epicondyle.

Shin splints, or medial tibial stress syndrome (MTSS), is a descriptive term for pain over the anterior tibia and should be distinguished from tibial stress fractures and chronic compartment syndromes (see Chapter 676.7). MTSS usually occurs in new runners with overpronation. Treatment includes running on soft surfaces, proper shoe selection, and, possibly, orthotics, NSAIDs, and relative rest (or cross-training). Compartment syndromes involve the deep posterior or anterior compartments, producing local pain confined to the muscle (not to the bone). Classically, the pain will have onset at the same time during the run and will be relieved by rest. Pain usually prevents further training, thus limiting the risk of permanent nerve damage. Diagnosis is made by measurement of increased intracompartmental pressures during exercise.

Plantar fasciitis is an inflammation of the supporting structure of the longitudinal arch owing to repetitive cyclic loading with foot strike. Pain increases with the first step out of bed in the morning and with running and is located on the medial aspect of the heel. Treatment includes calf stretching, proper shoes, night splints, corticosteroid injection, relative rest, and ice massage of the heel. Calcaneal stress fracture must be considered especially in the amenorrheic distance runner.

Soccer.

Injuries in soccer include abrasions, contusions, muscle strains, and ligament sprains (ankle, knee), owing partly to body-to-body contact, falls, running, and kicking. Hip problems include the “hip pointer” (iliac crest contusion), iliac crest apophysitis, and chronic groin pain (muscle strain, hernia, osteitis pubis). Femoral neck stress fractures, slipped femoral capital epiphysis, and avulsion fractures of the pelvis or femur are to be considered in the differential diagnosis yet are unusual causes of hip pain. All other lower and upper extremity injuries can occur in soccer.

Concussions occur in soccer. On the typical high school and college teams there would be approximately one concussion every three to four seasons and one concussion every season, respectively. The consensus is that heading, alone, does not lead to neurocognitive dysfunction. Concussion can lead to neurocognitive dysfunction, and concussions occur in soccer due to player/player, player/goal post, and player/ground contact. Proper heading technique should be taught in youth soccer; on long kicks, the receiving player traps the ball with the chest or leg, not the head; defenders kick the ball about 5 feet in front of their midfielders or forwards so the latter have to come to the ball and trap with their legs; players avoid heading the ball backward toward the goal (i.e., with cervical extension); referees, as with all sports, keep the game under control and penalize dangerous play; and guidelines for returning to play after a concussion should be followed. One study reported no evidence of impaired neurocognitive function or scholastic aptitude in college soccer players, with an average of 15 seasons of playing soccer and 28% of whom reported at least 1 concussion, compared with nonsoccer college athletes and student nonathletes.

Tennis.

Lower extremity injuries occur twice as often as upper extremity injuries, and, overall, injury rates are similar for boys and girls. Common areas of injury in tennis include muscles and tendons of the elbow, shoulder, back, wrist, and abdomen. The risk for injury is increased by increased training; by unrehabilitated injuries with resultant deficits in flexibility, strength, and endurance; and by poor technique. Acute injuries of the lower extremities include ankle, knee, lower leg, and groin strains. Overuse injuries of the back and lower and upper extremities occur. The lower extremity injury patterns are related to the fact that for accomplished players, there are an average of eight direction changes per point, creating eccentric and concentric loads on the lower extremities. In the back, injuries are related to the marked and rapid load and direction change associated with serving; and the shoulder, elbow, and wrist are moving at velocities of up to 1700, 900, and 350 degrees/sec, respectively, in a repetitive fashion. Injuries can be related to improper equipment, such as a racquet that is too big, or to trying to learn techniques, such as hitting with top spin or with power before proper coordination and technique in basic strokes has been established. Overuse injuries include stress fractures of the humerus, ulna, and metacarpals and traction apophysitis of the calcaneus, tibial tubercle (Osgood-Schlatter disease), and medial humeral epicondyle.

Rotator cuff tendonitis is caused by repetitive overuse and may be related to anterior-posterior glenohumeral instability. Subluxation of the glenohumeral joint may also be present. Biceps tendonitis can present as anterior shoulder pain.

“Tennis elbow,” or lateral epicondylitis, is due to repetitive overload of the wrist extensor/supinator mechanism, especially the extensor carpi radialis brevis (see Chapter 676.3). Medial epicondylitis is caused by repetitive overload of the wrist flexor/pronator muscle groups. This may secondarily involve the medial collateral ligament; however, the ligament is uncommonly the site of the primary injury. Nonunion of the medial and lateral humeral epicondyles is unusual. Medial epicondylar apophysitis may be associated with ulnar nerve dysfunction if there is an avulsion fracture. Olecranon apophysitis is similar to Osgood-Schlatter disease and is marked by pain at the olecranon with elbow extension.

Wrist problems include an enlarged dorsal ganglion cyst, radiocarpal joint capsular (impingement) synovitis, degenerative attrition (tears) of the triangular fibrocartilage complex, and fracture of the hook of the hamate.

Basic treatment includes relative rest, NSAIDs, application of ice, rehabilitation, learning proper mechanics, using properly sized racquets, protective counterforce bracing (elbow, wrist), strengthening exercises, and gradual return to tennis. Corticosteroid injections into the extensor/supinator muscle group for “tennis elbow” are not recommended because the outcome at 1 yr is poorer than for those treated with rehabilitation.

Skiing.

Injuries are related to falls (concussions, contusion, lacerations) and ski-specific mechanisms. Overall injuries have declined, partly because of better equipment (boots, bindings, poles) and slope conditions. It has been recommended that children and adolescents wear helmets for skiing and snowboarding.

Thumb injuries resulting from falls with the thumb in abduction and hyperextension produce a sprain of the ulnar collateral ligament (skier's thumb). Complete tears with a 45-degree joint opening require surgical intervention, whereas smaller degrees of joint opening may be treated with a thumb spica cast for 4 wk. A Salter-Harris type III fracture may also be present; if the epiphyseal fracture is displaced, it requires open reduction and internal fixation.

Lower extremity injuries include fractures (often spiral) of the tibia (“boot top”) and ankle and anterior cruciate ligament (ACL) sprains with or without tibial eminence fracture. Hemarthrosis is present in fractures and meniscal and ACL injuries. Some ACL sprains can be managed without surgery. However, for those that cannot, treatment of ACL sprains includes bracing, intra-articular reconstruction, and closed or open anatomic reduction of a tibial eminence fracture fragment.

Section 3 - *The Skeletal Dysplasias*

Chapter 682 - General Considerations

William A. Horton
Jacqueline T. Hecht

The terms skeletal dysplasias, bone dysplasias, and osteochondrodysplasias refer to a genetically and clinically heterogeneous group of disorders of skeletal development and growth. Their prevalence is estimated to be about 1 in 4,000 births. They can be divided into the osteodysplasias typified by osteogenesis imperfecta (see Chapter 689) and the chondrodysplasias. The latter result from mutations of genes that are essential for skeletal development and growth. The clinical picture is dominated by skeletal abnormalities. The manifestations may be restricted to the skeleton, but in most cases nonskeletal tissues are also involved. The disorders may be lethal in utero or mild with features that go undetected.

The chondrodysplasias are distinguished from other forms of short stature by a disproportionality of skeletal manifestations. They are separated into individuals with predominantly short limbs and those with predominantly short trunks. Efforts to define the extent of clinical heterogeneity resulted in the delineation of more than 100 distinct entities. Many of these disorders result from mutations of a relatively small group of genes, the “chondrodysplasia genes.”

An International Working Group on Bone Dysplasias named and classified these disorders based on genetic cause if known or on similarities of clinical and radiographic manifestations, which often imply a common pathogenesis and a common genetic basis, if the cause is unknown (Table 682–1). The classification differs from previous ones, which were based mainly on radiographic grounds. Disorders previously thought to be different were grouped together (e.g., pseudoachondroplasia, multiple epiphyseal dysplasia). By genetic definition, these are “allelic” disorders. In other instances, disorders believed to be related ended up in the different chondrodysplasia groups (e.g., achondrogenesis types Ia and II)

because the mutant genes differ.

The better defined chondrodysplasia groups, such as the achondroplasia and type II collagenopathy groups, contain graded series of disorders that range from very severe to very mild. This may be true for other groups as more mutations are found and the full spectrum of clinical phenotypes associated with mutations of a given gene is defined. These disorders are clinical phenotypes distributed along spectra of phenotypic abnormality associated with mutations of particular genes. For mutations of some genes such as *COL2A1*, the distribution is fairly continuous, with clinical phenotypes merging into one another across a broad range. There is much less clinical overlap for mutations of some other genes, such as *FGFR3*, in which the distribution is discontinuous. Because most clinicians and most reference materials refer to the disorders as distinct entities, this vernacular continues to be used.

Although a few chondrodysplasias can be easily diagnosed, most require the analysis of information from the history, physical examination, skeletal radiographs, family history, and laboratory testing. The process involves recognizing complex patterns that are characteristic of the different disorders (Tables 682–2 and 682–3 ; Box 682–2 and Box 682–2). Comprehensive descriptions of disorders and references are at the On-Line Mendelian Inheritance in Man (OMIM) Internet site (see the references at the end of this chapter). OMIM numbers are given for disorders discussed in this and related chapters in this section.

Clinical Manifestations

GROWTH RELATED.

The hallmark of the chondrodysplasias is disproportionate short stature. Although this refers to a disproportion between the limbs and the trunk, most disorders exhibit some shortening of both, and subtle degrees of disproportion may be difficult to appreciate, especially in premature, obese, or edematous infants. Disproportionate shortening of the limbs should be suspected if the upper limbs do not reach the mid pelvis in infancy or the upper thigh after infancy. Disproportionate shortening of the trunk is indicated by a short neck, small chest, and protuberant abdomen. Skeletal disproportion is usually accompanied by short stature (i.e., length and height below the 3rd percentile), but these measurements are occasionally within the low-normal range early in the course of certain conditions.

TABLE 682-1

Gene Locus	Chromosome Location	Protein	Protein Function	Clinical Phenotype
COL2A1	12q13.1-q13.3	Type II collagen a1 chain	Cartilage matrix protein	Achondrogenesis II
				Hypochondrogenesis
				SED congenita
				Kniest dysplasia
				Late-onset SED
				Stickler dysplasia
SEDL	Xp22.2-p22.1	Sedlin	Intracellular transporter	X-linked SED tarda
COL11A1	1p21	Type XI collagen a1 chain	Cartilage matrix protein	Stickler-like dysplasia
COL11A2	6p21.3	Type XI collagen a2 chain	Cartilage matrix protein	Stickler-like dysplasia
COMP	19p12-p13.1	Cartilage oligomeric matrix protein	Cartilage matrix protein	Pseudoachondroplasia
				MED
COL9A2	1p32.2-p33	Type IX collagen a2 chain	Cartilage matrix protein	MED
COL9A3	20q13.3	Type IX collagen a3 chain	Cartilage matrix protein	MED
MATN3	2p24-p23	Matrilin 3	Cartilage matrix protein	MED
COL10A1	6q21-q22.3	Type X collagen a1 chain	Hypertrophic cartilage matrix protein	Schmid metaphyseal chondrodysplasia
FGFR3	4p16.3	FGF receptor 3	Tyrosine kinase receptor for FGFs	Thanatophoric dysplasia I
				Thanatophoric dysplasia II
				Achondroplasia
				Hypochondroplasia
PTHR	3p21-p22	PTHrP receptor	G protein–coupled receptor for PTH and PTHrP	Jansen metaphyseal chondrodysplasia
DTDST	5q32-q33	DTD sulfate transporter	Transmembrane sulfate transporter	Achondrogenesis 1B
				Atelosteogenesis II

				Diastrophic dysplasia
SOX9	17q24.3-q25.1	SRY box 9	Transcription factor	Campomelic dysplasia
CBFA1	6p21	Core binding factor a subunit	Transcription factor	Cleidocranial dysplasia
LMX1B	9q34.1		Transcription factor	Nail-patella dysplasia
CTSK	1q21	Cathepsin K	Enzyme	Pyknodysostosis
RMPR	9p21-p12	Mitochondrial RNA–processing endoribonuclease	RNA-processing enzyme	CHH

SED = spondyloepiphyseal dysplasia; MED = multiple epiphyseal dysplasia; DTD = diastrophic dy factor; PTH = parathyroid hormone; PTHrP = parathyroid hormone–related protein; PTH = parathy sex-determining region of theY chromosome; CHH = cartilage-hair hypoplasia.

*Usually lethal.

There may also be disproportionate shortening of different segments of the limbs; the particular pattern may provide clues for specific diagnoses. Shortening is greatest in the proximal segments (upper arms and legs) in achondroplasia; this is termed *rhizomelic* shortening. Disproportionate shortening of the middle segments (forearms and lower legs) is called *mesomelic* shortening; *acromelic* shortening involves the hands and feet.

With some exceptions, there is a strong correlation between the age at onset and the clinical severity. Many of the so-called lethal neonatal chondrodysplasias are evident by the time routine fetal ultrasound examinations are performed at the end of the 1st trimester of gestation (see Box 682–1). Gestational standards exist for long-bone lengths; discrepancies are often detected between biparietal diameter of the skull and long-bone lengths. Many disorders become apparent around the time of birth; others manifest during the 1st yr of life. A number of disorders present in early childhood and a few in late childhood or later.

NON–GROWTH RELATED.

Most patients also have problems unrelated to growth. Skeletal deformities, such as abnormal joint mobility, protuberances at and around joints, angular deformities, and so on, are common and usually symmetric. Skeletal abnormalities may adversely affect nonskeletal tissues. Impaired growth at the base of the skull and of vertebral pedicles reduces the size of the spinal canal in achondroplasia and may contribute to spinal cord compression. Short ribs reduce thoracic volume, which may compromise breathing in patients with short trunk chondrodysplasias. Cleft palate is common to many disorders, presumably reflecting defective palatal growth.

Manifestations may be unrelated to the skeleton; they reflect expression of mutant genes in nonskeletal tissues. Examples include retinal detachment in spondyloepiphyseal dysplasia congenita, sex reversal in campomelic dysplasia, congenital heart malformations in Ellis-van Creveld syndrome, immune deficiency in cartilage-hair hypoplasia, and renal dysfunction in asphyxiating thoracic dystrophy. These nonskeletal problems provide valuable clues to specific diagnoses and must be managed clinically (see Table 682–3).

FAMILY AND REPRODUCTIVE HISTORY.

A careful family history may identify relatives with the condition; a mendelian inheritance pattern may be elicited. Because the presentation may vary substantially in some disorders, features that might be related to the disorder should be identified. Special attention should be given to mild degrees of short stature, disproportion, deformities, and other manifestations such as precocious osteoarthritis because they may be overlooked by the family. Physical examination of relatives may be useful, as may the review of photographs, radiographs, and medical records of family members.

TABLE 682-2 -- Major Problems Associated with Skeletal Dysplasias

Problem	Example
Lethality*	Thanatophoric dysplasia
Associated anomalies†	Ellis–van Creveld syndrome
Short stature	Common to almost all
Cervical spine dislocations	Larsen syndrome
Severe limb bowing	Metaphyseal dysplasia, type Schmid
Spine curvatures	Metatropic dysplasia
Clubfeet	Diastrophic dysplasia
Fractures	Osteogenesis imperfecta
Pneumonias, aspirations	Campomelic dysplasia
Hydrocephalus	Achondroplasia

Joint problems (hips, knees)	Most skeletal dysplasias
Hearing loss	Common (greatest with cleft palate)
Myopia/cataracts	Stickler syndrome
Immune deficiency‡	Cartilage-hair hypoplasia
Sudden infant death syndrome	Achondroplasia (rare)
Pulmonary hypertension§	Achondroplasia
Poor body image	Variable, but common to all
Sex reversal	Campomelic dysplasia

**Mostly due to severely reduced size of thorax.*
†See Table 682–3 .
‡At least four additional disorders, all involving the metaphyses, can have immunodeficiency.
§Uncommon.

A reproductive history may reveal previous stillbirths, fetal losses, and other abnormal pregnancy outcomes resulting from a skeletal dysplasia. Pregnancy complications, such as polyhydramnios or reduced fetal movement, are common in bone dysplasias, especially neonatal lethal variants.

Even though most of the skeletal dysplasias are genetic, it is common to have no family history of the disorder. New mutations are common for autosomal dominant disorders, especially lethal disorders in the perinatal period (thanatophoric dysplasia, osteogenesis imperfecta). The majority of achondroplasia cases result from new mutations. Germ cell mosaicism, in which a parent has clones of mutant germ cells, has been observed in osteogenesis

TABLE 682-3 -- **Associated Anomalies in Skeletal Dysplasias**

Anomaly	Example
Heart defects	Ellis–van Creveld syndrome
Polydactyly	Short rib polydactyly, Majewski type
Cleft palate	Diastrophic dysplasia
Ear cysts	Diastrophic dysplasia
Hydrocephalus	Achondroplasia
Encephalocele	Dyssegmental dysplasia
Hemivertebrae	Dyssegmental dysplasia
Micrognathia	Campomelic dysplasia
Nail dysplasia	Ellis–van Creveld syndrome
Conical teeth, oligodontia	Ellis–van Creveld syndrome
Multiple oral frenulae	Ellis–van Creveld syndrome
Dentinogenesis imperfecta	Osteogenesis imperfecta
Pretibial skin dimples	Campomelic dysplasia
Cataracts, retinal detachment	Stickler syndrome
Intestinal atresia	Saldino-Noonan
Renal cysts	Saldino-Noonan
Campodactyly	Diastrophic dysplasia
Craniosynostosis	Thanatophoric dysplasia
Ichthyosis	Chondrodystrophica punctata
Hitchhiker thumb	Diastrophic dysplasia
Sparse scalp hair	Cartilage-hair hypoplasia
Hypertelorism	Robinow syndrome
Hypoplastic nasal bridge	Acrodysostosis
Clavicular agenesis	Cleidocranial dysplasia
Genital hypoplasia	Robinow syndrome
Tail	Metatropic dysplasia
Omphalocele	Beemer-Langer syndrome
Blue sclera	Osteogenesis imperfecta

Box 682-1. Lethal Neonatal Dwarfism

USUALLY FATAL*

- Achondrogenesis (different types)
- Thanatophoric dyplasia
- Short rib polydactyly, Majewski type
- Short rib polydactyly, Saldino-Noonan type
- Homozygous achondroplasia
- Osteopetrosis (congenital form)
- Campomelic dysplasia
- Dyssegmental dysplasia, Silverman-Handmaker type
- Osteogenesis imperfecta, type II
- Hypophosphatasia (congenital form)
- Chondrodysplasia punctata (rhizomelic form)

OFTEN FATAL

- Asphyxiating thoracic dystrophy (Jeune syndrome)

OCCASIONALLY FATAL

- Ellis-van Creveld syndrome
- Diastrophic dysplasia
- Metatropic dwarfism
- Kniest dysplasia

- Metatropic dwarfism
- Kniest dysplasia

*A few prolonged survivors have been reported in most of these disorders.

imperfecta and in other dominant disorders. A negative family history is common in recessive disorders.

RADIOGRAPHIC FEATURES.

Radiographic evaluation for a chondrodysplasia should include plain films of the entire skeleton. Efforts should be made to identify which bones and which parts of bones (epiphyses, metaphyses, diaphyses) are most affected. If possible, films taken at different ages should be examined because the radiographic changes evolve with time. Films taken before puberty are generally more informative because pubertal closure of the epiphyses obliterates many of the signs needed for a radiographic diagnosis.

Diagnosis.

If an infant or child is short with disproportionate features, a diagnosis is established by matching the observed clinical picture (defined primarily from clinical, family, and gestational histories; physical examination; and radiographic evaluation) with clinical phenotypes of well-documented disorders. Pediatricians should be able to gather most of this information and, in consultation with a radiologist, diagnose the common chondrodysplasias. There are a number of reference texts and online databases that provide information about the disorders and comprehensive lists of current references. For less common disorders and for infants and children whose phenotypes do not closely match well-established clinical phenotypes, consultation with experts in the bone dysplasia field is warranted.

Laboratory testing has not been useful in diagnosing chondrodysplasias. An exception is osteogenesis imperfecta, in which

Box 682-2. Usually Nonlethal Dwarfing Conditions Recognizable at Birth or Within First New Months of Life

MOST COMMON

Achondroplasia

Osteogenesis imperfecta (types I, III, IV)

Spondyleopiphyseal dysplasia congenita

Diastrophic dysplasia

Ellis–van Creveld syndrome

LESS COMMON

Chondrodysplasia punctata (some forms)

Kniest dysplasia (not severe congenital forms)

Metatropic dysplasia

Langer mesomelic dysplasia

---

analysis of collagen synthesis by skin fibroblasts has helped establish a diagnosis. Osteogenesis imperfecta is not a chondrodysplasia, but it is frequently in the differential diagnosis, especially for newborns with severe skeletal deformities (see Chapter 689).

Molecular genetic testing for chondrodysplasias may be useful, especially for disorders in which recurrent mutations occur (typical achondroplasia has the same *FGFR3* mutation). Mutation testing for achondroplasia is available; however, the diagnosis can usually be made clinically. The greatest utility for testing may be for prenatal diagnosis for couples in whom both parents have typical (heterozygous) achondroplasia. They are at a 25% risk for the much more severe homozygous achondroplasia, which can be detected by mutation analysis. Another example is in disorders due to mutations of *DTDST*. These disorders are inherited in an autosomal recessive manner, and a limited number of mutant alleles have been found. If the mutations are identified in the patient, they should be detectable in the parents and potentially used for prenatal diagnosis. Nonetheless, most chondrodysplasia mutations tend to be dispersed throughout host genes. This phenomenon makes their detection more difficult and currently reduces the usefulness of such testing for diagnostic purposes.

Many of the chondrodysplasias have distinct histologic changes of the skeletal growth plate. Sometimes such tissues obtained at biopsy or discarded from a surgical procedure are helpful diagnostically. It is uncommon to make a diagnosis histologically if it was not already suspected on clinical grounds. An exception is for the lethal neonatal chondrodysplasias, in which an aborted fetus is macerated, thus making a clinical and radiographic assessment difficult.

Molecular Genetics.

A number of chondrodysplasia genes have been identified (see Table 682–1). They encode several categories of proteins, including cartilage matrix proteins, transmembrane receptors, ion transporters, and transcription factors. The number of identified gene loci is much smaller than anticipated from the number of recognized clinical phenotypes. The vast majority of patients have disorders that map to fewer than 10 loci; mutations at two loci (*COL2A1* and *FGFR3*) account for more than half of all cases. There may be a limited number of genes whose function is critical to skeletal development, especially linear bone growth; mutations in these genes give rise to a wide range of chondrodysplasia clinical phenotypes.

Mutations at the *COL2A1* and *FGFR3* loci illustrate different genetic characteristics. *COL2A1* mutations are distributed throughout the gene with few instances of recurrence in unrelated persons. In contrast, *FGFR3* mutations are restricted to a few locations within the gene, and occurrence of new mutations at these sites in unrelated individuals is the rule. There is a strong correlation between clinical phenotype and mutation site for *FGFR3*, but not *COL2A1,* mutations.

Pathophysiology.

Chondrodysplasia mutations act through different mechanisms. Most mutations involving cartilage matrix proteins cause disease when only one of the two copies (alleles) of the relevant gene is mutated. These mutations usually act through a *dominant negative mechanism* in which the protein products of the mutant allele interfere with the assembly and function of multimeric molecules that contain the protein products of both the normal and mutant alleles. The type II collagen molecule is a triple helix composed of three collagen chains, which are the products of the type II collagen gene, *COL2A1*. When chains from both normal and mutant alleles are combined to form triple helices, most molecules contain at least one mutant chain. It is not known how many mutant chains are required to produce a dysfunctional molecule but, depending on the mutation, it theoretically could be as few as one.

Mutations involving type X collagen differ from the model just described. They map to the region of the chain that is responsible for chain recognition; the chains must

recognize each other before they can assemble into collagen molecules. Mutations are thought to disrupt this process. As a result, none of the mutant chains are incorporated into molecules. This mechanism is haploinsufficiency because the products of the mutant allele are functionally absent and the normal allele is insufficient for normal function. Mutations involving ion transport genes also act through a loss of function of the transporters. Alternatively, mutations of transmembrane receptors studied to date appear to act through a gain of function; the mutant receptors initiate signals in a constitutive manner independent of their normal ligands.

Regardless of genetic mechanism, the mutations ultimately disrupt endochondral ossification, the biologic process responsible for the development and linear growth of the skeleton. Indeed, a wide range of morphologic abnormalities of the skeletal growth plate, the anatomic structure in which endochondral ossification occurs, have been described in the chondrodysplasias.

Diagnosis and Treatment.

The first step is to establish the correct diagnosis. This allows one to predict a prognosis and to anticipate the medical and surgical problems associated with a particular disorder. Establishing a diagnosis helps to distinguish between lethal disorders and nonlethal disorders in a premature or newborn infant (see Boxes 682–1 and 682–2). A poor prognosis for long-term survival may argue against initiating extreme lifesaving measures for thanatophoric dysplasia or achondrogenesis types Ib or II, whereas such measures may be indicated for infants with spondyloepiphyseal dysplasia congenita or diastrophic dysplasia, which have a good prognosis if the infant survives the newborn period.

Because there is no definitive therapy to normalize bone growth in any of the disorders, management is directed at preventing and correcting skeletal deformities, treating nonskeletal complications, genetic counseling, and helping patients and families learn to cope. Each disorder has its own unique set of problems, and consequently management must be tailored to each disorder. Medical information for a few disorders can be found at the Medical Information on Dwarfism website (see references at the end of the chapter).

There are a number of problems common to many chondrodysplasias for which general recommendations can be made. Children with most chondrodysplasias should avoid contact sports and other activities that cause injury or stress to joints. Good dietary habits should be established in childhood to prevent or minimize obesity in adulthood. Dental care should be started early to minimize crowding and malalignment of teeth. Children and relatives should be given the opportunity to participate in support groups, such as the Little People of America and Human Growth Foundation.

Two controversial approaches have been used to increase bone length. Surgical limb lengthening has been employed for a few disorders. Its greatest success has been in achondroplasia in which nonskeletal tissues tend to be redundant and easily stretched. The procedure is usually performed during adolescence. Injections of human growth hormone in pharmacologic doses comparable to those used to treat Turner syndrome have also been tried in several disorders; the results have been equivocal.

Chapter 683 - Disorders Involving Cartilage Matrix Proteins

William A. Horton
Jacqueline T. Hecht

Some bone and joint disorders result from functional disturbances of cartilage matrix proteins. They fall into four groups corresponding primarily to the defective proteins: three collagens and the noncollagenous proteins COMP (cartilage oligomeric matrix protein) and matrilin 3. The clinical phenotypes differ between and within the groups, especially the spondyloepiphyseal dysplasia (SED) group. In some groups, there is substantial variation in clinical severity.

SPONDYLOEPIPHYSEAL DYSPLASIAS

The term *spondyloepiphyseal dysplasia* refers to a heterogeneous group of disorders characterized by shortening of the trunk and, to a lesser extent, the limbs. Severity ranges from achondrogenesis type II to the slightly less severe hypochondrogenesis (these two types are lethal in the perinatal period) to SED congenita and its variants, including **Kniest dysplasia** (which are apparent at birth and are usually nonlethal), to late-onset SED (which may not be detected until adolescence or later). The radiographic hallmarks are abnormal development of the vertebral bodies and of epiphyses, the extent of which corresponds to the clinical severity. All the SEDs result from heterozygous mutations of *COL2A1*; they are autosomal dominant disorders. The mutations are dispersed throughout the gene; there is a poor correlation between the mutation's location and the resultant clinical phenotype.

Lethal Spondyloepiphyseal Dysplasias.

Achondrogenesis type II (OMIM 200610) is characterized by severe shortening of the neck and trunk and especially the limbs and by a large, soft head. Fetal hydrops and prematurity are common; infants are stillborn or die shortly after birth. Hypochondrogenesis (OMIM 12014002) refers to a clinical phenotype intermediate between achondrogenesis type II and SED congenita. It is typically lethal in the newborn period.

The severity of radiographic changes correlate with the clinical severity (Fig. 683–1). Both conditions produce short, broad tubular bones with cupped metaphyses. The pelvic bones are hypoplastic, and the cranial bones are not well mineralized. The vertebral bodies are poorly ossified in the entire spine in achondrogenesis type II and in the cervical and sacral spine in hypochondrogenesis. The pedicles are ossified in both.

Spondyloepiphyseal Dysplasia Congenita.

The phenotype of this group, SED congenita (OMIM 183900), is apparent at birth. The head and face are usually normal, but a cleft palate is common. The neck is short and the chest is barrel shaped (Fig. 683–2). Kyphosis and exaggeration of the normal lumbar lordosis are common. The proximal segments of the limbs are shorter than the hands and feet, which often appear normal. Some infants have clubfoot or exhibit hypotonia.

Figure 683-1 Stillborn with achondrogenesis type II. Note poor ossification of calvaria, vertebral bodies, and sacrum; hypoplasia of pelvic bones; and short tubular bones with cupped metaphyses.

Skeletal radiographs of the newborn reveal short tubular bones, delayed ossification of vertebral bodies, and proximal limb bone epiphyses (Fig. 683–3). Hypoplasia of the odontoid process; a short, square pelvis with a poorly ossified symphysis pubis; and mild irregularity of metaphyses are apparent.

Infants usually have normal developmental milestones; a waddling gait typically appears in early childhood. Childhood complications include respiratory compromise from spinal deformities and spinal cord compression due to cervicomedullary instability. The disproportionateness and shortening become progressively worse with age, and adult heights range from 95 to 128?cm. Myopia is typical; adults are predisposed to retinal detachment. Precocious osteoarthritis occurs in adulthood and requires surgical joint replacement.

Kniest Dysplasia.

The Kniest dysplasia variant of SED (OMIM 156550) presents at birth with a short trunk and limbs associated with a flat face, prominent eyes, enlarged joints, cleft palate, and clubfoot. Radiographs show vertebral defects and short tubular bones with epiphyseal irregularities and metaphyseal enlargement that gives rise to a dumbbell appearance.

Motor development is often delayed because of the joint deformities, although intelligence is normal. Hearing loss and myopia commonly develop during childhood, and retinal detachment may occur as a late complication. Joint enlargement progresses during childhood and becomes painful; it is accompanied by flexion contractures and muscle atrophy, which may be incapacitating by adolescence.

Figure 683-2 Spondyloepiphyseal dysplasia congenita is shown in infancy and early childhood. Note

the short extremities, relatively normal hands, flat facies, and exaggerated lordosis.

Late-Onset Spondyloepiphyseal Dysplasia.

This term refers to a mild to very mild clinical phenotype characterized by slightly short stature associated with mild epiphyseal and vertebral abnormalities on radiographs. It is typically detected during childhood or adolescence but may go unrecognized until adulthood when precocious osteoarthritis appears. This designation is nosologically distinct from SED tarda, which is clinically

Figure 683-3 Radiograph of spondyloepiphyseal dysplasia congenita pelvis demonstrating squared pelvis, hypoplastic capital femoral epiphyses, and femoral necks that are wide and short.

similar but results from mutation of the X-linked gene *SEDL.*

STICKLER DYSPLASIA (HEREDITARY OSTEOARTHRO-OPHTHALMOPATHY

Short stature is not a feature of Stickler dysplasia (OMIM 184840). It resembles SED because of its joint and eye manifestations. Mutations of genes encoding type XI collagen, which functionally interacts with type II collagen, have been identified in Stickler-like disorders (OMIM 184840, OMIM 215150). Stickler dysplasia is often identified in the newborn because of cleft palate and micrognathia (Pierre Robin anomaly). Infants typically have severe myopia and additional ophthalmologic complications, including choroidoretinal and vitreous degeneration; retinal detachment is common during childhood (Fig. 683–4). Sensorineural hearing loss may arise during adolescence, which is when symptoms of osteoarthritis may begin. Special attention must be given to the eye complications even in childhood.

SCHMID METAPHYSEAL DYSPLASIA

Schmid metaphyseal dysplasia (OMIM 156500) is one of several chondrodysplasias in which metaphyseal abnormalities dominate the radiographic features. It typically presents in early childhood with mild short stature, bowing of the legs, and a waddling gait (Fig. 683–5). Enlargement of joints, such as the wrist, may be found. Radiographs show flaring and irregular mineralization of the metaphyses of tubular bones of the proximal limbs (Fig. 683–6). Coxa vara is usually present and may

Figure 683-4 Stickler syndrome in mother and child. The facies are flat and the eyes are prominent.

Figure 683-5 Female patient with metaphyseal dysplasia, type Schmid. The facies are normal and stature is mildly reduced. Mild tibia vara is present.

require surgical correction. Short stature becomes more evident with age and affects the lower extremities more than the upper extremities; the manifestations are limited to the skeleton.

Schmid metaphyseal chondrodysplasia is due to heterozygous mutations of the gene encoding type X collagen; it is an autosomal dominant trait. The distribution of type X collagen is restricted to the region of growing bone in which cartilage is converted into bone. This may explain why radiographic changes are confined to the metaphyses.

PSEUDOACHONDROPLASIA AND MULTIPLE EPIPHYSEAL DYSPLASIA

Pseudoachondroplasia (OMIM 177170) and multiple epiphyseal dysplasia (MED) (OMIM 600969) are two distinct phenotypes that are grouped together because they result from mutations of the gene encoding COMP. The mutations are heterozygous in both; they are autosomal dominant traits. The clinical phenotypes are restricted to skeletal tissues.

Newborns with pseudoachondroplasia are average in size and appearance. Gait abnormalities and short stature mainly affect the limbs and become apparent in late infancy. The short stature becomes marked as the child grows and is associated with generalized joint laxity (Fig. 683–7). The hands are short, broad, and deviated in an ulnar direction; the forearms are bowed. Developmental milestones and intelligence are usually normal.

Figure 683-6 Radiograph of lower extremities in Schmid metaphyseal dysplasia showing short tubular bones and metaphyseal flaring and irregularities, abnormal capital femoral epiphyses, and femoral necks. The epiphyses are normal. Coxa vara is present.

Lumbar lordosis and deformities of the knee develop during childhood; the latter frequently requires surgical correction. Pain is common in weight-bearing joints during childhood and adolescence, leading to osteoarthritis late in the second decade of life. Adults range in height from 105 to 128?cm.

Skeletal radiographs show distinctive abnormalities of vertebral bodies and of both epiphyses and metaphyses of tubular bones (Fig. 683–8).

The MED phenotype has skeletal abnormalities that predominantly affect the epiphyses as noted on radiographs. Two classic forms are a severe Fairbank type and a mild Ribbing type. Because of overlap in clinical features and because COMP mutations are found in both types, they may be considered clinical variants.

The more severe clinical phenotype has its onset during childhood, with mild short-limbed short stature, pain in weight-bearing joints, and a waddling gait. Radiographs show delayed and irregular ossification of epiphyses. More mildly affected individuals may not be recognized until adolescence or adulthood. Radiographic changes may be limited to the capital femoral epiphyses. In the latter case, mild MED must be distinguished from bilateral Legg-Perthes disease. Precocious osteoarthritis of hips and knees is the major complication in adults with MED. Adult heights range from 136 to 151?cm.

Figure 683-7 *A,* Pseudoachondroplasia in an adolescent male. The facies and head circumference are normal. There is shortening of all extremities and bowing of the lower extremities. *B*, Photograph of hands, demonstrating short stubby fingers.

Figure 683-8 *A,* Lateral thoracolumbar spine radiograph of patient with pseudoachondroplasia showing central protrusion (tonguing) of the anterior aspect of upper lumbar and lower thoracic vertebrae. Note reduced vertebral body heights (platyspondyly) and secondary lordosis. *B,* Lower extremity radiograph of patient with pseudoachondroplasia showing large metaphyses, poorly formed epiphyses, and marked bowing of the long bones.

There are families with clinical and radiographic manifestations of MED that are not due to mutations of COMP. Some are linked to the gene encoding one of the type IX collagen chains. It has been suggested that COMP and type IX collagen interact functionally in cartilage matrix, thus explaining why mutations of different genes produce similar pictures. Mutations of the gene coding for another cartilage matrix protein, matrilin 3, have also been found in patients with MED.

Chapter 684 - Disorders Involving Transmembrane Receptors

William A. Horton
Jacqueline T. Hecht

Disorders involving transmembrane receptors result from heterozygous mutations of genes encoding these receptors: *FGFR3* and *PTHR*. The mutations cause the receptors to become activated in the absence of physiologic ligands, which accentuates normal receptor function of negatively regulating bone growth. The mutations act by gain of negative function. In the *FGFR3* mutation group, in which the clinical phenotypes range from severe to mild, the severity appears to correlate with the extent to which the receptor is activated. Both *PTHR* and especially *FGFR3* mutations tend to recur in unrelated individuals.

ACHONDROPLASIA GROUP

The achondroplasia group represents a substantial percentage of patients with chondrodysplasias and contains thanatophoric dysplasia, the most common lethal chondrodysplasia with an incidence of 1 in 35,000 births; achondroplasia, the most common nonlethal chondrodysplasia with an incidence of 1 in 15,000 to 1 in 40,000 births, and hypochondroplasia. All three have mutations in a small number of locations in the *FGFR3* gene. There is a strong correlation between the mutation site and the clinical phenotype.

Thanatophoric Dysplasia.

Thanatophoric dysplasia (TD) (OMIM 187600, OMIM 187610) presents before or at birth. In the former situation, ultrasonographic examination in mid gestation or later reveals a large head and very short limbs; the pregnancy is often accompanied by polyhydramnios and premature delivery. Very short limbs, short neck, long narrow thorax, and large head with midfacial hypoplasia dominate the clinical phenotype at birth (Fig. 684–1). The cloverleaf skull deformity known as **kleeblattschädel** is sometimes found. Newborns have severe respiratory distress because of their small thorax. Although this distress can be treated by intense respiratory care, the long-term prognosis is poor.

Skeletal radiographs distinguish two slightly different forms called TD I and TD II. In

the more common TD I, radiographs show large calvariae with a small cranial base, marked thinning and flattening of vertebral bodies visualized best on lateral view, very short ribs, severe hypoplasia of pelvic bones, and very short and bowed tubular bones with flared metaphyses (Fig. 684–2). The femurs are curved and shaped like a telephone receiver. TD II differs mainly in that there are longer and straighter femurs.

Figure 684-1 Stillborn infant with thanatophoric dysplasia. Limbs are very short, with upper limbs extending only two thirds of the way down the abdomen. The chest is narrow, exaggerating the protuberance of the abdomen. The head is relatively large.

The TD II clinical phenotype is associated with mutations that map to codon 650 of *FGFR3,* causing the substitution of a glutamic acid for the lysine. This activates the tyrosine kinase activity of a receptor that transmits signals to intracellular pathways. Mutations of the TD I phenotype map mainly to two regions in the extracellular domain of the receptor, where they substitute cysteine residues for other amino acids. Free cysteine residues are thought to form disulfide bonds promoting dimerization of receptor molecules, leading to activation and signal transmission.

TD I and TD II represent new mutations to normal parents. The recurrence risk is low. Because the mutated codons in TD are mutable for unknown reasons and because of the theoretical risk for germ cell mosaicism, parents are offered prenatal diagnosis for subsequent pregnancies.

Achondroplasia.

Achondroplasia (OMIM 100800) is the prototype chondrodysplasia. It typically presents at birth with short limbs, a long narrow trunk, and a large head with midfacial hypoplasia and prominent forehead (Fig. 684–3). The limb shortening is greatest in the proximal segments, and the fingers often display a trident configuration. Most joints are hyperextensible, but extension is restricted at the elbow. A thoracolumbar gibbus is often found. Usually, birth length is slightly less than normal but occasionally plots within the low-normal range.

DIAGNOSIS.

Skeletal radiographs confirm the diagnosis (Fig. 684–4). The calvarial bones are large, whereas the cranial base and facial bones are small. The vertebral pedicles are short

Figure 684-2 *A*, Neonatal radiograph of a child with thanatophoric dysplasia. Note medial acetabular spurs *(black arrow)*, hypoplastic iliac bones, bowed femora with rounded protrusion of proximal femurs, hypoplastic thorax, and wafer-thin vertebral bodies. *B*, Lateral radiograph of the thoracolumbar spine in thanatophoric dysplasia, showing marked vertebral flattening and short ribs. Ossification defect of the central portion of the vertebral bodies is present.

Figure 684-3 Infant with achondroplasia. The cranium is large and the forehead prominent. The nasal bridge is moderately flat, and the chest is small compared with the abdomen. Note medial arm and forearm creases, which reflect bowing at the sharpest concavity of the limbs.

throughout the spine as noted on a lateral radiograph. The interpedicular distance, which normally increases from the first to the fifth lumbar vertebrae, decreases in achondroplasia. The iliac bones are short and round, and the acetabular roofs are flat. The tubular bones are short with mildly irregular and flared metaphyses. The fibula is disproportionately long compared with the tibia.

CLINICAL MANIFESTATIONS.

Infants usually exhibit delayed motor milestones, frequently not walking alone until 18–24 mo. This is due to hypotonia and mechanical difficulty balancing the large head on a normal-sized trunk and short extremities. Intelligence is normal unless central nervous system complications develop. As the child begins to walk, the gibbus usually gives way to an exaggerated lumbar lordosis.

Infants and children with achondroplasia progressively fall below normal standards for length and height. They can be plotted against standards established for achondroplasia. Adult heights typically range between 118 and 145?cm for males and between 112 and 136?cm for females. Surgical limb lengthening and human growth hormone treatment have been used to increase height; both are controversial.

There are several potential neurologic complications. Virtually all infants and children with achondroplasia have large heads, although only a fraction has true hydrocephalus. Head circumference should be carefully monitored using standards developed for achondroplasia, as should neurologic function in general. The spinal canal is stenotic, and spinal cord compression may occur at the foramen magnum and in the lumbar spine. The former most often presents in infants and small children; it may be associated with hypotonia, failure to thrive, quadriparesis, central and obstructive apnea, and sudden death. Surgical correction may be required for severe stenosis. Lumbar spinal stenosis usually does not present until early adulthood. Symptoms include paresthesias, numbness, and claudication in the legs. Loss of bladder and bowel control may be late complications.

Bowing of the legs is common and may need to be corrected surgically. Other common problems include dental crowding, articulation difficulties, obesity, and frequent episodes of otitis media, which may contribute to hearing loss.

Figure 684-4 Radiograph of infant with achondroplasia, demonstrating interpedicular narrowing of the first through fifth lumbar vertebrae, short round iliac bones, and flat acetabular roofs. The tubular bones are short and show mild irregularities of the metaphyses.

GENETICS.

All patients with typical achondroplasia have mutations at *FGFR3* codon 380. The mutation maps to the transmembrane domain of the receptor and is thought to stabilize receptor dimers that enhance receptor signals, the consequences of which inhibit linear bone growth. Achondroplasia behaves as an autosomal dominant trait; most cases arise from a new mutation to normal parents.

Because of the high frequency of achondroplasia among dwarfing conditions, it is relatively common for adults with achondroplasia to marry. Such couples have a 50% risk of transmitting their condition, heterozygous achondroplasia, to each offspring, as well as a 25% risk for homozygous achondroplasia. The latter condition exhibits intermediate severity between thanatophoric dysplasia and heterozygous achondroplasia and is usually lethal in the newborn period.

Hypochondroplasia.

Hypochondroplasia (OMIM 146000) resembles achondroplasia but is milder. Usually, it is not apparent until childhood, when mild short stature affecting the limbs becomes evident. Children have a stocky build and slight frontal bossing of the head. Radiographic changes are mild and consistent with the mild achondroplastic phenotype. Complications are rare; some patients are never diagnosed. Adult heights range from 116 to 146?cm. An *FGFR3* mutation at codon 540 has been found in many patients with hypochondroplasia.

JANSEN METAPHYSEAL DYSPLASIA

Jansen metaphyseal chondrodysplasia (OMIM 156400) is a rare, dominantly inherited chondrodysplasia characterized by severe shortening of limbs associated with an unusual facial appearance. Sometimes it is accompanied by clubfoot and hypercalcemia. At birth, a diagnosis can be made from these clinical findings and radiographs that show short tubular bones with characteristic metaphyseal abnormalities that include flaring, irregular mineralization, fragmentation, and widening of the physeal space. The epiphyses are normal.

The joints become enlarged and limited in mobility with age. Flexion contractures develop at the knees and hips, producing a bent-over posture. Intelligence is normal, although there may be hearing loss.

Jansen metaphyseal chondrodysplasia is the only disorder due to mutations of *PTHR*. This G protein–coupled transmembrane receptor serves as a receptor for both *PTH* and *PTHrP*. Signaling through this receptor serves as a brake on the terminal differentiation of cartilage cells at a critical step in bone growth. Because the mutations activate the receptor, they enhance the braking effect and thereby slow bone growth.

Chapter 685 - Disorders Involving Ion Transporter

William A. Horton
Jacqueline T. Hecht

In order of decreasing severity, the disorders involving ion transporters include achondrogenesis type 1B, atelosteogenesis type II, and diastrophic dysplasia. They result from the functional loss of the sulfate ion transporter called *diastrophic dysplasia sulfate transporter* (DTDST), which is also referred to as SLC26A2 (solute carrier family 26, member 2). This protein transports sulfate ions into cells and is important for cartilage cells that add sulfate moieties to newly synthesized proteoglycans destined for cartilage extracellular matrix. Matrix proteoglycans are responsible for many of the properties of cartilage that allow it to serve as a template for skeletal development. The clinical manifestations result from defective sulfation of cartilage proteoglycans.

A number of mutant alleles have been found for the *DTDST* gene; they variably disturb transporter function. None is sufficient to cause disease alone; hence, the disorders are recessive traits requiring the presence of two mutant alleles. The phenotype is determined by the combination of mutant alleles; some alleles are present in more than one disorder.

Diastrophic Dysplasia (OMIM 22600).

This well-characterized disorder is recognized at birth by the presence of very short extremities, clubfoot, and short hands with proximal displacement of the thumb producing a hitchhiker appearance (Fig. 685–1). The hands are usually deviated in an ulnar direction. Bony fusion of the metacarpophalangeal joints (symphalangism)

Figure 685-1 Child with diastrophic dysplasia. The extremities are dramatically shortened *(top)*. Clubfoot is commonly observed *(middle left)*. The fingers are short, especially the index finger; the thumb characteristically is proximally placed and has a hitchhiker appearance *(middle right)*. The upper helix of the ears becomes swollen 3–4 wk postnatally *(lower left)*, and this inflammation spontaneously resolves, leaving a cauliflower deformity of the pinnae *(lower right)*.

is common, as is restricted movement of many joints, including hips, knees, and elbows. The external ears frequently become inflamed soon after birth. The inflammation resolves spontaneously but leaves the ears fibrotic and contracted (“cauliflower” ear deformity). Many newborns have a cleft palate.

Radiographs reveal short and broad tubular bones with flared metaphyses and flat, irregular epiphyses (Fig. 685–2).

The capital femoral epiphyses are hypoplastic, and the femoral heads are broad. The ulnae and fibulae are disproportionately short. Carpal centers may be developmentally advanced; the first metacarpal is typically ovoid, and the metatarsals are twisted medially. There may be vertebral abnormalities, including clefts of cervical vertebral lamina and narrowing of the interpedicular distances in the lumbar spine.

Complications are primarily orthopedic and tend to be severe and progressive. The clubfoot deformity in the newborn resists usual treatments, and multiple corrective surgeries are common. Scoliosis typically develops during early childhood. It often requires multiple surgical procedures to control and sometimes compromises respiratory function in older children. Despite the orthopedic problems, patients typically have a normal life span and reach adult heights in the 105–130?cm range, depending on the severity of scoliosis. Growth curves are available for diastrophic dysplasia.

Some patients are mildly affected and exhibit slight short stature and joint contractures, no clubfoot or cleft palate, and correspondingly mild radiographic changes. The mild phenotype tends to recur within families. The recurrence risk for this autosomal recessive condition is 25%. Ultrasonographic examination can be employed for prenatal diagnosis, but if *DTDST* mutations can be identified in the parents, molecular genetic diagnosis is possible.

Achondrogenesis Type 1B (OMIM 600972) and Atelosteogenesis Type II (OMIM 256050).

Both of the conditions are rare recessive lethal chondrodysplasias. The most serious is achondrogenesis type 1B, which demonstrates a severe lack of skeletal development usually detected in utero or after a miscarriage. The limbs are extremely short, and the head is soft. Skeletal radiographs show poor to missing ossification of skull bones, vertebral bodies, fibulas, and ankle bones. The pelvis is hypoplastic, and the ribs are short. The femurs are short and exhibit a trapezoid shape with irregular metaphyses.

Infants with *atelosteogenesis type II* are stillborn or die soon after birth; prematurity is common. They exhibit very short limbs, especially the proximal segments. Clubfoot and dislocations of the elbows and knees may be detected. Hypoplasia of vertebral bodies, especially in the cervical and lumbar spine, is found on radiographs. The femora and humeri are hypoplastic and display a club-shaped appearance. The distal limb bones, including the ulna and fibula, are poorly ossified.

Both disorders carry a 25% recurrence risk and are potentially detectable in utero by mutation analysis if the mutant alleles are identified in the parents. Prenatal

diagnosis should be possible with fetal ultrasonography.

Figure 685-2 Radiograph of hands in diastrophic dysplasia. The metacarpals and phalanges are irregular and short. The first metacarpal is ovoid.

Chapter 686 - Disorders Involving Transcription Factors

William A. Horton
Jacqueline T. Hecht

There are three disorders involving transcription factors that result in bone dysplasias. One, campomelic dysplasia, is historically considered a chondrodysplasia. The other two, cleidocranial dysplasia and nail-patella syndrome, have been regarded as dysostoses, or abnormalities of single bones. The mutant genes that encode these transcription factors are *SOX9*, *CBFA1*, and *LMX1B*, respectively and are members of much larger gene families. For instance, *SOX9* is a member of the *SOX* family of genes related to the *SRY* (sex-determining region of the Y chromosome) gene; *CBFA1* belongs to the runt family of transcription factor genes, and *LMX1B* is one of the *LIM* homeodomain gene family. All three disorders are due to haploinsufficiency of the respective gene products; the disorders are dominant traits.

Campomelic Dysplasia.

Apparent in newborn infants, campomelic dysplasia (OMIM 114290) is characterized by bowing of long bones (especially in the lower legs), short bones, respiratory distress, and other anomalies that include defects of the cervical spine, central nervous system, heart, and kidneys. Several cases of sex reversal of XY males have been reported. Radiographs confirm the bowing and often show hypoplasia of the scapulae and

Figure 686-1 Radiograph of lower extremities of a child with campomelic dysplasia. Note bowed femurs, which are not particularly wide as compared with the thick bowed tibiae and fibulae.

Figure 686-2 Cleidocranial dysplasia demonstrating approximation of the shoulder girdle in the midline. Note prominent high forehead and hypertelorism.

pelvic bones (Fig. 686–1). Affected infants usually die of respiratory distress in the neonatal period.

Cleidocranial Dysplasia.

Cleidocranial dysplasia (OMIM 114290) is recognized in infants because of drooping shoulders, open fontanelles, prominent forehead, mild short stature, and dental abnormalities (Fig. 686–2). Radiographs reveal hypoplastic or absent clavicles, delayed ossification of the cranial bones with multiple ossification centers (wormian bones), and delayed ossification of pelvic bones. The course is usually uncomplicated except for dislocations, especially of the shoulders, and dental anomalies that require therapy.

Nail-Patella Syndrome.

Dysplasia of the nails, absence or hypoplasia of the patella, abnormalities of the elbow, and spurs or “horns” extending from the iliac bones characterize the nail-patella syndrome (OMIM 119600), which is also called *osteo-onychodysostosis.* Some patients have nephritis that resembles chronic glomerulonephritis. There is a wide spectrum of severity; some patients present in early childhood, whereas others are asymptomatic as adults.

Chapter 687 - Disorders Involving Defective Bone Resorption

William A. Horton
Jacqueline T. Hecht

Many bone dysplasias display increased bone density; most are rare. Osteopetrosis, which has many subtypes, and pyknodysostosis, and probably others in this category of bone dysplasias, result from defective bone resorption.

OSTEOPETROSIS

Two main forms of osteopetrosis have been delineated: a severe, autosomal recessive form (OMIM 259700) and a mild, autosomal dominant form (OMIM 166600). Disturbances of osteoclast function due to mutations in a gene encoding an osteoclast-specific subunit of the vacuolar proton pump *(TCIRG1)* are found in many patients with the recessive form. The dominant form of osteopetrosis has been genetically mapped to chromosome 1p21. The severe form is usually detected in infancy or earlier because of macrocephaly, hepatosplenomegaly, deafness, blindness, and severe anemia. Radiographs reveal diffuse bone sclerosis. Later films show a bone within a bone, which is characteristic. With time, infants typically fail to thrive and show psychomotor delay and worsening of cranial neuropathies and anemia. Dental problems, osteomyelitis of the mandible, and pathologic fractures are common. The most severely affected patients die during infancy; less severely affected individuals rarely survive beyond the 2nd decade. Those who survive beyond infancy usually have learning disorders but may have normal intelligence despite hearing and visual loss.

Clinical Manifestations.

Most of the manifestations are due to failure to remodel growing bones. This leads to narrowing of cranial nerve foramina and encroachment on marrow spaces, which results in secondary complications, such as optic and facial nerve dysfunction, and anemia accompanied by compensatory extramedullary hematopoiesis in the liver

and spleen.

The autosomal dominant form of osteopetrosis (Albers-Schönberg disease, osteopetrosis tarda, or marble bone disease) usually presents during childhood or adolescence with fractures and mild anemia and, less frequently, as cranial nerve dysfunction, dental abnormalities, or osteomyelitis of the mandible. Skeletal radiographs reveal a generalized increase in bone density and clubbing of metaphyses (Fig. 687–1). Alternating bands of lucent and dense bands produce a sandwich appearance to vertebral bodies. The radiographic changes are sometimes incidental findings in otherwise asymptomatic adolescents and adults.

Treatment.

The basic defect is thought to involve osteoclast differentiation because bone marrow transplantation with reconstitution of osteoclasts from donor cells has been successful in some patients. Calcitriol and interferon gamma have been used with some benefit in some patients. Symptomatic care, such as dental care, transfusions for anemia, and antibiotic treatment of infections, is important for patients who survive infancy.

PYKNODYSOSTOSIS

An autosomal recessive bone dysplasia, pyknodysostosis (OMIM 265800) presents in early childhood as short limbs, characteristic facies, an open anterior fontanelle, a large skull with frontal and occipital bossing, and dental abnormalities.

Figure 687-1 Lateral radiograph showing bone-in-bone appearance that is characteristic of osteopetrosis.

The hands and feet are short and broad, and the nails may be dysplastic. The sclerae may be blue. Minimal trauma often leads to fractures. Treatment is symptomatic and focused mainly on the management of dental problems and fractures. The prognosis is generally good, and patients typically reach heights of 130–150?cm.

Skeletal radiographs show a generalized increase in bone density. In contrast to many disorders in this group, the metaphyses are normal. Other changes include wide sutures and wormian bones in the skull, a small mandible, and hypoplasia of the distal phalanges.

Several mutations have been found in the gene encoding cathepsin K, a cysteine protease that is highly expressed in osteoclasts. The mutations predict loss of enzyme function, suggesting that there is an inability of osteoclasts to degrade bone matrix and remodel bones.

Chapter 688 - Disorders for Which Defects Are Poorly Understood or Unknown

William A. Horton
Jacqueline T. Hecht

There are many chondrodysplasias, or chondrodysplasia clinical phenotypes, for which the genetic cause or basic mechanism is poorly understood or not known. Many illustrate features not found in other disorders and have historical significance in the evolution of chondrodysplasia nomenclature and classification.

Ellis-Van Creveld Syndrome.

The Ellis-van Creveld syndrome (OMIM 225500), also known as *chondroectodermal dysplasia,* is a skeletal and an ectodermal dysplasia. The skeletal dysplasia presents at birth with short limbs, especially the middle and distal segments, accompanied by postaxial polydactyly of the hands and sometimes of the feet. Nail dysplasia and dental anomalies (including neonatal, absent, and premature loss of teeth, and upper lip defects) constitute the ectodermal dysplasia. Common manifestations also include atrial septum defects and other congenital heart defects.

Skeletal radiographs reveal short tubular bones with clubbed ends, especially the proximal tibia and ulna (Fig. 688–1). Carpal bones display extra ossification centers and fusion; cone-shaped epiphyses are evident in the hands. A bony spur is often noted above the medial aspect of the acetabulum.

Ellis-van Creveld syndrome is an autosomal recessive trait that occurs most often in the Amish. Mutations have been identified in a novel gene, *EvC,* although the function of its protein product is unknown. About 30% of patients die of cardiac or respiratory problems during infancy. Life span is otherwise normal; adult heights range from 109–152?cm.

Asphyxiating Thoracic Dystrophy.

Asphyxiating thoracic dystrophy (OMIM 208500), or Jeune syndrome, is an autosomal recessive chondrodysplasia that resembles Ellis-van Creveld syndrome. Newborn infants present with a long, narrow thorax and respiratory insufficiency associated with pulmonary hypoplasia. Neonates often die. Other neonatal manifestations include slightly short limbs and postaxial polydactyly.

Skeletal radiographs show very short ribs with anterior expansion. Tubular limb bones are short with bulbous ends; cone-shaped epiphyses occur in hand bones. The iliac bones are short and square with a spur above the medial aspect of the acetabulum.

If infants survive the neonatal period, respiratory function usually improves as the rib cage grows. Progressive renal dysfunction frequently develops during childhood. Intestinal malabsorption and hepatic dysfunction have also been reported.

Short-Rib Polydactyly Syndromes.

Four types of short-rib polydactyly syndrome (types I–IV) (OMIM 263530, 263520, 263510, 269860) have been described. All are lethal in the newborn period. Neonates present with respiratory distress, an extremely small thorax, very short extremities, polydactyly, and a variety of nonskeletal defects. Radiographs demonstrate very short ribs and tubular bones with changes characteristic for each type. All four types are autosomal recessive traits.

Cartilage-Hair Hypoplasia.

Cartilage-hair hypoplasia (OMIM 250250) is also known as metaphyseal chondrodysplasia– McKusick type. It is recognized during the 2nd year because of growth deficiency affecting the limbs, accompanied by flaring of the lower rib cage, a prominent sternum, and bowing of the legs.

Figure 688-1 Radiograph of lower extremities in Ellis-van Creveld syndrome. Tubular bones are short, and proximal fibula is short. Ossification is retarded in lateral tibia epiphyses, causing a knock-knee deformity.

The hands and feet are short, and the fingers are very short with extreme ligamentous laxity. The hair is thin, sparse, and light colored, and nails are hypoplastic. The skin is hypopigmented.

Radiographs show short tubular bones with flared, irregularly mineralized and cupped metaphyses (Fig. 688–2). The knees are more affected than are the hips, and the fibula is disproportionately longer than the tibia. The metacarpals and phalanges are short and broad. Spinal radiographs reveal mild platyspondyly.

Nonskeletal manifestations associated with cartilage-hair hypoplasia include immune deficiency (T-cell abnormalities, neutropenia, leukopenia, and susceptibility to chickenpox; children also may have complications from smallpox and polio vaccinations), malabsorption, celiac disease, and Hirschsprung disease. Adults are at risk for malignancy, especially skin tumors and lymphoma. Adults reach heights of 107–157?cm.

Cartilage-hair hypoplasia shows autosomal recessive inheritance. Although rare, its highest prevalence is in the Amish and Finnish populations. It results from mutations of a gene coding for a large untranslated RNA component of an enzyme complex involved in processing mitochondrial RNA (RMRP). Loss of this gene product may interfere with processing of 5.8S ribosomal RNA, disturbing protein translation and control of mitosis.

Metatropic Dysplasia.

There are at least two forms of metatropic dysplasia (OMIM 156530, 250600), an autosomal dominant and an autosomal recessive form. Regardless of type, newborn infants present with a long narrow trunk and short extremities.

Figure 688-2 Radiograph of lower extremities in cartilage hair hypoplasia. The tubular bones are short and the metaphyses are flared and irregular. The fibula is disproportionately long compared with the tibia. The femoral necks are short.

A tail-like appendage sometimes extends from the base of the spine. Odontoid hypoplasia is common and may be associated with cervical instability. Kyphoscoliosis appears in late infancy and progresses through childhood, often becoming severe

Figure 688-3 *A*, Radiograph of the lateral thoracolumbar spine in metatropic dysplasia showing severe platyspondyly. *B*, Radiograph of lower extremities in metatropic dysplasia showing short tubular bones with widened metaphyses. The femurs have a dumbbell appearance.

enough to compromise cardiopulmonary function. The joints are large and become progressively restricted in mobility, except in the hands. Contractures often develop in the hips and knees during childhood. Although severely affected infants may die at a young age from respiratory failure, patients usually survive, although they may become disabled as adults from the progressive musculoskeletal deformities. Adult heights range from 110–120?cm.

Skeletal radiographs show characteristic changes dominated by severe platyspondyly and short tubular bones with expanded and deformed metaphyses that exhibit a dumbbell appearance (Fig. 688–3). The pelvic bones are hypoplastic and exhibit a halberd appearance because of a small sacrosciatic notch and a notch above the lateral margin of the acetabulum.

Spondylometaphyseal Dysplasia—Kozlowski Type.

The Kozlowski type of spondylometaphyseal dysplasia (OMIM 184252) presents in early childhood with mild short stature involving mostly the trunk and a waddling gait. The hands and feet may be short and stubby. Radiographs show flattening of vertebral bodies. The metaphyses of tubular bones are widened and irregularly mineralized, especially at the proximal femur. The pelvic bones manifest mild hypoplasia.

Scoliosis may develop during adolescence. The disorder is otherwise uncomplicated, and manifestations are limited to the skeleton. Adults reach heights of 130–150?cm. The Kozlowski type of spondylometaphyseal dysplasia is an autosomal dominant trait.

Juvenile Osteochondroses.

The juvenile osteochondroses are a heterogeneous group of disorders in which regional disturbances in bone growth cause noninflammatory arthropathies. They are summarized in Table 688–1 . Some have localized pain and tenderness (Freiberg disease, Osgood-Schlatter disease, osteochondritis dissecans), whereas others present with painless limitation of joint movement (Legg-Calvé-Perthes disease, Scheuermann disease). Bone growth may be disrupted, leading to deformities. The diagnosis is usually confirmed radiographically, and treatment is symptomatic. The pathogenesis of these disorders is believed to involve ischemic necrosis of primary and

---

TABLE 688-1 -- Juvenile Osteochondroses

Eponym	Affected Region	Age at Presentation
Legg-Calvé-Perthes disease	Capital femoral epiphysis	3–12 yr
Osgood-Schlatter disease	Tibial tubercle	10–16 yr
Sever disease	Os calcaneus	6–10 yr
Freiberg disease	Head of second metatarsal	10–14 yr
Scheuermann disease	Vertebral bodies	Adolescence
Blount disease	Medial aspect of proximal tibial epiphysis	Infancy or adolescence

Osteochondritis dissecans	Subchondral regions of knee, hip, elbow and ankle	Adolescence

secondary ossification centers. Although familial forms have been reported, these disorders usually occur sporadically. **REFERENCES**

Chapter 689 - Osteogenesis Imperfecta

Joan C. Marini

Osteoporosis, a feature of both inherited and acquired disorders, classically demonstrates fragility of the skeletal system and a susceptibility to fractures of the long bones or vertebral compressions from mild or inconsequential trauma. Osteogenesis imperfecta (OI) (brittle bone disease), the most common genetic cause of osteoporosis, is a generalized disorder of connective tissue. The spectrum of OI is extremely broad, ranging from a form that is lethal in the perinatal period to a mild form in which the diagnosis may be equivocal in an adult.

Etiology.

All types of OI are caused by structural or quantitative defects in type I collagen, the primary component of the extracellular matrix of bone and skin. In about 10% of clinically indistinguishable cases, no biochemical or molecular defect of collagen can be demonstrated. It is not clear whether these cases represent limitations in detection or genetic heterogeneity of the disorder.

Epidemiology.

OI is an autosomal dominant disorder that occurs in all racial and ethnic groups. The incidence of OI that is detectable in infancy is about 1 in 20,000. There is a similar incidence of the mild form, OI type I.

Pathology.

The collagen structural mutations cause OI bone to be globally abnormal. The bone matrix contains abnormal type I collagen fibrils and relatively increased levels of types III and V collagen. In addition, several noncollagenous proteins of bone matrix are also reduced. The hydroxyapatite crystals deposited on this matrix are poorly aligned with the long axis of fibrils.

Pathogenesis.

Type I collagen is a heterotrimer, composed of two a1(I) chains and one a2(I) chain. The chains are synthesized as procollagen molecules with short globular extensions

on both ends of the central helical domain. The helical domain is composed of uninterrupted repeats of the sequence Gly-X-Y, where Gly is glycine, X is often proline, and Y is often hydroxyproline. The presence of glycine at every third residue is crucial to helix formation because its small side chain can be accommodated in the spatial constraints of the interior of the helical trimer. The chains are assembled into helices using crucial alignment sites in the carboxyl-terminal extension. Helix formation then proceeds linearly in a carboxyl to amino direction. Concomitant with helix assembly and formation, the chains are glycosylated at lysine residues.

The collagen structural defects are predominately of two types: 85% are point mutations causing substitutions of glycine residues by other amino acids, and 12% are single exon splicing defects. The clinically mild OI type I has a quantitative defect with mutations that cause one a1(I) allele to be functionally null. These patients make a reduced amount of normal collagen.

The relationship between genotype and phenotype remains elusive for the structural mutations. Lethal and nonlethal mutations occur with about equal frequency on both chains. For a2(I) mutations, lethal and nonlethal mutations occur in alternating regions along the chain. For mutations on the a1(I) chain, no model adequately predicts phenotype.

OI is an autosomal dominant disorder. A minority of OI cases with apparent recessive inheritance are caused by parental mosaicism and are also dominant.

Clinical Manifestations.

OI has the triad of fragile bones, blue sclerae, and early deafness. OI was once divided into “congenita,” the forms detectable at birth, and “tarda,” the forms detectable later in childhood; this did not account for the variability of OI. The current classification divides OI into four types based on clinical and radiographic criteria.

TYPE I OSTEOGENESIS IMPERFECTA (MILD).

This form is sufficiently mild that it is often found in large pedigrees. Many type I families have blue sclerae, recurrent fractures in childhood, and presenile hearing loss (30–60%). Both types I and IV are divided into A and B subtypes, depending on the absence (A) or presence (B) of dentinogenesis imperfecta. Other possible connective tissue abnormalities include easy bruising, joint laxity, and mild short stature compared with family members. Fractures result from mild to moderate trauma and decrease after puberty.

OSTEOGENESIS IMPERFECTA TYPE II (PERINATAL LETHAL).

These infants may be stillborn or die in the 1st yr of life. Birthweight and length are small for gestational age. There is extreme fragility of the skeleton and other connective tissues. There are multiple intrauterine fractures of long bones, which have a crumpled appearance on radiographs. There is striking micromelia and bowing of extremities; the legs are held abducted at right angles to the body in the “frog-leg position.” Multiple rib fractures create a beaded appearance and the small thorax contributes to respiratory insufficiency. The skull is large for body size with enlarged anterior and posterior fontanelles. Sclerae are dark blue-gray.

OSTEOGENESIS IMPERFECTA TYPE III (PROGRESSIVE DEFORMING).

This is the most severe nonlethal form of OI and results in significant physical disability. Birthweight and length are often low normal. Fractures usually occur in utero. There is relative macrocephaly and triangular facies (Fig. 689–1). Postnatally, fractures occur from inconsequential trauma and heal with deformity. Disorganization of the bone matrix results in a “popcorn” appearance at the metaphyses (Fig. 689–2). The rib cage has flaring at the base, and pectal deformity is frequent.

Figure 689-1 Infant with type III OI displays shortened bowed extremities, thoracic deformity, and relative macrocephaly.

Virtually all type III patients have scoliosis and vertebral compression. Growth falls below the curve by the first year; all type III patients have extreme short stature. Scleral hue ranges from white to blue.

OSTEOGENESIS IMPERFECTA TYPE IV (MODERATELY SEVERE).

Patients with OI type IV may present at birth with in utero fractures or bowing of lower long bones. They may also present with recurrent fractures after ambulation. Most children have moderate bowing even with infrequent fractures. Children with OI type IV require orthopedic and rehabilitation intervention, but they are usually able to attain community ambulation skills. Fracture rates decrease after puberty. Radiographically, they are osteoporotic and have metaphyseal flaring and vertebral compressions. Patients with type IV have moderate short stature. Scleral hue may be blue or white.

OSTEOGENESIS IMPERFECTA TYPE V (HYPERPLASTIC CALLUS).

There has been a proposal to distinguish as a distinct type a group of patients who are clinically within OI type IV. These patients have hyperplastic callus, calcification of the interosseus membrane of the forearm, and a radiodense metaphyseal band. Bone histology has a distinct meshlike appearance of the lamellae under polarized light. Collagen mutation screening is negative in this small group.

Laboratory Findings.

The diagnosis is confirmed by collagen biochemical studies using fibroblasts cultured from a skin punch

Figure 689-2 Typical features of type III OI radiographs in 6-yr-old child. *A*, Lower long bones are osteoporotic, with metaphyseal flaring, “popcorn” formation at growth plates, and placement of

intramedullary rods. *B*, Vertebral bodies are compressed and osteoporotic.

biopsy. Most collagen structural mutations cause a delay in helix formation, which results in overmodification of chains and the presence of broad or delayed bands on protein electrophoresis. In OI type I, the reduced amount of type I collagen results in an increase in the type III:type I collagen ratio detected by protein electrophoresis. Molecular techniques can identify the particular collagen mutation. This allows family members to be diagnosed using leukocyte DNA.

Severe OI can be detected prenatally by level II ultrasonography as early as 16 wk of gestation. OI and thanatophoric dysplasia may be confused. Fetal ultrasonography may not detect OI type IV and rarely detects OI type I. For recurrent cases, chorionic villus biopsy can be used for biochemical or molecular studies. Amniocytes produce false-positive biochemical studies but can be used for molecular studies in appropriate cases.

In the neonatal period, the normal to elevated alkaline phosphatase levels present in OI distinguish it from hypophosphatasia.

Complications.

The morbidity and mortality hasis>of OI are cardiopulmonary. Recurrent pneumonias and transient cardiac failure occur in childhood, and cor pulmonale is seen in adults.

Neurologic complications include basilar invagination, brainstem compression, hydrocephalus, and syringohydromyelia. Most children with OI types III and IV have basilar invagination, but brainstem compression is infrequent. Basilar invagination is best detected with spiral CT of the craniocervical junction (Fig. 689–3).

Treatment.

There is no cure for OI. For severe nonlethal OI, active physical rehabilitation in the early years allows children to attain a higher functional level than does orthopedic management alone. Children with OI type I and some with type IV are spontaneous ambulators. Children with type III and severe type IV benefit from long-leg plastic braces, gait aids, and a program of swimming and conditioning. Severely affected individuals require a wheelchair for community mobility but can acquire transfer and self-care skills. Teens with OI may require psychologic support with body image issues.

Orthopedic management of OI is aimed at fracture management and correction of deformity to enable function. Fractures

Figure 689-3 Typical features of basilar invagination shown in the sagittal MRI of an asymptomatic child with type III OI. There is invagination of the odontoid above the Chamberlain line causing compression and kinking at the pontomedullary junction *(arrow)*.

should be promptly splinted or cast; OI fractures heal well, and cast removal should be aimed at minimizing immobilization osteoporosis. Correction of deformity of the long bones requires an osteotomy procedure and placement of an intramedullary rod.

Treatments with calcium or fluoride supplements or calcitonin do not improve OI. Growth hormone improves bone histologic characteristics in growth-responsive children (usually types I and IV). Treatment with bisphosphonate drugs is effective in improving mobility and decreasing symptoms in many patients. Intravenous pamidronate or oral alendronate improves quality of life and inhibits bone resorption, thus increasing bone mineralization; these agents decrease fractures and bone pain, although the matrix still contains mutant type I collagen. The benefit for trabecular bone appears most promising, with increased vertebral bone density and height. The treatment effect may be independent of severity, mutation type, or age at onset of therapy. The effect of bisphosphonates on development and on the mechanical properties of cortical bone in long bones is under investigation.

Prognosis.

OI is a chronic condition that limits both life span and functional level. Infants with OI type II usually die within months to a year of life. An occasional child with radiographic type II and extreme growth deficiency may survive to the teen years. Persons with OI type III have a reduced life span with clusters of mortality from pulmonary causes in early childhood, the teen years, and the 40s. OI types I and IV are compatible with a full life span.

Individuals with OI type III are usually wheelchair dependent. With aggressive rehabilitation, they may attain transfer skills and household ambulation. OI type IV children usually attain community ambulation skills either independently or with gait aids.

Genetic Counseling.

OI is an autosomal dominant disorder, and the risk of an affected individual passing the gene to his or her offspring is 50%. An affected child usually has about the same severity of OI as the parent; however, there is variability of expression and the child's condition can be either more or less severe than that of the parent.

The recurrence risk to an apparently unaffected couple of having a second child with OI is empirically noted to be 5–7%; this is the statistical chance that one parent has a germ line mosaicism. The collagen mutation in the unaffected parent is present in some germ cells and may be present in somatic tissues. If genetic testing reveals that a parent is a mosaic carrier, the risk of recurrence may be as high as 50%.

Chapter 690 - Marfan Syndrome

Luther K. Robinson

Marfan syndrome is an autosomal dominantly inherited disorder with nearly complete penetrance but variable expressivity. The incidence of this disorder is about 1 per 5,000–10,000 births; nearly 30% of affected newborns represent sporadically occurring new mutations. Diagnosis of Marfan syndrome is based on clinical findings, some of which are age and maturation dependent (see Table 690–1 (Table Not Available)).

Pathogenesis.

Pathogenesis is related to abnormal biosynthesis of fibrillin-1, a 350-kd extracellular glycoprotein that is the major constituent of microfibrils that provide the scaffolding network of elastic fibers and have an anchoring function in nonelastic tissue such as aortic adventitia and the suspensory ligament of the eye. The fibrillin-1 *(FBN1)* locus resides within the long arm of chromosome 15 (15q21). More than 100 mutations distributed throughout *FBN1* have been described, each appearing to be unique to a given family. The relatively even distribution of mutations throughout *FBN1* likely contributes to the phenotypic variability of the disorder.

Clinical Manifestations.

The diagnosis of the Marfan syndrome is based on the overall pattern of malformation (typically skeletal, cardiovascular, and ocular); many manifestations are age or maturation dependent. Tall stature may be present at birth and persist postnatally. Diminished subcutaneous fat may suggest failure to thrive in early infancy, but aggressive intervention (e.g., hyperalimentation) seldom is indicated. Hypotonia and ligamentous laxity may suggest developmental delays, but cognitive performance is normal for family. Neonatal (infantile, congenital)

Figure 690-1 Marfan syndrome. Note the elongated facies, droopy lids, apparent dolichostenomelia,

and mild scoliosis.

Marfan syndrome is more severe than cases observed in older children and may have clinical similarity to congenital contractural arachnodactyly (CCA), presenting as hypotonia, arachnodactyly, joint laxity and dislocations, and flexion contractures. The face is long, and the skin is lax with diminished recoil. The ears may appear large and pliant. Ocular examination may disclose megalocornea, iridodonesis, or frank lens dislocation. Cardiac examination often reveals murmurs of either mitral valve prolapse with regurgitation or aortic insufficiency, and aortic root dilatation may be documented echocardiographically. Older individuals display tall stature and a long, thin face with narrowness of the maxilla and dental crowding. Ocular abnormalities reflect the connective tissue defect and include blue sclerae, myopia, and suspensory ligament laxity with iridodonesis. Slit lamp examination as early as infancy may disclose lens dislocation, which may be congenital. Iridodonesis is a helpful clinical sign, but patients suspected of having Marfan syndrome should have ophthalmologic evaluations that include slit lamp examinations even in the absence of gross ocular abnormality.

Examination of the musculoskeletal system discloses dolichostenomelia (long thin limbs), and the arm span substantially exceeds the height. The lower segment (distance from pubis to heel) is increased in comparison with the upper segment (height minus lower segment) and contributes to a diminished upper segment/lower segment ratio (U_s /L_s). Hand findings are nonspecific and include long, thin fingers (arachnodactyly) that are hyperextensible. The thumb may be adducted across the narrow palm (Steinberg sign), and the thumb may appreciably overlap the fifth finger when encircling the wrist (wrist sign).

Long gracile ribs may contribute to various sternal anomalies including pectus excavatum (“funnel chest”) or pectus carinatum (“pigeon breast”). The risk of scoliosis among adolescents is increased.

The connective tissue defect contributes to increased distensibility of lung parenchyma and dura and increases the risks of spontaneous pneumothorax and dural ectasia, respectively.

Progressive cardiovascular defects contribute to the substantial morbidity of Marfan syndrome. Echocardiography facilitates early detection of patients with cardiac complications. Progressive aortic root dilatation, whether or not accompanied by auscultatory evidence of aortic disease, occurs in 80–100% of cases and may be congenital. Some aortic root dilatation is seen in 90% of patients by age 20 yr.

In contrast to adults, frank aortic regurgitation is less common in children (seen in about 25% by age 20 yr), perhaps because the amount and duration of distention required to cause aortic dysfunction does not manifest until later life. Mitral valve prolapse (MVP) occurs as frequently as aortic dilatation and tends to be progressive, in contrast to the more static lesion of idiopathic MVP. MVP is usually present in most 8–10 yr old affected children; at this time it is asymptomatic and detected by echocardiography. Progressive MVP is the most common cause of morbidity in children with Marfan syndrome and may manifest as arrhythmias, heart failure, thromboemboli, or endocarditis. Mitral valve regurgitation is seen in about 50% of patients younger than 20 yr of age.

Diagnosis.

Diagnosis of Marfan syndrome is based on clinical criteria (Table 690–1 (Table Not Available)). In general, diagnosis of a sporadic or new mutation case requires that major manifestations of the disorder be present. In cases with an unequivocally affected first-degree relative, milder manifestations with at least one major malformation are supportive of the diagnosis. Tall stature with an abnormally U_s /L_s ratio or an increased span to height ratio (i.e., greater than 1.05) is the most consistent presenting feature. Echocardiography or MRI should show at least aortic root dilatation for age. Other abnormalities such as mitral valve prolapse, mitral regurgitation, or aortic regurgitation are supportive findings. A slit lamp examination is indicated in all suspected cases. Only 60–70% of patients who meet clinical criteria for Marfan syndrome have a known mutation in the fibrillin gene, whereas 12% of patients not meeting criteria have a gene mutation.

Laboratory evaluation should document a negative urinary cyanide nitroprusside test or specific amino acid studies to exclude cystathionine synthase deficiency (homocystinuria). Other conditions that should be excluded include idiopathic MVP, familial thoracic aneurysm (cystic medial necrosis/annuloaortic ectasia, Erdheim disease), congenital contractural arachnodactyly (CCA), Stickler (hereditary arthro-ophthalmopathy), pseudoxanthoma elasticum, and Shprintzen-Goldberg (craniosynostosis marfanoid habitus) syndrome. Although no genotype phenotype correlations have emerged, molecular genetic studies may be applicable to pedigrees with multiple affected family members.

Treatment.

Therapy focuses on prevention of complications and genetic counseling. In view of the potential complexity of management required by some affected individuals, periodic referral to a multidisciplinary center with experience in the Marfan syndrome is advisable.

Pediatricians should work in concert with pediatric subspecialists to develop and coordinate a rational approach to expectant monitoring and treatment of potential complications. Yearly evaluations for such problems as cardiac valvular disease, scoliosis, joint dislocations, or ophthalmologic problems are imperative. Physical therapy may improve neuromuscular tone and strength in affected infants. Moderate nontraumatic physical activity such as bicycling or swimming should be encouraged as tolerated. Maximal exertion should be discouraged because of the stresses that increased cardiac output place on the aorta. Endocarditis prophylaxis should be instituted before dental or other invasive procedures.

** US/LS indicates the ratio of the upper segment (in meters) to the lower segment (in meters).*

ß-Adrenergic blockade with agents such as propranolol or atenolol slows the progression of aortic dilatation and lessens the risk of catastrophic cardiac events. Acute aortic dissection may be managed by composite graft.

Optimal management of the pregnant adolescent has not been established. The risk that pregnancy will worsen cardiovascular abnormalities is of concern. Although substantial data are lacking, patients with minor cardiac manifestations and mild aortic root dilatation may tolerate pregnancy well and experience good maternal and fetal outcomes. Patients with aortic dilatation should be monitored echocardiographically at regular intervals. Although ß-adrenergic blocking agents have not been shown to be teratogenic, the prenatally exposed fetus of a woman with Marfan syndrome should be monitored in the neonatal period for such drug-induced neonatal problems as hypotension, bradycardia, hypothermia, or hypoglycemia.

Prognosis.

Longevity in the Marfan syndrome is diminished in comparison with population norms, primarily because of the increased risk of cardiovascular complications. Progressive dilatation of the aorta and aortic root may lead to aneurysm formation and dissection. These and other concerns pose not only medical but also psychologic stresses for the affected child and his or her parents, particularly during adolescence. Awareness of these issues and referral for support services may facilitate a positive perspective toward this condition.

Genetic Counseling.

The heritable nature of the Marfan syndrome makes recurrence risk (genetic) counseling mandatory. As noted previously, 15–30% of cases are the first affected individuals in their families. Fathers of these sporadic cases have been, on average, 7–10 years older than fathers in the general population. This paternal age effect suggests that these cases represent new dominant mutations with minimal recurrence risks to the future offspring of the normal parents. Each child of an affected individual, however, has a 50% risk of inheriting the chromosome 15 with mutant *FBN1* allele and thus being affected. Recurrence risk counseling is best managed by professionals with expertise in the issues surrounding the chronic nature of this condition.

Section 4 - *Metabolic Bone Disease*

Russell W. Chesney

Chapter 691 - Bone Structure, Growth, and Hormonal Regulation

---

2341

Also see Chapter 44.10 , Chapter 44.11 , Chapter 48.9 , and Chapter 564 .

Bone is a dynamic organ capable of rapid turnover, weight bearing, and withstanding the stresses of various physical activities. It is constantly being formed (modeling) and re-formed (remodeling). It is the major body reservoir for calcium, phosphorus, and magnesium. Disorders that affect this organ and the process of mineralization are designated metabolic bone diseases.

Because bone growth and turnover rates are high during childhood, many clinical features of metabolic bone diseases are more prominent in children than in adults.

The human skeleton consists of a protein matrix, largely composed of a collagen-containing protein, osteoid, on which is deposited a crystalline mineral phase. Although collagen-containing osteoid accounts for 90% of bone protein, other proteins are present, including osteocalcin, which contains ?-carboxyglutamic acid. Synthesis of osteocalcin is vitamin K and vitamin D dependent; and in high bone turnover states, serum osteocalcin values are often elevated.

The microfibrillar matrix of osteoid permits deposition of highly organized calcium phosphate crystals, including hydroxyapatite [$C_{10} (PO_4)_6 \cdot 6H_2O$] and octacalcium phosphate [$Ca_8 (H_2PO_4)_6 \cdot 5H_2O$], plus less organized amorphous calcium phosphate, calcium carbonate, sodium, magnesium, and citrate. Hydroxyapatite is deep within bone matrix, whereas amorphous calcium phosphate coats the surface of newly formed or remodeled bone.

Bone growth occurs in children by the process of calcification of the cartilage cells present at the ends of bone. In accord with the prevailing extracellular fluid (ECF) calcium and phosphate concentrations, mineral is deposited in those chondrocytes or cartilage cells set to undergo mineralization. The main function of the vitamin D/parathyroid hormone (PTH)/endocrine axis is to maintain the ECF calcium and phosphate concentrations at appropriate levels to permit mineralization.

Other hormones also appear to regulate the growth and mineralization of cartilage, including growth hormone acting through insulin-like growth factors, thyroid hormones, insulin, and androgens, and estrogens during the pubertal growth spurt. By contrast, supraphysiologic concentrations of glucocorticoids impair cartilage function and bone growth and augment bone resorption.

Phosphate homeostasis is regulated by the kidneys, because intestinal phosphate absorption is nearly complete and renal excretion determines the serum level. Excessive intestinal phosphate absorption causes a fall in serum levels of ionized calcium and a rise in PTH secretion, resulting in phosphaturia, thus lowering the serum phosphate level and permitting the calcium level to rise. Hypophosphatemia blocks PTH secretion and promotes renal $1,25(OH)_2$ D synthesis. This latter compound also promotes greater intestinal phosphate absorption.

Rates of bone formation are coordinated with alterations in mineral metabolism at both the intestine and kidneys. Inadequate dietary intake or intestinal absorption of calcium causes a fall in serum levels of calcium and its ionized fraction. This serves as the signal for PTH synthesis and secretion, resulting in greater bone resorption to raise the serum calcium level, enhanced distal tubular reabsorption of calcium, and higher rates of synthesis by the kidneys of 1,25-dihydroxyvitamin D ($1,25[OH]_2$ D), or calcitriol, the most active metabolite of vitamin D (Fig. 691–1). Calcium homeostasis thus is

Figure 691-1 The metabolic pathway of vitamin D, indicating its conversion to the hormone $1,25(OH)_2 D_3$ and to $24,25(OH)_2 D_3$. Vitamin D_2 (ergosterol) of plant origin appears to undergo similar metabolic steps.

2342

controlled at the intestine, because the availability of $1,25 (OH)_2$ D ultimately determines the fraction of ingested calcium that is absorbed.

The growth pattern of bones is an acceleration of bone growth (length) of the limbs during prepubescence, increased growth (length) of the trunk (spine) during early adolescence, and increased bone mineral deposition in late adolescence. The use of dual-energy x-ray absorptiometry (DEXA) or quantitative computed tomography (QCT) permits measurement of both bone mineral content and bone density in healthy subjects and in children with metabolic bone disease.

An understanding of the metabolism of vitamin D is necessary to appreciate metabolic bone disease and rickets (see Fig. 691–1). The skin contains 7-dehydrocholesterol, which is converted to vitamin D_3 by ultraviolet radiation; other

inactive vitamin D sterols are also produced (see Chapter 44.10). Vitamin D_3 is then transported in the bloodstream to the liver by a vitamin D–binding protein (DBP); DBP binds all forms of vitamin D. The plasma concentration of free or nonbound vitamin D is much lower than the level of DBP-bound vitamin D metabolites.

Vitamin D also can enter the metabolic pathway by ingestion of dietary vitamin D_2 (ergocalciferol) or vitamin D_3 (cholecalciferol), both of which are absorbed from the intestine because of the action of bile salts. After absorption, ingested vitamin D is transported by chylomicrons to the liver, where, along with skin-derived vitamin D_3 , it is converted to 25-hydroxyvitamin D(25[OH]D) by the action of a hepatic microsomal enzyme requiring oxygen, NADPH, and magnesium to hydroxylate vitamin D at the 25th carbon atom. The 25(OH)D is next transported by DBP to the kidneys, where it undergoes further metabolism. 25(OH)D is the main circulating

TABLE 691-1 -- **Vitamin D Metabolic Values in Plasma of Normal Healthy Subjects**

Metabolite	Plasma Value
Vitamin D_2	1–2?ng/mL
Vitamin D_3	1–2?ng/mL
25(OH) D_2	4–10?ng/mL
25(OH) D_3	12–40?ng/mL
Total 25(OH) D	15–50?ng/mL
24,25$(OH)_2$ D	1–4?ng/mL
1,25$(OH)_2$ D	
Infancy	70–100?pg/mL
Childhood	30–50?pg/mL
Adolescence	40–80?pg/mL
Adulthood	20–35?pg/mL

vitamin D metabolite in humans at a concentration of 20–80?ng/mL (Table 691–1). Because its synthesis is weakly regulated by feedback, its plasma level rises in summer and falls in winter. High vitamin D intake raises the plasma level of 25(OH)D to many times above normal, but the parent vitamin D itself is absorbed by adipose tissue.

In the kidneys, 25(OH)D undergoes further hydroxylation, depending on the prevailing serum concentration of calcium, phosphate, and PTH. If the calcium or phosphate level is reduced or the PTH level is elevated, the enzyme 25(OH)D-1-hydroxylase is activated and 1,25$(OH)_2$ D is formed. This metabolite circulates at a level that is only 0.1% of the level of 25(OH)D (see Table 691–1) and acts on the intestine to increase the active transport of calcium and stimulate

phosphate absorption. Because 1a-hydroxylase is a mitochondrial

TABLE 691-2 -- **Clinical Variants of Rickets and Related Conditions**

Type	Serum Calcium Level	Serum Phosphorus Level	Alkaline Phosphatase Activity	Urine Concentration of Amino Acids	Genetics
I. Calcium deficiency with secondary hyperparathyroidism (deficiency of vitamin D; low 25(OH)D ar no stimulation of higher 1,25$(OH)_2$ D values)					
1. Lack of vitamin D					
a. Lack of exposure to sunlight	N or L	L	E	E	
b. Dietary deficiency of vitamin D	N or L	L	E	E	
c. Congenital	N or L	L	E	E	
2. Malabsorption of vitamin D	N or L	L	E	E

4. Anticonvulsive drugs	N or L	L	E	E	
5. Renal osteodystrophy	N or L	E	E	V	
6. Vitamin D–dependent type I	L	N or L	E	E	AR
II. Primary phosphate deficiency (no secondary hyperparathyroidism)					
1. Genetic primary hypophosphatemia	N	L	E	N	XD
2. Fanconi syndrome					
a. Cystinosis	N	L	E	E	AR
b. Tyrosinosis	N	L	E	E	AR
c. Lowe syndrome	N	L	E	E	XR
d. Acquired	N	L	E	E	
3. Renal tubular acidosis, type II proximal	N	L	E	N	
4. Oncogenic hypophosphatemia	N	L	E	N	

5. Phosphate deficiency or malabsorption						
a. Parenteral hyperalimentation	N	L	E	N		
b. Low phosphate intake	N	L	E	N		
III. End-organ resistance to $1,25(OH)_2\ D_3$						
1. Vitamin D–dependent type II (several variants)	L	L or N	E	E	AR	
IV. Related conditions resembling rickets						
1. Hypophosphatasia	N	N	L	Phosphoethanolamine elevated	AR	
2. Metaphyseal dysostosis						
a. Jansen type	E	N	E	N	AD	
b. Schmid type	N	N	N	N	AD	

N = normal; L = low; E = elevated; V = variable; X = X-linked; A = autosomal; D = dominant; R = recessive; Yes =Y.

enzyme that is tightly feedback regulated, the synthesis of $1,25(OH)_2$ D declines after serum calcium or phosphate values return to normal. Excessive $1,25(OH)_2$ D is converted to an inactive metabolite. In the presence of normal or elevated serum calcium or phosphate concentrations, the renal 25(OH)D-24-hydroxylase is activated, producing 24,25-dihydroxyvitamin D ($24,25[OH]_2$ D), which is a pathway for the removal of excess vitamin D, because the serum levels of $24,25(OH)_2$ D (1–5?ng/mL) become higher after ingestion of large amounts of vitamin D. Although hypervitaminosis D and production of inactive metabolites can occur after oral dosing (see Chapter 44.12), extensive skin exposure to sunlight does not usually produce toxic levels of $25(OH)D_3$, suggesting natural regulation of the production of this metabolite in cutaneous tissue.

Serum $1,25(OH)_2$ D levels are higher in children than in adults, are not as subject to seasonal variability, and peak in the 1st yr of life and again during the adolescent growth spurt. These values must be interpreted in light of the prevailing serum calcium, phosphate, and PTH values and with regard to the entire vitamin D metabolite profile.

Mineral deficiency prevents the normal process of bone mineral deposition. If mineral deficiency occurs at the growth plate, growth slows and bone age is retarded—a condition called rickets. Poor mineralization of trabecular bone resulting in a greater proportion of unmineralized osteoid is the condition of osteomalacia. Rickets is found only in growing children before fusion of the epiphyses, whereas osteomalacia is present at all ages. All patients with rickets have osteomalacia, but not all patients with osteomalacia have rickets. These conditions should not be confused with osteoporosis, a condition of equal loss of bone volume and mineral, caused in childhood by glucocorticoid administration, found in Turner and Klinefelter syndromes, following organ transplantation, or as an idiopathic condition.

Rickets may be classified as calcium-deficient or phosphate-deficient rickets. Because both calcium and phosphate ions constitute bone mineral, the insufficiency of either type in the ECF that bathes the mineralizing surface of bone results in rickets and osteomalacia. The two types of rickets are distinguishable by their clinical manifestations (Table 691–2). Rickets may also occur in the face of mineral deficiency, despite adequate vitamin D stores. True dietary calcium deficiency rickets is found in some parts of Africa but not in North America or Europe. A new form of phosphate-deficiency rickets may occur in infants given prolonged administrations of phosphate-sequestering aluminum salts as a treatment for colic or gastroesophageal reflux. This results in the phosphate depletion syndrome.

Chapter 692 - Primary Chondrodystrophy (Metaphyseal Dysplasia)

In this condition, bowing of the legs, short stature, and a waddling gait appear in the absence of abnormalities of serum levels of calcium and phosphate, alkaline phosphatase activity, or vitamin D metabolites. *Metaphyseal chondrodysplasia (Jansen type)* is typified by cupped and ragged metaphyses, which develop mottled calcification at the distal ends of bone over time. Hypercalcemia, with serum values of 13–15?mg/dL, may occur. The spine may also be deformed by the irregular growth of vertebrae. A defect in the parathyroid hormone receptor type I is associated with this syndrome. *Schmid type* of metaphyseal chondrodysplasia is less severe, although the radiographic appearance of the knees and extreme bowing of the lower limbs resemble signs seen in patients with familial hypophosphatemia. It is associated with defects in collagen type X. The hip abnormalities are more debilitating. Patients with both types of metaphyseal chondrodysplasia have lifelong short stature.

Metaphyseal dysotosis, or *Pyle disease,* results from defects in endochondral bone formation and metaphyseal modeling. The long ends of bones are splayed, resulting in an Erlenmeyer flask defect. Short stature is not present, and serum chemical levels are normal. Leonine features develop if the facial bones are involved.

No effective forms of treatment are available for the chondrodystrophies or dysostosis.

Chapter 693 - Idiopathic Hypercalcemia

Excessive quantities of vitamin D used to enrich food or milk for infants can be associated with hypercalcemia. Although many infants may have been exposed to high levels of vitamin D, only a few develop hypercalcemia, failure to thrive, nephrolithiasis, and decline in renal function. These infants may have radiographic evidence of osteosclerosis and dense bones at the metaphyses. This disorder disappeared with reduction in the vitamin D content of milk but has been reported sporadically when errors in vitamin D formulation of milk have occurred. It may also be observed when growing premature infants are not appropriately weaned from specialized preterm formula enriched with calcium and vitamin D. In addition, at least three separate forms of hypercalcemia have been described.

Williams syndrome, or the elfin facies syndrome, consists of a constellation of manifestations of which hypercalcemia is an infrequent finding. The characteristic facial features include a small mandible, prominent maxilla, and upturned nose. The upper lip has a Cupid's bow curve. Small peglike teeth with numerous caries are common. Feeding problems and failure to thrive during the 1st yr of life are usual. Mild mental retardation and an unusual “cocktail party patter” personality are typical. The types of cardiac lesions found separately or together include supravalvular aortic stenosis, peripheral pulmonary stenosis, hypoplasia of the aorta, coronary artery stenosis, and atrial or ventricular septal defects. Sudden death may be secondary to arrhythmias or coronary artery disease. In hypercalcemic patients, nephrocalcinosis and sclerotic long bones are sometimes evident.

Williams syndrome is sporadic, and some children have hypervitaminosis D without evidence of increased maternal or infantile vitamin D intake. The fundamental defect is a mutation in the elastin gene. In most cases, the circulating values for vitamin D metabolites are normal. Patients with this disorder slowly excrete an infused calcium load and have evidence of increased production of 25(OH)D from vitamin D. Impaired calcitonin secretion to an infused calcium load has also been reported. Treatment is directed at cardiac, social, and educational problems.

Children may also have mild idiopathic hypercalcemia, which is usually transient. Phenotypic features of Williams syndrome

---

are not found. These patients have hypercalciuria and sometimes nephrocalcinosis, possibly resembling infants who received excessive vitamin D. However, no evidence for abnormalities in vitamin D metabolism has been found.

Familial hypocalciuric hypercalcemia is an autosomal dominant condition in which affected children have asymptomatic hypercalcemia without hypercalciuria (see Chapters 564 and 567). Pancreatitis may occur in some families, and in a few kindreds neonates may present with life-threatening parathyroid hyperplasia. Instead of serum calcium levels of 12–15?mg/dL typically found in the parent, these infants have levels exceeding 18?mg/dL. All of these children have had mild parathyroid hyperplasia despite hypercalcemia, suggesting that the parathyroid gland does not respond appropriately to the signal of hypercalcemia. The gene for the calcium-sensing receptor in parathyroid, kidney, and other tissues is abnormal in families with familial benign hypocalciuric hypercalcemia. This gene is located on chromosome 3 in 90% of families, and the gene defect impairs the responsiveness of the calcium receptor to ionized calcium. Vitamin D metabolism is normal. Only the infants with serious hyperparathyroidism require an emergency parathyroidectomy. Although the serum magnesium level is elevated, it is not a serious concern.

If hypercalcemia persists in any of these conditions, therapy with bisphosphonates, which blocks bone resorption, has been useful in normalizing serum calcium values.

Chapter 694 - Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder that radiographically resembles rickets and is defined by low serum alkaline phosphatase activity. It is an inborn error of metabolism in which activity of the tissue-nonspecific (liver/bone/kidney) alkaline phosphatase (TNSALP) is deficient. Single point mutations of the gene for alkaline phosphatase prevent the expression of the activity of this enzyme in vitro and indicate the necessity of this enzyme for normal skeletal mineralization. Missense mutations of the gene for the tissue nonspecific isoenzyme have been found, but other patients may have a regulatory defect involving this enzyme. Activity of the intestinal and placental enzyme is normal.

There is considerable heterogeneity in the severity of the disease. Some cases appear at birth, and diagnosis has even been made in utero by radiographic examination of a fetus. The disease may appear in a lethal neonatal or perinatal form *(congenital lethal hypophosphatasia),* a severe infantile form, or a milder form occurring in childhood or late adolescence *(hypophosphatasia tarda).* The lethal form is characterized by a moth-eaten appearance at the ends of the long bones, by severe deficiency of ossification throughout the skeleton, and by marked shortening of the long bones. Patients with the mild disease may present with bowing of the legs and variable statural shortening. Because calcium accumulation by mature chondrocytes does not occur, patients may appear to have rickets; hypercalcemia is common in the neonatal and infantile forms.

Unusual clinical manifestations include wormian bones in the calvaria, poor calcification of the frontal, parietal, and occipital bones, and premature loss of deciduous or permanent teeth, owing to hypoplasia of dental cementum. Because of the hypercalcemia in the infantile form, nephrocalcinosis is also found. In the childhood form, bone pain, frequent fractures, and milder skeletal deformities are evident, as well as premature tooth loss. The metaphyseal defect consists of irregular ossification, punched-out areas, and metaphyseal cupping.

In hypophosphatasia, large quantities of phosphoethanolamine are found in the urine because this compound cannot be degraded in the absence of TNSALP activity. Plasma inorganic pyrophosphate and pyridoxal–5-phosphate levels are also elevated for the same reason. Seizures in the lethal and infantile form of the disease may relate to impaired pyridoxine metabolism. Although no satisfactory therapy has been found, infusion of plasma rich in alkaline phosphatase activity has been helpful in healing bone in short-term studies. Bone marrow transplantation is successful using donors with normal TNSALP values. The clinical course of this condition often improves spontaneously as an affected child matures, although early death due to renal failure or flail chest leading to pneumonia may also occur in the severe infantile form of the disorder. Rare patients presenting identical clinical and radiographic

patterns have normal serum alkaline phosphatase activities. Their disease has been labeled *pseudohypophosphatasia* and may represent the presence of a mutant alkaline phosphatase isozyme that reacts to artificial substrates in an alkaline environment (i.e., in a test tube) but not in vivo with natural substrates.

Chapter 695 - Hyperphosphatasia

Excessive elevation of the bone isozyme of alkaline phosphatase in serum and significant growth failure characterize hyperphosphatasia. Osteoid proliferation in the subperiosteal portion of bone results in separation of the periosteum from the bone cortex. Bowing and thickening of the diaphyses are common, along with osteopenia. The disease usually has its onset by 2–3 yr of age, when painful deformity developing in the extremities leads to abnormal gait and sometimes fractures. Other common findings include pectus carinatum, kyphoscoliosis, and rib fraying. The skull is large, and the cranium is thickened (widened diploë) and may be deformed. Radiographically, the bony texture is variable; dense areas (showing a teased cotton-wool appearance) are interspersed with radiolucent areas and general demineralization. Long bones appear cylindrical, lose metaphyseal modeling, and contain pseudocysts showing a dense, bony halo.

In this autosomal recessive disorder, serum levels of both calcium and phosphate are normal, whereas urinary leucine amino acid peptidase activity and serum acid phosphatase levels are increased. This disorder is often called *juvenile Paget disease,* because, as in adult-onset Paget disease, calcitonin may reduce the rapid bone turnover found in this disorder; in children, the disorder is more generalized and symmetric. This disorder is distinct from Paget disease because histology of bone reveals a lack of normal cortical bone remodeling and an absence of the classic mosaic pattern of lamellar bone found in that adult condition. Hence, the term *juvenile Paget disease* is inappropriate.

Transient hyperphosphatasia occurs between 2 mo and 2 yr of age, has no associated manifestations other than some mild gastrointestinal symptoms, and is usually detected during routine (screening) laboratory evaluation for some unrelated complaint. Both liver and bone isoenzyme fractions are elevated;

---

there are no other manifestations of hepatic or bone dysfunction. The cause is unknown. Resolution usually occurs within 4–6 mo.

Familial hyperphosphatemia, an autosomal dominant trait, is another benign condition that is distinguished from the transient infantile form by persistent and asymptomatic elevations of serum alkaline phosphatase levels.

A more serious autosomal dominant variant, *expansile skeletal hyperplasia*, is

characterized by early-onset deafness, premature loss of teeth, progressive hyperostotic widening of long bones causing painful phalanges in the hands, episodic hypercalcemia, and enhanced bone remodeling. A defect in the gene that encodes receptor activation of nuclear factor ?B [NF-?B] is relevant. This gene appears to be necessary for osteogenesis, and the defect leads to increased activity in the skeleton of NF-?B.

Chapter 696 - Familial Hypophosphatemia (Vitamin D–Resistant Rickets, X-Linked Hypophosphatemia)

The most commonly encountered non-nutritional form of rickets is familial hypophosphatemia. The usual mode of inheritance is X-linked dominant; some mothers of affected children exhibit clinical evidence of disease, such as bowing or short stature, whereas others show only fasting hypophosphatemia. Autosomal dominant and sporadic forms have also been reported.

Pathogenesis.

Pathogenic mechanisms involve defects in the proximal tubular reabsorption of phosphate and in the conversion of 25(OH)D to $1,25(OH)_2$ D. The latter defect is evidenced by low-normal serum $1,25(OH)_2$ D levels despite hypophosphatemia and by the finding that further phosphate depletion of subjects with familial hypophosphatemia does not stimulate $1,25(OH)_2$ D synthesis as it does in normal subjects. Both a renal tubular reabsorption defect and reduced $1,25(OH)_2$ D synthesis are found in an animal model of this disease. In addition, oral phosphate supplementation alone cannot completely heal bone disease; the correction of osteomalacia requires $1,25(OH)_2$ D therapy. The activity of the Na^+ -dependent phosphate transporter in the renal proximal tubule is reduced, resulting in excessive urinary phosphate excretion; however, this transporter protein is encoded on chromosome 5. Because the X-linked dominant disorder has an X-linked inheritance pattern, the abnormal gene found at Xp 22.1 is termed *PHEX* or *p*hosphate-regulating gene with *h*omologies to *e*ndopeptidases on the *X* chromosome. In the autosomal dominant form of hypophosphatemic rickets, mutations in the fibroblast growth factor, F6F23, are found. F6F23 appears to be a natural substrate for PHEX; and if F6F23 is not cleaved, it will diminish renal tubular phosphate transport and the synthesis of $1,25(OH)_2$ D.

Clinical Manifestations.

Children with familial hypophosphatemia present with bowing of the lower extremities related to weight bearing at the age of walking. Tetany is not present, and the profound myopathy, rachitic rosary, and Harrison groove (pectus deformity) characteristic of calcium-deficient rickets are not evident (see Chapter 44.10). These children develop a waddling gait, smooth (rather than angular) bowing of the lower extremities, coxa vara, genu varum, genu valgum, and short stature. The adult height of untreated patients is 130–165?cm.

Pulp deformities and lesions of **intraglobular dentin** are characteristic tooth abnormalities, although enamel defects are found only occasionally. By contrast, calcium-deficient rickets usually results in enamel defects. Periapical infections are found in both forms of rickets. Therapy for metabolic bone disease does not correct the defect in intraglobular dentin in this condition.

Radiographic findings include metaphyseal widening and fraying and coarse-appearing trabecular bone. Cupping of the metaphysis occurs at the proximal and distal tibia and at the distal femur, radius, and ulna.

Laboratory Findings.

Patients have a normal or slightly reduced serum calcium level (9–9.4?mg/dL; 2.24–2.34?mM), a moderately reduced serum phosphate level (1.5–3?mg/dL; 0.48–0.96?mM), elevated alkaline phosphatase activity, and no evidence of secondary hyperparathyroidism. Urinary phosphate excretion is large, despite hypophosphatemia, indicating a defect in renal tubular phosphate reabsorption possibly related to failure of PHEX to cleave and reduce F6F23 action. This disorder is typical of pure phosphate-deficient rickets, because aminoaciduria, glucosuria, bicarbonaturia, and kaliuria are never found. In potential obligate heterozygotes, who later develop disease, serum phosphate levels may remain normal for the first several months of life. The first laboratory abnormality is often a rise in serum alkaline phosphatase activity. The serum phosphate level probably remains normal for several months, because the glomerular filtration rate is quite low in neonates. Parathyroid hyperplasia with elevated serum parathyroid hormone (PTH) values is occasionally found, sometimes in sporadic cases.

Treatment.

Oral phosphate supplements coupled with a vitamin D analogue to offset the secondary hyperparathyroidism that may accompany an oral phosphate load is the preferred treatment. Oral phosphate is usually given every 4?hr at least five times a day, because urinary excretion is constant and patients quickly become hypophosphatemic. Young children should receive 0.5–1?g/24?hr, whereas older children require 1–4?g/24?hr. Phosphate can be given as Joulie solution (dibasic sodium phosphate, 136?g/L, and phosphoric acid, 58.8?g/L), which contains 30.4?mg of phosphate/mL. Thus, a 5?mL dose given every 4?hr five times daily provides 760?mg of phosphate. This solution must be formulated by a pharmacist. A capsule form of phosphate (Neutra-Phos) is commercially available and provides 250?mg of phosphorus per capsule. Patient compliance is readily assessed because most of this dose is excreted in a 24-hr urine collection. The main side effect of oral phosphate therapy is diarrhea, which often improves spontaneously.

Providing a vitamin D analogue is important for complete bone healing and prevention of secondary hyperparathyroidism. Classically, vitamin D_2 was used at 2,000?IU/kg/24?hr, but more recently, dihydrotachysterol at a dosage of 0.02?mg/kg/24?hr or $1,25(OH)_2$ D at 50–65?ng/kg/24?hr has been effectively used. Hydrochlorothiazide may reduce the hypercalciuria evident after vitamin D therapy.

Familial hypophosphatemia was previously treated with 50,000–200,000?IU/24?hr (1.25–10?mg) of vitamin D_2 , but this caused hypervitaminosis D with nephrocalcinosis, hypercalcemia, and permanent renal damage (see Chapter 44.12).

The term *vitamin D–resistant rickets* was used in the past to describe rickets in which patients failed to respond to a dose of vitamin D that would cure vitamin D deficiency. If appropriate doses of vitamin D or any of its metabolites fail to heal rickets, and if serum phosphate is not reduced, metaphyseal dysplasia should be considered (see Chapter 692).

With early diagnosis and good compliance, the bowing deformities can be minimized, and an adult height above 170?cm may be achievable. However, the influence of therapy on final height is controversial, because most patients remain short while in some studies good growth patterns are evident. For this reason trials of growth hormone therapy have been employed. Corrective osteotomies should always be deferred until rickets appears healed radiographically and until the serum alkaline phosphatase level is in the normal range. Surgery before bone healing may be followed by redevelopment of deformity and bowing. In some patients, aggressive medical management may obviate the need for surgical intervention. Patients undergoing osteotomy should stop taking all vitamin D preparations before surgery and should not start them again until they are again ambulating to avoid immobilization hypercalcemia. Because $1,25(OH)_2$ D has such a short half-life, it can be stopped just before surgery, whereas vitamin D_2 should be discontinued at least 1 mo before surgery. An additional advantage of $1,25(OH)_2$ D therapy is that it augments intestinal phosphate absorption and may improve phosphate balance. However, $1,25(OH)_2$ D should not be used without concomitant oral phosphate.

Certain patients have hypophosphatemia and hyperphosphaturia but no radiographic evidence of rickets. This condition, inherited as an autosomal dominant disorder, has been called *hypophosphatemic bone disease.* The serum concentrations of $1,25(OH)_2$ D are normal, and the renal tubular phosphate excretion defect is not as marked as in familial hypophosphatemic rickets, possibly because PHEX is normal and substrates other than F6F23 may influence phosphate transport. Short stature is not as prominent. Oral phosphate and $1,25(OH)_2$ D have been used to treat this disorder.

Chapter 697 - Vitamin D–Dependent Rickets (Pseudovitamin D Deficiency, Hypocalcemic Vitamin D–Resistant Rickets)

Vitamin D–dependent rickets appears at age 3–6 mo in children who have been receiving dosages of vitamin D (400–600?IU/24?hr) that ordinarily prevent rickets (see Chapter 44.10). Serum calcium and phosphate levels are low, and alkaline phosphatase activity is elevated. This condition is a calcium-deficient form of rickets because patients have secondary hyperparathyroidism, aminoaciduria, glucosuria, renal tubular bicarbonate wasting, and renal tubular acidosis. These children also develop dental enamel hypoplasia. Although the rickets and biochemical features of this autosomal recessive disorder can be treated with a massive dose of vitamin D_2 (200,000–1 million IU/24?hr), the use of relatively low-dose $1,25(OH)_2$ D at 1–2?µg/24?hr heals this disorder. The gene for the enzyme 25(OH)D-1 a-hydroxylase is mutated and the enzyme activity reduced. The serum levels of $1,25(OH)_2$ D are low, despite hypocalcemia, hypophosphatemia, and elevated parathyroid hormone levels.

Some cases of vitamin D–dependent rickets fail to reverse after treatment with either high-dose vitamin D_2 or 1,25 $(OH)_2$ D at 1–2?µg/24?hr. Hypocalcemia, hypophosphatemia, aminoaciduria, and rickets persist in the presence of extremely high circulating levels of $1,25(OH)_2$ D, usually above 180?pg/mL. Patients with hereditary $1,25(OH)_2$ D_3 -resistant rickets have (1) reduced or absent $1,25(OH)_2$ D_3 binding to the human vitamin D nuclear receptor; (2) decreased affinity of this receptor for DNA so that transcription cannot occur; or (3) defective nuclear translocation or retention. An abnormal gene product is produced by the vitamin D receptor gene in these patients. A single amino acid substitution in an important DNA-binding site in the receptor may cause this disorder, thus preventing the binding of $1,25(OH)_2$ D and its receptor to the nucleus. Missense and truncation mutations of the DNA binding– or the steroid $(1,25[OH]_2$ D_3)–binding portions of the vitamin D receptor have been found. This form of the disease, which is particularly prevalent among children of 1st-cousin marriages, is termed *vitamin D dependence, type II,* or *hereditary resistance to* $1,25(OH)_2$ *D*. Some patients have short stature and alopecia totalis. Rickets can sometimes be reversed by administration of 15–30?µg/24?hr of $1,25(OH)_2$ D, but missing hair does not regrow.

Chapter 698 - Oncogenous Rickets (Primary Hypophosphatemic Rickets Associated with Tumor)

Rickets associated with a tumor of mesenchymal origin that resolves on removal of the tumor is characterized by phosphaturia, hypophosphatemia, and, in adults, osteomalacia. Hemangiopericytomas are a common tumor type producing this syndrome. These tumors, which cause a phosphate-deficient form of rickets, are mostly benign, may become apparent only years after the development of rickets, and may be located in sites difficult to detect, such as the small bones of the hands and feet, the abdominal sheath, the nasal antrum, and the pharynx. This syndrome may also be associated with the epidermal nevus syndrome, neurofibromatosis (von Recklinghausen disease), and linear nevus syndrome.

In addition to hypophosphatemia and hyperphosphaturia, glycinemia and glycinuria are sometimes found in this form of rickets. These tumors elaborate massive amounts of F6F23, the phosphate-regulating gene product, which causes phosphaturia and impairs the conversion of 25(OH)D to 1,25$(OH)_2$ D. Serum 25(OH)D levels are normal, and serum 1,25$(OH)_2$ D levels are low but rapidly rise to normal after tumor excision. Hypophosphatemia in this syndrome is

presumably caused by ectopic production by tumor cells of this specific fibroblast growth factor, which inhibits renal tubular reabsorption of phosphate. Surgery also cures the bone pain and myopathy, which, if untreated, may confine the child to a wheelchair. Children with acquired or late-appearing hypophosphatemic rickets should undergo bone radiographic examination or bone scan to search for tumors. If a tumor cannot be removed or is metastatic, treatment with 1,25$(OH)_2$ D and oral phosphate or octreotide is often beneficial.

Chapter 699 - Osteoporosis

Osteoporosis is a condition of multiple causes in which bone volume is reduced and increased fractures are evident. In contrast to osteomalacia with undermineralization and normal bone volume, histologic sections of bone in osteoporosis reveal a normal degree of mineralization but a reduction in the volume of bone, especially trabecular bone. Childhood osteoporosis may be primary, as in idiopathic juvenile osteoporosis, osteoporosis-pseudoglioma syndrome, and osteogenesis imperfecta, or secondary to conditions such as Klinefelter syndrome, Turner syndrome, leukemia, homocystinuria, or chronic glucocorticoid administration (Box 699–1). When no obvious secondary cause can be detected, idiopathic juvenile osteoporosis should be entertained if the following clinical features are evident: onset prior to puberty, long bone and lower back pain, fractures of the vertebrae, long bone and metatarsal fractures, washed-out appearance of the spine and long bones, and improvement after puberty. Trabecular bones such as the spine are particularly affected. In general, blood values of minerals, vitamin D metabolites, alkaline phosphatase, and parathyroid hormone are normal. DEXA evaluation shows markedly reduced bone mineral content and bone density. Although several modes of therapy (including oral calcium supplements, calcitriol, bisphosphonates, and calcitonin) have been used with some success, the effect of these treatments is difficult to gauge because spontaneous recovery may occur after puberty.

Osteoporosis-pseudoglioma is an autosomal recessive disorder manifested by variable age at onset, low bone mass, fractures in childhood, and abnormal eye development and is mapped to chromosome 11q12-13. The mutation is a loss of function in the gene for low-density lipoprotein receptor–related protein 5 *(LRP5).* Gain-of-function mutations in this gene produce increased bone density.

The life cycle implications of demineralization or osteoporosis in childhood on final bone mineral accretion should be understood—an important factor in the avoidance of postmenopausal osteoporosis in adults is the bone mass at the time of its decline (bone mass peaks at about 20 yr of age). For this reason, it is important to emphasize dietary vitamin D (400–800?IU daily), calcium intake (= 1200?mg daily), and weight bearing exercise to children and adolescents (see Chapter 679). Avoidance of cigarettes and alcohol is helpful. Dairy products, bony fish, green vegetables, and calcium-supplemented drinks (e.g., orange juice) form the major dietary sources of calcium. Adult-onset osteoporosis is also determined by as yet unidentified genetic factors that can influence

Part 32 - Environmental Health Hazards

Chapter 700 - Pediatric Radiation Injuries

Fred A. Mettler Jr.
Madelyn M. Stazzone

Radiation injuries to children can usually be divided into four categories. The first is external exposure handling lost highly radioactive metallic sources used in industrial radiography. These exposures usually result in severe skin burns and sometimes bone marrow depression. A second type of injury occurs from internal incorporation of radioactive substances. The third type of injury results from accidents in radiation therapy. Radiation therapy normally has an accepted complication rate, but accidental overexposure can also result from miscalculations or machine malfunctions. Finally, potential neoplasms can occur years or decades after radiation exposure. Examples of these include a high rate of breast cancers in children treated for Hodgkin disease and thyroid cancer in children exposed to radioiodine around Chernobyl.

Radiation accidents involving children per se are rare. Between 1946 and 2000, about 150 fatalities worldwide could be attributed to radiation accidents, and only several of these occurred in children. The rarity of radiation injuries makes their recognition difficult. The public perception about radiation also makes management difficult because patients, their families, and medical staff are usually misinformed about the effects of radiation exposure.

When a radiation accident occurs, the pediatrician needs to be aware not only of the basic principles and management of the early phases of radiation injury but also of the later or delayed manifestations of radiation illness. In some accidents, children have presented with lethargy, nausea and vomiting, leukopenia, thrombocytopenia, or skin burns as manifestations of exposure to a highly radioactive source whose

presence was not appreciated. Recognition of radiation exposure as the cause of these symptoms is often necessary for the exposure to be terminated.

Basic Principles.

Ionizing radiation includes x-rays and gamma rays. These forms of radiation easily penetrate body tissues, depending on their energy, and can deposit their potentially harmful energy deep in the body. Particulate radiations include a particles and ß particles. The a particles present a hazard only when they are inhaled, ingested, or deposited in an open wound, because they have extremely poor penetration capability and are unable to penetrate the outer layer of skin or even a sheet of paper. The ß particles may penetrate as much as a few centimeters of tissue.

Although ionizing radiation is not appreciated by the human senses, it is easily detected, localized, and quantified through the use of various devices. If the radiation source is no longer present, recognition of radiation injury is made on the basis of history, the observed effects, and their temporal course.

Radiation was historically measured in three different units: the roentgen, rad, and rem. The roentgen is a unit of exposure based on the number of ion pairs produced in a volume of air. The rad (radiation absorbed dose) is based on energy deposited per gram of tissue. The absorbed dose depends on the type of radiation and the size, shape, and composition of the object absorbing the radiation. A rem (roentgen equivalent in man) takes into account the biologic effects of various kinds of radiation. For x-rays and gamma rays, a rad and a rem are essentially equivalent. Most literature now uses international units. These include the gray (Gy), which is equal to 100 rads, and the sievert (Sv), which is equal to 100 rem. Radioactivity was historically expressed in units of curies (Ci). The international unit is the becquerel (Bq), and 1 curie equals 37 gigabecquerels (GBq).

Pathophysiology.

Radiation injury involves energy deposited in a cell with subsequent formation of free radicals from water. Most of the free radicals that are formed recombine quickly because they are very reactive chemically, but they may occasionally interact with other nearby macromolecules.

At high radiation doses, parenchymal cells may die. The clinical effect may be insignificant if the cell is not critical to the survival of the individual. However, if a large number of cells are killed or they are essential, clinical symptoms become apparent. Not all cells in the body are equally radiosensitive. In general, rapidly dividing cells (e.g., the intestinal mucosa and bone marrow) are the most sensitive to cell killing by radiation, whereas cells that are slowly dividing or are nondividing (e.g., neurons) are quite resistant. Endothelial cells, arterioles, and capillaries have moderate radiosensitivity, and damage to these can reduce blood supply and result in effects months or several years after exposure.

At radiation doses less than 100 rads (1.0?Gy), most cell types survive, although they may be subject to transformation owing to faulty repair of DNA breaks, and there is the possibility of subsequent malignancy. Radiation-induced neoplasms (both benign and malignant) may occur after radiation exposure. Most leukemias (except chronic lymphocytic leukemia) can be induced by radiation and usually appear from 2–15 yr after exposure. Tumors of solid organs can also occur, although the tissues have varying sensitivity. The thyroid, female breast, and lung are among the most sensitive. Most solid tumors appear 10–50 yr after exposure. Thyroid and bone cancer may appear as early as 5 yr. Over a wide dose range, the risk of a radiation-induced tumor for many tissues is directly proportional to the radiation dose; however, for a given radiation dose, children appear to be at a 2- to 3-fold greater risk of subsequent tumors than adults. The wide use of CT scanning has raised concern about the possible induction of cancer in children in the future, but whether this will actually occur remains a matter of conjecture.

Although radiation principally affects DNA and although genetic effects of radiation have been observed in animals, hereditary effects of radiation exposure have not been observed in large epidemiologic studies over several generations (i.e., the Hiroshima and Nagasaki survivors). Concern about prenatal preconception radiation as a cause of childhood cancer has been shown to be unfounded.

WHOLE BODY IRRADIATION

Clinical Manifestations.

Table 700–1 presents dose effect relationships for acute whole body penetrating radiation. A large single

---

TABLE 700-1 -- **Dose Effect Relationships After Acute Whole Body Irradiation from Gamma or X-rays**

Whole Body Absorbed Dose, Rads (Gy)	Findings
5 (0.05)	Asymptomatic
15 (0.15)	Asymptomtic (but chromosome aberrations may be present in cultured peripheral lymphocytes)
50 (0.5)	Asymptomatic (minor depression of white blood cells and platelets in a few persons)

100 (1.0)	Nausea and vomiting in approximately 10% of patients within 2 days of exposure
200 (2.0)	Nausea and vomiting in most persons exposed, with clear hematologic depression
400 (4.0)	Nausea, vomiting, and diarrhea within 48?hr; 50% mortality without medical treatment
600 (6.0)	100% mortality within 30 days from bone marrow failure without medical treatment
5,000 (50.0)	Cardiovascular collapse and central nervous system damage, with death in 24–72?hr

exposure of penetrating radiation can result in the *acute radiation syndrome*. The signs and symptoms of this syndrome result from damage to major organ systems that have different levels of radiation sensitivity, modulated by the rate at which the radiation exposure occurred. For example, 100 rads (1.0?Gy) delivered in 1?min would be symptomatic but 1 rad (0.01?Gy)/day for 100 days would not be symptomatic.

The *hematopoietic syndrome* occurs from acute whole body doses above 200 rads (2.0?Gy). A prodromal phase consists of nausea and vomiting within the first 12?hr, with symptoms usually lasting up to 48?hr. There follows a latent period of 2–3 wk during which patients may feel quite well. Although patients are asymptomatic, bone marrow impairment has occurred. The most obvious laboratory finding is lymphocyte depression (Table 700–2). Maximal bone marrow depression occurs approximately 30 days after exposure, when hemorrhage and infection can be major problems. If the bone marrow is not completely eradicated, a recovery phase then ensues. This radiation effect is similar to what occurs when whole body irradiation (given as 1,200 rads [12?Gy] in two treatments) is used to obliterate the bone marrow in leukemic children before bone marrow transplantation.

The *gastrointestinal syndrome* occurs from acute whole body doses above 800 rads (8?Gy). Prompt onset of nausea, vomiting, and diarrhea follows. There is a latent period of approximately 1 wk and then recurrence of gastrointestinal symptoms, sepsis, electrolyte imbalance, and, ultimately, death.

At dose levels over 3,000 rad (>30?Gy), the *cardiovascular/central nervous system (CNS) syndrome* predominates. Nausea, vomiting, prostration, hypotension, ataxia, and convulsions are almost immediate. Death usually occurs promptly.

TABLE 700-2 -- **Expected Outcome Based on Absolute Lymphocyte Count After Acute Penetrating Whole Body Irradiation**

Minimal Lymphocyte Count Within First 48 Hr After Exposure	Prognosis
1,000–3,000 normal range	No significant injury
1,000–1,500	Significant but probably nonlethal injury, good prognosis
500–1,000	Severe injury, fair prognosis
100–500	Very severe injury, poor prognosis
Under 100	Lethal without compatible bone marrow donor

Treatment.

For the hematopoietic and gastrointestinal syndromes, treatment is supportive, involving transfusions, fluids, antibiotics, and antiviral agents. The cardiovascular/CNS syndrome is fatal within 1–14 days.

LOCALIZED IRRADIATION

Clinical Manifestations.

Because localized exposure involves a small amount of tissue, systemic manifestations are less severe, and patients may survive even if local absorbed doses are very high. The hand is the most common site for accidental localized irradiation injuries, usually as a result of picking up or playing with lost radiation sources. The second most common site is the thigh and buttocks, predominantly from placing unsuspected highly radioactive radiography sources in the pockets. Most industrial radiography sources are easily capable of causing skin erythema or radiation burns from only a few minutes of direct contact.

There are several major differences between thermal burns and radiation burns. The effects of a thermal burn are present almost immediately, and patients invariably know what it was that burned them. If patients present with burnlike symptoms but no known cause, radiation should be suspected as the cause. Table 700–3 lists the

findings expected after localized skin doses.

The penetrability of the radiation is an important factor in the outcome of local radiation injury. In cases of low-energy irradiation, recovery and skin grafting are possibilities, even after high absorbed skin doses. Gamma and x-rays, on the other hand, penetrate substantially and cause progressive obliterative endarteritis that may result in necrosis and gangrene. Very few initial symptoms occur in the first 12?hr unless the dose has been extremely high. Under these circumstances, patients may complain of hypersensitivity, tingling, or pain.

Erythema is similar to that seen with a first-degree burn. If erythema is seen within the first 48?hr, ulceration will probably occur. The erythema may come in waves. That is, it will be present, disappear, and return days or 1–3 wk later. Transepidermal injury is similar to a second-degree thermal burn. Blister formation may occur at 1–2 wk with doses in the range of 10,000 rads (100?Gy) and at 3 wk at dose levels of 3,000–5,000 rads (30–50?Gy).

Some tissues that may receive localized radiation exposure are relatively radiosensitive. These include the lens of the eye and the gonads. Cataract formation may occur with single gamma ray exposures in the range of 200–500 rads (2.0–5.0?Gy). Such cataracts usually take between 2 mo to several years to develop. Gonadal exposure has occurred in several accidental situations. Oligospermia may take up to 2 mo to develop. Transient infertility may result from doses as low as 15 rads (0.15?Gy), and permanent sterility may occur in men at dose levels between 300–600 rads (3.0–6.0?Gy). Both cataracts and infertility are common after whole body irradiation used to treat leukemia.

Treatment.

Skin therapy is directed at prevention of infections. Treatment of localized injuries usually involves plastic surgery and grafting, if the radiation exposure was not very penetrating. The nature of the surgery depends on the dose at various depths

TABLE 700-3 -- **Skin Changes After Single Acute Exposure**

Absorbed Dose in Rads (Gy)	Findings
300 (3.0)	Threshold for erythema (100 keV diagnostic x-ray)
600 (6.0)	Threshold for erythema (10 MeV therapeutic x-ray)
1,500 (15.0)	Moist desquamation
2,000 (20.0)	Skin ulceration with slow healing
3,000 + (>30.0)	Gangrenous changes

in tissue and the location of the lesion. The full expression of radiation injury often is not apparent for 1–2 yr, owing to slow arteriolar narrowing that can cause delayed necrosis. After relatively penetrating radiation, amputation may be necessary because of obliterative changes in small vessels.

INTERNAL CONTAMINATION

Epidemiology.

Accidents involving internal contamination are rare and generally are a result of misadministration in hospital settings or voluntary ingestion of unsuspected contaminated radioactive materials. Other relevant examples of potential internal contamination of children include that caused by breast-feeding mothers who have diagnostic nuclear medicine scans and radiation exposure of children when a parent or sibling receives a therapeutic dose of iodine 131. When such patients are allowed to go home, they will be excreting a moderate amount of activity through their urine (and to a lesser extent though saliva and sweat) for 1–2 wk, and it is best to have children use a separate bathroom and have their food prepared by somebody else, if possible, during this period. External exposure received by children as a result of radiation emanating directly from such a patient is not a problem, provided the children remain more than 3–6 feet away for about 5 days.

Clinical Manifestations.

The hazards from internal contamination depend on the nature of the radionuclide (particularly in terms of its solubility in water, half-life, and radioactive emission), as well as the nature of the chemical compound. The signs and symptoms are similar to those described under whole body and local irradiation, depending on the dose and circumstances of ingestion.

Treatment.

Internal contamination presents the physician with a dilemma. The most effective treatment requires knowledge of both the radionuclide and the chemical form, yet unless treatment is instituted very quickly, it rarely is effective. The general classes of treatment for internal contamination include removal, dilution, blocking, and chelation. Removal treatment involves cleaning a contaminated wound and performing stomach lavage or administration of cathartics in the case of ingestion. Administration of alginate-containing antacids (such as Gaviscon) also usually helps in removal by decreasing absorption in the gastrointestinal tract. An example of blocking therapy is the administration of potassium iodine or other stable iodine-containing compounds to patients with known internal contamination with radioactive iodine. The recommended dosage is 65?mg for children 3–18 yr old, 32?mg for children 1 mo–3 yr old, and 16?mg for infants younger than 1 mo old. The stable iodine effectively blocks the thyroid, although the effectiveness decreases rapidly as time increases after the contamination occurred. Another example of

blocking therapy is the use of Prussian blue in cases of internal contamination by cesium. Dilution therapy is used in cases of tritium (radioactive hydrogen as water) contamination. Forcing fluids promotes excretion. Finally, cases of internal contamination with transuranic elements (e.g., americium and plutonium) may require chelation therapy with calcium diethylene triaminepentaacetic acid (DTPA).

EXTERNAL CONTAMINATION

The presence of external radioactive contamination on a patient's skin is not an immediate medical emergency. Management involves removing and controlling the spread of radioactive materials. If a patient has suspected surface contamination and no physical injuries, decontamination can be performed relatively easily. If there is substantial physical trauma or other life-threatening injuries that are combined with external contamination, only after the patient has been stabilized physiologically should surface decontamination proceed. In many accident situations, essential medical care is inappropriately delayed by hospital emergency staff owing to fear of radiation or spread of contamination in the hospital.

Treatment of a patient who is externally contaminated and has other life-threatening injuries requires advance planning. The basic principles involved are as follows:

1. Bring the patient to a room where the traffic can be controlled.
2. While wearing protective clothing (universal precautions), remove the patient's clothing, and treat nonradiation life-threatening injuries first.
3. Call the hospital Radiation Safety Officer. Only after the patient is medically stable, wash potentially contaminated areas with washcloths, lukewarm water, and regular soap.
4. Get a complete blood cell count, ask the patient about nausea and vomiting, and consider possible therapy for internal contamination.

RADIATION THERAPY COMPLICATIONS AND ACCIDENTS

Radiation therapy uses high doses to kill malignant cells. Unfortunately, the sensitivity of normal cells is quite close to that of malignant cells, and to achieve significant cure rates, radiation oncologists also must accept a given percentage of serious complications (5–10%). This leaves little room for error either in calculations of dose or in the actual mechanical functioning of the machine. Radiation therapy protocols are reasonably standardized. Most regimens use about 5,000 rads (50?Gy) given in about 25 fractions over 5 wk. A treatment scheme that either uses doses much more than 10% higher than this or uses this dose with significantly fewer fractions poses a very high incidence of severe and potentially catastrophic complications.

The exact complications depend on the location of the treatment field. In children, because of the location of many childhood tumors, the CNS is commonly in the treatment field and suffers complications. Standard irradiation of the brain in children results in cortical atrophy in more than half of patients who received 2,000–6,000 rads (20–60?Gy); 26% have white matter changes (leukoencephalopathy), and 8% have calcifications (Fig. 700–1). The younger the age of the child at irradiation, the worse is the atrophy. Some patients also develop *mineralizing microangiopathy* (Fig. 700–2). Clinical findings after routine irradiation may include poor school performance and dysfunction of the pituitary and hypothalamus. As a result of overexposure to radiation, adverse effects may be severe and include lethargy, ataxia, spasticity, and progressive dementia. Radiation-induced changes of the brain are potentiated by methotrexate administered before, during, or after radiation therapy.

Cerebral necrosis is a serious and irreversible complication of radiation-induced vascular disease. It is usually diagnosed 1–5 yr after irradiation but can occur up to a decade later. Radiation-induced necrosis occurs with a moderate probability when radiation therapy schemes exceed 4,000 rads (40?Gy) in 10 fractions, 5,000 rads (50?Gy) in 20 fractions, or 6,000 rads (60?Gy) in 30 fractions or when individual fractions exceed 300 rads (3?Gy). The probability of necrosis is very high when treatment schemes exceed 5,000 rads (50?Gy) in 15 fractions, 6,000 rads (60?Gy) in 20 fractions, or 7,000 rads (70?Gy) in 30 fractions. Brain necrosis may be manifested by headache, increased intracranial pressure, seizures, sensory deficits, and psychotic changes.

Spinal cord irradiation may result in *radiation myelitis*, which may be either transient or permanent. Acute transient myelitis often appears 2–4 mo after irradiation. Patients with myelitis usually present with **Lhermitte sign,** a sensation of little electrical shocks in the arms and legs occurring with neck flexion or other movements that stretch the spinal cord.

Figure 700-1 T2-weighted MRI of a child after radiotherapy shows white matter changes (*arrows*).

Reversal of transient myelopathy usually occurs between 8–40 wk and does not necessarily progress to late delayed necrosis.

Delayed myelopathy occurs after a mean latent period of 20 mo, but it can occur earlier if the total dose or dose per fraction is high. This is usually manifested by discontinuous deterioration and is irreversible. In the cervical and thoracic region, sensory dissociation develops, followed by spastic paresis and then flaccid paresis. In the lumbar cord, flaccid paresis is dominant. The mortality for high thoracic and cervical lesions reaches 70%, with death due to pneumonia and urinary tract infections. A 25–50% incidence of thoracic myelopathy occurs when treatment schemes exceed 6,000 rads (60?Gy) at 200 rads (2?Gy) per fraction, 4,000 rads (40?Gy) at 300 rads (3?Gy) per fraction, or 3,500 rads (35?Gy) at 400 rads (4?Gy) per fraction.

Irradiation also causes other effects specific to children. The *effect on growth* is most pronounced when children are younger than 6 yr and during their adolescent growth spurt. Scoliosis and hypoplasia of bones may occur if fractionated treatment schemes exceed 4,000 rads (40?Gy). Fractionated doses in excess of 2,500 rads (25?Gy) can result in slipped capital femoral epiphyses. An increase in the incidence of benign osteochondromas has also been reported after irradiation in children. Chest wall irradiation of girls with 1,500–2,000 rads (15–20?Gy) over 1 wk impairs breast development, and fractionated doses of 3,000–4,000 rads (30–40?Gy) cause

fibrosis and atrophy of breast tissue. Virtually any tissues in a radiation therapy field may show disturbances in growth.

RADIATION CARCINOGENESIS

Radiation carcinogenesis is a potential late expression of radiation injury, and children are more sensitive to induction of tumors than adults. Breast cancer data from Hiroshima and Nagasaki indicate that per 100 rem (1.0 Sv), the relative risk in children is about 3.5 compared with 1.5 or so for women irradiated at 40 yr of age. Epidemiologic studies of children irradiated

Figure 700-2 Generalized brain changes after radiotherapy. T1-weighted MRI of a child shows both central and cortical atrophy as well as high signal areas (*arrows*), owing to mineralizing microangiopathy.

as infants for presumed thymic hyperplasia, of children treated with radiation for ringworm (tinea capitis) and for acne, and of children treated for hemangiomas and other disorders confirm that radiation can increase the risk of leukemia and cancer of the breast, thyroid, brain, skin, and other sites. Over 800 cases of thyroid cancer occurred in children around Chernobyl, mostly in children who were 0–2 yr of age at the time of the accident. There has been no increase in childhood leukemia or malformations in the Chernobyl children.

The incidence of second tumors is also increased in children who have received radiation therapy for childhood tumors, particularly neuroblastoma, retinoblastoma, and Hodgkin disease. A significant increase in soft tissue sarcomas has been noted in children treated for retinoblastoma, and genetic susceptibility has been implicated as well as radiation. In other large studies of children treated for childhood cancer, no increase in leukemia was observed, but there were increases in thyroid and breast cancer as well as bone sarcoma.

Chapter 701 - Chemical Pollutants

Philip J. Landrigan
Joel A. Forman

Children today are at risk of exposure to more than 80,000 synthetic chemicals, most of which have been developed since World War II. They are especially likely to be exposed to the 2,863 high-production-volume (HPV) chemicals that are produced in amounts of 1 million pounds or more per year and are most widely dispersed in the environment. Fewer than half of the HPV chemicals have been tested for their potential hazards to health, and less than 10% have been assessed for their pediatric or developmental toxicity.

Children are uniquely vulnerable to chemical pollutants for several reasons:

1. They have proportionally greater exposures to many environmental pollutants than adults. Because they drink more water, eat more food, and breathe more air per kilogram of body weight, children are more heavily exposed to pollutants in water, food, and air. Children's hand-to-mouth behavior and their play close to the ground further magnify their exposures.
2. Children's metabolic pathways, especially in the first months after birth, are immature. In some instances, children are better able than adults to cope with environmental toxicants because they are unable to metabolize them to their active form. Commonly, however, children are less able to detoxify and excrete chemical pollutants.
3. Infants and children are growing and developing, and their developmental processes are uniquely sensitive to disruption by chemical pollutants. The disability resulting from exposures to chemicals during windows of early vulnerability can be severe and lifelong (Box 701–1).
4. Because children have many future years of life, they have time to develop multistage chronic diseases that may be triggered by early exposures.

CHEMICAL POLLUTANTS OF MAJOR CONCERN

Air Pollutants.

Outdoor air pollutants of greatest concern are photochemical oxidants (especially ozone), oxides of nitrogen (NO_x), fine particulates, sulfur oxides, and carbon monoxide. These pollutants result principally from the combustion of fossil fuels. Automotive emissions are the major source of air pollution worldwide.

Elevated levels of air pollutants, especially elevations of ozone and NO_x , are associated with respiratory problems in children, including decreased pulmonary expiratory flow, wheezing, and exacerbations of asthma. Fine particulate air pollution, even at low levels, is associated with slight increases in cardiopulmonary mortality and with an increased death rate from sudden infant death syndrome (SIDS).

Box 701-1. Examples of the Vulnerability of Infants and Children to Chemical Pollutants

Diethylstilbestrol and adenocarcinoma of the vagina

Thalidomide and phocomelia

Elevated risk of leukemia after prenatal exposure to trichloroethylene

Fetal alcohol syndrome

Neurobehavioral toxicity of low-dose exposure to lead

Increased risk of cancer after intrauterine exposure to nitrosamine, vinyl chloride, or ionizing radiation

Developmental neurotoxicity of organophosphate insecticides

Environmental tobacco smoke and the increased risk of sudden infant death syndrome and asthma

Indoor air can also be an important source of respiratory irritation, because many children spend 80–90% of their time indoors. Indoor air pollution has become especially important in the United States since the energy crises of the 1970s, which led to the construction of tighter, more energy-efficient homes. Allergens in indoor air can contribute to respiratory problems and include cockroach, mite, mold, cat, and dog allergens. Some indoor molds produce chemical toxins called mycotoxins. Environmental tobacco smoke is another major contributor to exacerbations of

childhood asthma.

Lead (see Chapter 703).

Lead exposure occurs worldwide. Exposure is especially common in countries that still permit leaded gasoline. In the United States, pediatric blood lead levels have declined by more than 90% in the past 20 yr, principally as a result of removal of lead from gasoline. Nevertheless, the Centers for Disease Control and Prevention estimates that more than 900,000 children 1–6 yr of age still have blood lead levels of 10?µg/dL and higher. Prevalence is especially high among poor minority children in inner cities. Lead-based paint is the major source of exposure in the United States. Blood lead levels exceeding 10?µg/dL, and possibly even levels of 5–10?µg/dL, are associated with deficits in intellectual function, shortening of attention span, and increased risk of asocial behavior. The extent of injury is directly proportional to lead dose. Because intact lead-painted surfaces invariably break down, efforts to further reduce the number of lead poisoned children in the United States must focus on the identification and permanent removal of all lead-based paint, intact or not, from residences.

Mercury (see Chapter 702).

Children may be exposed to either inorganic or organic mercury. Inorganic mercury produces dermatitis, gingivitis, stomatitis, tremor, and acrodynia. Organic or methyl mercury is fat soluble, readily penetrates the central nervous system (CNS), and produces a neurotoxic syndrome. Exposure to organic mercury occurs principally through consumption of fish that have accumulated mercury deposited in lakes and oceans as atmospheric fallout from combustion of coal; coal normally contains small quantities of mercury. Even low-dose exposure to organic mercury has been shown to be hazardous to the developing fetal brain, and pregnant women are therefore advised to curtail consumption of mercury containing fish such as tuna and swordfish. Although adverse neurologic effects have not been related to exposure from the preservative thimerosal, which contains ethyl mercury, thimerosal has been removed from routine childhood vaccines and maternal Rh vaccine (RhoGam) as a precautionary measure.

Asbestos.

Between 1947 and 1973, asbestos was sprayed as insulation on classroom walls and ceilings in about 10,000 schools in the United States. Subsequent deterioration of this asbestos has released inhalable asbestos fibers into the air and thus poses a

risk to children. Asbestos is a human carcinogen, and the two principal cancers caused by asbestos are lung cancer and mesothelioma. U.S. Federal law requires that all schools be inspected periodically for asbestos and the results made public. Removal is required only when asbestos is visibly deteriorating or is within the reach of children. In most cases, placement of barriers (dry walls or dropped ceilings) provides appropriate protection.

Environmental Tobacco Smoke.

Smoking during pregnancy poses a hazard to the fetus (see Chapter 85). Infants born to women who smoke are, on the average, 10% smaller than infants born to nonsmoking women. Infants of parents who smoke have a higher risk of sudden infant death syndrome. Nicotine from tobacco smoke appears to be a developmental neurotoxin.

Passive smoking is also a hazard to children; 43% of children younger than 12 yr old in the United States live in a home with at least one smoker. Children exposed to environmental tobacco smoke have more lower respiratory illness, more middle-ear effusions, and more viral respiratory illnesses than unexposed children.

Pesticides.

Pesticides are a diverse group of chemicals used to control insects, weeds, fungi, and rodents. Approximately 600 pesticides are registered with the U.S. Environmental Protection Agency.

Diet is a major route of children's exposure to pesticides; children are exposed to residues of multiple pesticides on fruit and vegetables. Children may also be exposed in homes or schools, on lawns, and in gardens. They may be exposed to pesticide drift from agricultural areas that have been sprayed. Children employed in agriculture or living in migrant farm camps are at risk of exposure to many pesticides.

Pesticides can cause a range of chronic toxic effects: polyneuropathy and CNS dysfunction (organophosphates), hormonal disruption and reproductive impairment (DDT, kepone, dibromochloropropane), cancer (aldrin, dieldrin, chlorphenoxy herbicides [2,4,5-T]), and pulmonary fibrosis (paraquat). Pesticide exposures to children can be reduced by minimizing applications to lawns, gardens, schools, and playgrounds; by adapting techniques of integrated pest management; and by reducing pesticide applications to food crops.

Children can be acutely overexposed to pesticides (see Chapter 704). The organophosphates and carbamates, both of which cause neurotoxicity through inhibition of acetylcholinesterase, cause the largest number of acute poisoning cases. Symptoms include meiosis (though not in all cases), excess salivation, abdominal cramping, vomiting, diarrhea, and muscle fasciculation. In severe cases, loss of consciousness, cardiac arrhythmias, and death by respiratory arrest occur. The war gas sarin is an organophosphate. See Chapter 704 for treatment of poisoning from drugs, chemicals, and plants.

PCBs, DDT, Dioxins, and Other Chlorinated Hydrocarbons.

Chlorinated hydrocarbons are used as insecticides (DDT), plastics (polyvinyl chloride [PVC]), electrical insulators (polychlorinated biphenyls, [PCBs]), and solvents (trichloroethylene). Highly toxic dioxins and furans can be formed during synthesis of chlorinated herbicides or as by-products of plastic combustion. All of these materials are widely dispersed in the environment. DDT, PCBs, and dioxins are highly

persistent.

The embryo, fetus, and young child are at particularly high risk of injury from PCBs, DDT, and dioxins. All these compounds are lipid soluble. They readily cross the placenta, and they accumulate in breast milk. Intrauterine exposure to PCBs has been repeatedly linked to persistent neurobehavioral dysfunction in children.

Fish from contaminated waters are a major source of children's exposure to PCBs. Children can be exposed in utero or through breast milk. To protect children and pregnant women in the United States against PCBs in fish, government agencies have issued fish consumption advisories for certain lakes and rivers. Combustion of medical wastes containing PVC and the bleaching of paper products with chlorine are major preventable sources of environmental dioxin and should be discouraged.

Endocrine Disruptors.

A number of chemicals have been shown to adversely affect the endocrine systems of animals and humans, including diethylstilbestrol (DES), DDT, PCBs, and dioxins. Other chemicals are also suspected of possessing endocrine disruptor effects, including other pesticides and phthalates (plasticizers). Effects on wildlife include eggshell thinning in birds, sterility in seals, feminization and cryptorchidism in panthers, low hatching rates in alligators, and many others. In humans, endocrine disruption has been implicated in the epidemiologic observations of a trend toward earlier thelarche and menarche in girls, the increasing rates of testicular cancer and hypospadias, and decreasing sperm counts. The most clearly observed effects include adenocarcinoma of the vagina in women and cryptorchidism in men whose mothers took DES. The presence of elevated plasma phthalate esters has been associated with early thelarche in Puerto Rican girls. Some endocrine disruptors may also have adverse effects on brain development. Continuing research in this area is of particular importance because of the widespread human exposure to, and the long-term biopersistence of, many of these chemicals.

Environmental Carcinogens.

Children may be exposed to carcinogenic pollutants in utero or after birth. Children appear more sensitive than adults to certain chemical carcinogens and also to radiation (see Chapter 700). The potential for in utero carcinogenesis was first recognized with the discovery that clear cell adenocarcinoma of the vagina could occur in women after intrauterine exposure to DES.

Several examples exist of carcinogenesis associated with exposures in the home and community. Children of asbestos workers and children who have grown up in communities near asbestos plants have been found to have a higher incidence of mesothelioma than unexposed populations. Children who grow up on farms have elevated rates of leukemia; pesticides are suspected of playing an etiologic role. Intrauterine exposure to trichloroethylene by way of contaminated drinking water has been associated with an increased incidence of leukemia among girls living near an industrial facility and industrial waste site.

The National Cancer Institute (NCI) reports that incidence rates of leukemia and cerebral glioma, the two most common forms of childhood malignancy, have been increasing for the past 3 decades, despite greatly improved therapy and declining death rates. The cumulative increase in incidence for glioma is now about 30%. Similar increases in incidence of childhood cancer have been seen in the United Kingdom. Research is ongoing to determine whether chemical pollutants in the environment have contributed to this reported increasing incidence of childhood cancer.

ROUTES OF EXPOSURE

Transplacental.

Heavy metals and fat-soluble compounds such as PCBs and DDT readily cross the placenta. They may produce serious and irreversible toxic effects on the developing nervous, endocrine, and reproductive organs even at very low levels.

Water.

About 200 chemicals have been found in various amounts in water supplies. Lead is especially common. In some older neighborhoods, lead in water derives from lead pipes. More commonly, it is dissolved (leached) from solder by soft, acidic water. The highest levels of lead occur in water that has been standing in pipes overnight; therefore, it is wise to run water for 2–3?min each morning before making up infant formula. Solvents and components of gasoline such as methyl tertiary-butyl

ether (MTBE) and benzene are commonly encountered in ground water.

Air.

Vehicular emissions are the major source of urban air pollution. Diesel exhaust is a human carcinogen. In rural areas, wood smoke can contribute to air pollution. Children living in the vicinity of smelters and chemical production plants can be exposed to toxic industrial emissions such as lead, benzene, and 1,3-butadiene.

Food.

Many chemicals are intentionally added to food to improve appearance, taste, texture, or preservation. Many such chemicals have been poorly tested for potential toxicity. Residues of many pesticides are found in both raw and processed foods.

Work Clothes.

Illnesses in children are at times traceable to contaminated dust from parents' work clothes; toxicity from lead, beryllium, dioxin, organophosphate pesticides, and asbestos has occurred. Prevention is achieved by providing facilities at work for changing and showering.

Schools.

Children may be exposed in schools, kindergartens, and nurseries to lead paint, molds, asbestos, environmental tobacco smoke, pesticides, and hazardous arts and crafts materials. Substantial opportunities for prevention exist in the school environment, and pediatricians are often consulted for advice.

Child Labor.

Four to 5 million children and adolescents in the United States work for pay, and child labor is widespread around the world. Working children are at high risk of physical trauma and injury. Also, they may be exposed to a wide range of toxic chemicals, including pesticides in agriculture and lawn work, asbestos in construction and building demolition, and benzene in pumping gasoline.

THE PHYSICIAN'S ROLE

Pediatricians should always be alert to the possibility that a chemical pollutant has caused disease in a child. In considering the origins of noninfectious disease, they should ask about the home environment, parental occupation, unusual exposures, and neighborhood factories. Especially when several unusual cases of disease or constellations of findings occur together, an environmental cause is possible. Any adolescent with a traumatic injury may have been injured at work.

The history is the single most important instrument for obtaining information on environmental exposures. Information about current and past exposures should routinely be sought through a few brief screening questions. Changes in patterns of exposure or new exposures may be especially important. If suspicious information is elicited, more detailed follow-up should be pursued. Referral to a pediatric environmental health specialty unit may be indicated. Accurate diagnosis of an environmental cause of disease can lead to better care of sick children and prevention of disease in other children.

Chapter 702 - Heavy Metal Intoxication

Collin S. Goto

Metals are electropositive elements characterized by properties such as luster, malleability, and the ability to conduct electricity. Severe illness may result when humans are exposed to the group known as the heavy metals. These substances have an immense range of industrial applications, and the majority of human poisonings result from occupational and household exposures or consumption of contaminated food, water, or medicinal preparations.

Heavy metal intoxication tends to result in diverse multiorgan toxicity through widespread disruption of vital cellular functions. After ingestion, gastrointestinal, renal, hematologic, and nervous system toxicity are common. Cutaneous abnormalities are also seen, and inhalation of fumes and vapors may cause a severe pneumonitis. The protean manifestations of heavy metal intoxication can easily be misdiagnosed unless a meticulous history of environmental exposure is obtained. Among the most common causes of heavy metal intoxication, arsenic and mercury are discussed in this section. Lead poisoning is discussed in Chapter 703 . Also see Chapter 706 and Chapter 713 .

ARSENIC

Epidemiology.

Arsenic exists in the following forms: elemental arsenic, arsine gas, inorganic arsenic salts, and organic arsenic compounds. Children may be poisoned after exposure to inorganic arsenic found in pesticides, herbicides, dyes, homeopathic medicines, and certain folk remedies from China, India, and Southeast Asia. Soil deposits may contaminate artesian well water. Occupational exposure may occur in industries such as glass manufacturing, pottery, electronic components, semiconductors, mining, smelting, and refining. Organic arsenic compounds may be found in seafood, pesticides, and some veterinary pharmaceuticals. In contrast to mercury, the organic forms of arsenic found in seafood are nontoxic.

Pharmacokinetics.

Elemental arsenic is insoluble in water and bodily fluids and therefore is insignificantly absorbed and nontoxic. Inhaled arsine gas is rapidly absorbed through the lungs. The inorganic arsenic salts are well absorbed through the gastrointestinal tract and lungs. The organic arsenic compounds are well absorbed through the gastrointestinal tract.

After acute exposure, arsenic is rapidly distributed to all tissues. Inorganic arsenic is methylated and eliminated predominantly by the kidneys, with about 95% excreted in the urine and 5% excreted in the bile. The majority of the arsenic is eliminated in the first few days, with the remainder slowly excreted over a period of several weeks.

Pathophysiology.

After exposure to arsine gas, absorbed arsine enters red blood cells (RBCs) and is oxidized to arsenic dihydride and elemental arsenic. Complexing of these derivatives with RBC sulfhydryl groups results in cell membrane instability and massive hemolysis. The inorganic arsenic salts poison enzymatic processes vital to cellular metabolism. Trivalent arsenic binds to sulfhydryl groups, resulting in decreased production of adenosine triphosphate through the inhibition of enzyme systems such as the pyruvate dehydrogenase and a-ketoglutarate complexes. Pentavalent arsenic may be biotransformed to trivalent arsenic or substituted for phosphate in the glycolytic pathway, resulting in uncoupling of oxidative phosphorylation.

Clinical Manifestations.

Arsine gas is colorless, odorless, nonirritating, and highly toxic. Inhalation causes no immediate symptoms. After a latent period of 2–24?hr, massive hemolysis occurs, along with malaise, headache, weakness, dyspnea, nausea, vomiting, abdominal pain, hepatomegaly, pallor, jaundice, hemoglobinuria, and renal failure.

Gastrointestinal toxicity begins within minutes to hours of an acute ingestion of the inorganic arsenic salts, manifested by nausea, vomiting, abdominal pain, and diarrhea. Hemorrhagic gastroenteritis with extensive fluid loss and third spacing may result in hypovolemic shock. Cardiovascular toxicity includes QT interval prolongation, polymorphous ventricular tachycardia, congestive cardiomyopathy, pulmonary edema, and cardiogenic shock. Acute neurologic toxicity includes delirium, seizures, cerebral edema, encephalopathy, and coma. A delayed sensorimotor peripheral neuropathy may appear days to weeks after acute exposure, secondary to axonal degeneration. Early effects include painful dysesthesias, followed by diminished vibratory, pain, touch, and temperature sensation; decreased deep tendon reflexes; and, in the most severe cases, an ascending paralysis with respiratory failure mimicking Guillain-Barré syndrome. Other effects include fever, hepatitis, rhabdomyolysis, renal failure, hemolytic anemia, pancytopenia, and alopecia.

Subacute toxicity is characterized by prolonged fatigue, malaise, weight loss, headache, chronic encephalopathy, peripheral sensorimotor neuropathy, leukopenia, anemia, thrombocytopenia, chronic cough, and gastroenteritis. Transverse striae in

the nails, known as Mees lines, become apparent 1–2 mo after exposure in about 5% of patients. Dermatologic findings include alopecia, oral ulceration, peripheral edema, a pruritic macular rash, and desquamation.

Chronic exposure to low levels of arsenic is usually from environmental or occupational sources. Well water contaminated with arsenic leached from ground mineral deposits has resulted in millions of cases of chronic arsenic toxicity in Bangladesh, Taiwan, Mexico, and other locations worldwide. Over the course of years, dermatologic lesions develop, including hyperpigmentation, hypopigmentation, hyperkeratoses (especially on the palms and soles), squamous and basal cell carcinomas, and Bowen disease. Encephalopathy and peripheral neuropathy may be present. In addition, hepatomegaly, hypersplenism, noncirrhotic portal fibrosis, and portal hypertension are known to occur. Blackfoot disease is an obliterative arterial disease of the lower extremities associated with chronic arsenic exposure in Taiwan.

Laboratory Findings.

The diagnosis of arsenic intoxication is based on characteristic clinical findings, a history of exposure, and elevated urinary arsenic levels, which confirm the exposure. A spot urine arsenic level should be determined for symptomatic patients before chelation, although the result may be negative acutely. Because urinary excretion of arsenic is intermittent, definitive diagnosis depends on a 24-hr urine collection. Concentrations greater than 50?µg/L in a 24-hr urine collection are consistent with arsenic intoxication. Urine specimens must be collected in metal-free containers. Ingestion of seafood containing nontoxic arsenobetaine and arsenocholine can cause elevated urinary arsenic levels. Blood arsenic levels are rarely helpful because of their high variability and the rapid clearance of arsenic from the blood in acute poisonings. Elevated arsenic levels in the hair or nails must be interpreted cautiously because of the possibility of external contamination. Abdominal radiographs may demonstrate ingested arsenic, which is radiopaque.

Later in the course of illness, a complete blood cell count may show anemia, thrombocytopenia, and leukocytosis, followed by leukopenia, karyorrhexis, and basophilic stippling of RBCs. The serum levels of creatinine, bilirubin, and transaminases may be elevated; urinalysis may show proteinuria, pyuria, and hematuria; and examination of the cerebrospinal fluid may show elevated protein levels.

MERCURY

Epidemiology.

Mercury exists in three forms: elemental mercury, inorganic mercury salts, and organic mercury. Elemental mercury is present in thermometers, sphygmomanometers, barometers, batteries, and some latex paints produced before 1991. Workers in industries producing these products may expose their children to the toxin when mercury is brought home on contaminated clothing. Vacuuming of carpet contaminated with mercury and breaking of mercury fluorescent light bulbs may result in elemental mercury vapor exposure. In addition, severe inhalation poisonings have resulted from attempts to separate gold from gold ore by heating mercury and forming a gold-mercury amalgam. Elemental mercury has also been used in folk remedies by Asian and Mexican populations for chronic stomach pain and by Latin Americans and Caribbean natives in occult practices (see Chapter 3). Dental amalgams containing elemental mercury release trace amounts of mercury that do not pose a credible risk to health. An expert panel for the National Institutes of Health has concluded that existing scientific evidence does not indicate that dental amalgams pose a health risk. They should not be replaced merely to decrease mercury exposure.

Inorganic mercury salts are found in pesticides, disinfectants, antiseptics, pigments, dry batteries, and explosives and as preservatives in some medicinal preparations.

Organic mercury in the diet, especially fish containing methyl mercury, is a major source of mercury exposure to the general population. Industries that may produce mercury-containing effluents include chlorine and caustic soda productions, mining and metallurgy, electroplating, chemical and textile manufacturing, paper and pharmaceutical manufacturing, and leather tanning. Mercury compounds in the environment are methylated to methyl mercury by soil and water microorganisms. Methyl mercury in turn in the water rapidly accumulates in fish and other aquatic organisms, which are in turn consumed by humans. Well-known large outbreaks of methyl mercury intoxication include the incidents in Japan in the 1950s (from consumption of contaminated seafood) and in Iraq in 1971 (from consumption of grain treated with a methyl mercury fungicide).

Thimerosal is a mercury-containing preservative used in some vaccines. Thimerosal contains 49.6% mercury by weight and is metabolized to ethyl mercury and thiosalicylate. During an ongoing review of biologic products in response to the Food and Drug Administration (FDA) Modernization Act of 1997, the FDA determined that infants who received thimerosal-containing vaccines at multiple visits may have been exposed to more

mercury than recommended by federal guidelines. As a precautionary measure, the American Academy of Pediatrics, American Academy of Family Physicians, Advisory Committee on Immunization Practices, and U.S. Public Health Service issued a joint recommendation in 1999 that thimerosal be removed from vaccines as quickly as possible. In the United States, thimerosal has been removed from all vaccines in the recommended childhood immunization schedule.

Pharmacokinetics.

Inhaled elemental mercury vapor is 80% absorbed by the lungs and rapidly distributed to the central nervous system (CNS) because of its high lipid solubility. The elemental mercury is oxidized by catalase to the mercuric ion, which is the reactive form causing cellular toxicity. Elemental mercury liquid is poorly absorbed from the gastrointestinal tract, with less than 0.1% being absorbed. The half-life of elemental mercury in the tissues is about 60 days, with most of the excretion being in the urine.

Inorganic mercury salts are about 10% absorbed from the gastrointestinal tract and

cross the blood-brain barrier to a lesser extent than elemental mercury. Mercuric salts are more soluble than mercurous salts and therefore produce greater toxicity. Elimination occurs primarily in the urine, with a half-life of about 40 days.

Methyl mercury is the most avidly absorbed of the organic mercury compounds, with about 90% absorbed from the gastrointestinal tract. Its lipophilic, short-chain alkyl structure enables methyl mercury to distribute rapidly across the blood-brain barrier and placenta. Methyl mercury is about 90% excreted in the bile, with the remainder being excreted in the urine. The half-life is 70 days.

Pathophysiology.

After absorption, mercury is distributed to all tissues, particularly the CNS and kidneys. Mercury reacts with sulfhydryl, phosphoryl, carboxyl, and amide groups, resulting in disruption of enzymes, transport mechanisms, membranes, and structural proteins. Widespread cellular dysfunction or necrosis results in the multiorgan toxicity characteristic of mercury poisoning.

Clinical Manifestations.

Five syndromes describe the clinical presentation of mercury poisoning:

Acute inhalation of elemental mercury vapor results in rapid onset of cough, dyspnea, chest pain, fever, chills, headaches, and visual disturbances. Gastrointestinal findings include metallic taste, salivation, nausea, vomiting, and diarrhea. Depending on the severity of the exposure, the illness may be self-limited or may progress to necrotizing bronchiolitis, interstitial pneumonitis, pulmonary edema, and death from respiratory failure. Younger children are more susceptible to pulmonary toxicity. Survivors may develop restrictive lung disease. Renal dysfunction and neurologic disturbances may develop subacutely.

Acute ingestion of inorganic mercury salts can present in a few hours with corrosive gastroenteritis manifested by oropharyngeal burns, nausea, hematemesis, severe abdominal pain, hematochezia, acute tubular necrosis, cardiovascular collapse, and death.

Chronic inorganic mercury intoxication produces the classic triad of tremor, neuropsychiatric disturbances, and gingivostomatitis. The syndrome may result from chronic exposure to elemental mercury, inorganic mercury salts, or certain organic mercury compounds, all of which may be metabolized to mercuric ions. The tremor starts as a fine intention tremor of the fingers that is abolished during sleep, but it may later involve the face and progress to choreoathetosis and spasmodic ballismus. Mixed sensorimotor neuropathy and visual disturbances may also be present. The neuropsychiatric disturbances include emotional lability, delirium, headaches, memory loss, insomnia, anorexia, and fatigue. Renal dysfunction ranges from asymptomatic proteinuria to nephrotic syndrome.

Acrodynia, or **pink disease,** is a rare idiosyncratic hypersensitivity reaction to mercury that occurs predominantly in children. The symptom complex includes generalized pain, paresthesias, and an acral rash that may spread to involve the face. It is typically pink, papular, and pruritic and may progress to desquamation and ulceration. Morbilliform, vesicular, and hemorrhagic variants have been described. Other important features include anorexia, apathy, and hypotonia, especially of the pectoral and pelvic girdles. Irritability, tremors, diaphoresis, insomnia, hypertension, and tachycardia may be present. The outcome is good after removal of the source of mercury exposure.

Methyl mercury intoxication is also referred to as **Minamata disease** after the widespread mercury poisoning that occurred at Minamata Bay in Japan after the ingestion of contaminated fish. Methyl mercury poisoning presents as delayed neurotoxicity after a latent period of weeks to months, characterized by ataxia; dysarthria; paresthesias; tremors; movement disorders; impairment of vision, hearing, smell, and taste; memory loss; progressive dementia; and death. Infants exposed in utero are the most severely affected, with low birthweight, microcephaly, profound developmental delay, cerebral palsy, deafness, blindness, and seizures.

Laboratory Findings.

The diagnosis of mercury intoxication is based on characteristic clinical findings, a history of exposure, and elevated whole blood or urine mercury levels, which confirm the exposure. Levels less than 10?µg/L in whole blood and 20?µg/L in a 24-hr urine collection are considered normal. Although blood mercury levels may reflect acute exposure, they decrease as mercury redistributes into the tissues. Urine mercury levels are most useful for identifying chronic exposures, except in the case of methyl mercury, because methyl mercury undergoes minimal urinary excretion. Hair analysis for mercury is not reliable because hair reflects endogenous as well as exogenous mercury exposure (hair avidly binds mercury from the environment). Abdominal radiographs may demonstrate ingested radiopaque mercury.

Urinary markers of early nephrotoxicity include microalbuminuria, retinol-binding protein, $ß_2$ -microglobulin, and *N*-acetyl-ß-d-glucosaminidase. Early neurotoxicity may be detected with neuropsychiatric testing and nerve conduction studies, whereas severe CNS toxicity is apparent on CT or MRI.

TREATMENT OF ARSENIC AND MERCURY INTOXICATION

The principles of management for arsenic and mercury intoxication include prompt removal from the source of poisoning, aggressive stabilization and supportive care, decontamination, and chelation therapy when appropriate. Once the diagnosis is suspected, the local poison control facility should be contacted and care coordinated with physicians who are familiar with the management of heavy metal poisoning.

Supportive care for patients exposed to arsine gas requires close monitoring for signs of hemolysis, including evaluation of the peripheral blood smear and urinalysis. Transfusion of packed RBCs may be necessary, as well as administration of intravenous fluids, sodium bicarbonate, and mannitol to prevent renal failure secondary to the deposition of hemoglobin in the kidneys. After inhalation of elemental mercury vapor, patients require careful monitoring of respiratory status, which may include pulse oximetry, arterial blood gas analysis, and chest radiography. Supportive care includes administration of supplemental oxygen and, in severe cases, intubation and mechanical ventilation.

Acute ingestion of inorganic arsenic and mercury salts results in hemorrhagic gastroenteritis, cardiovascular collapse, and multiorgan dysfunction. Fluid resuscitation, pressor agents, and transfusion of blood products may be required for management of cardiovascular instability. Severe respiratory distress, coma

with loss of airway reflexes, intractable seizures, and respiratory paralysis are indications for intubation and mechanical ventilation. Renal function must be carefully monitored for signs of renal failure and the need for hemodialysis.

Gastrointestinal decontamination after ingestion of the inorganic arsenic and mercury salts has not been well studied. Because of the corrosive effects of these compounds, induced emesis is not recommended, and endoscopy may be considered before gastric lavage. Although arsenic and mercury are not well adsorbed to activated charcoal, its use is generally advocated, especially if co-ingestants are suspected. Whole bowel irrigation is used to remove any radiopaque material remaining in the gastrointestinal tract.

Chelation for acute arsenic and mercury poisoning is most effective when administered as soon as possible after the exposure. Chelation should be continued until 24-hr urinary arsenic or mercury levels return to normal (<50?µg/L for arsenic and <20?µg/L for mercury), the patient is symptom free, or the remaining toxic effects are believed to be irreversible. The efficacy of chelation in chronic exposures is reduced because heavy metal in the tissue compartment is relatively unexchangeable and some degree of irreversible toxicity has already occurred.

Dimercaprol, also known as 2,3-dimercaptopropanol or British antilewisite (BAL), is the chelator of choice if a patient cannot tolerate oral therapy. This is often the case in critically ill patients and after ingestion of the corrosive inorganic arsenic and mercury salts. BAL is available suspended in peanut oil and benzyl benzoate in 3-mL ampules at a concentration of 100?mg/mL for deep intramuscular (IM) injection. For arsenic poisoning, the recommended regimen of BAL is 2.5?mg/kg IM q6h for the first 2 days, 2.5?mg/kg IM q12h on the third day, then 2.5?mg/kg/day IM for 10 days. For severe arsenic poisoning, the dose of BAL is increased to 3?mg/kg IM q4h for 2 days, 3?mg/kg IM q6h on day 3, then 3?mg/kg IM q12h for 10 days. The dose of BAL for inorganic mercury poisoning is 5?mg/kg IM on the first day, then 2.5?mg/kg IM q12–24h for 10 days. The BAL-heavy metal complex is excreted in the urine and bile. A period of 5 days between courses of chelation is recommended. Adverse effects of BAL include pain at the injection site, hypertension, tachycardia, diaphoresis, nausea, vomiting, abdominal pain, a burning sensation in the oropharynx, and a feeling of constriction in the chest. BAL may cause hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient individuals. It is important to note that BAL is contraindicated for chelation of methyl mercury because BAL redistributes methyl mercury to the brain from other tissue sites, resulting in increased neurotoxicity.

Oral chelating agents are used to replace the painful BAL injections when the patient is stable enough to tolerate oral therapy and prolonged chelation is necessary. Succimer, also known as 2,3-dimercaptosuccinic acid (DMSA), is an orally administered water-soluble derivative of BAL. DMSA is available in 100-mg capsules. The recommended regimen of DMSA is 1,050?mg/m^2 /24?hr (or 30?mg/kg/24?hr) orally in three divided doses for 5 days, then 700?mg/m^2 /24?hr (or 20?mg/kg/24?hr) orally in two divided doses for 14 days. The DMSA-heavy metal complex is excreted in the urine and bile. A period of 2 wk between courses of chelation is recommended. Mild adverse effects include nausea, vomiting, diarrhea, loss of appetite, and transient elevations in liver enzyme levels. DMSA may also cause hemolysis in G6PD-deficient patients.

Chapter 703 - Lead Poisoning

Morri Markowitz

Epidemiology.

Lead exists in four isotopic forms and is classified as a metal. Chemically, its low melting point and ability to form stable compounds has made it useful for hundreds of products. Clinically, it is purely a toxicant; no organism has an essential function that is lead dependent. Medical knowledge pertaining to its toxicity has existed for more than 2,000 years. Nevertheless, its commercial attractiveness has resulted in the processing of millions of tons of lead ore. The result is widespread dissemination of lead in the human environment.

The threshold level at which lead causes biochemical, subclinical, or clinical disturbance has been redefined many times during the past 50 yr as a result of extensive research efforts. In clinical medicine, the blood lead level (BLL) is the gold standard for determining health effects. An ideal BLL is 0. However, since 1991, the Centers for Disease Control (CDC), followed by the American Academy of Pediatrics, has considered a BLL up to 10?µg/dL as being acceptable. This number is likely to decline with further research into the effects of lead.

Using 10?µg/dL as a reference point for children at risk for lead poisoning, public health measures have had remarkable success. In a major survey, the National Health and Nutrition Examination Survey II, conducted on a representative sample of the U.S. population between 1976 and 1980, showed greater than 85% of preschool-aged children had elevated BLLs; 98% of African-American preschoolers had elevated levels. Over the next 15 yr, government regulations resulted in the significant reduction of three main contributors to lead exposure: (1) the elimination of the use of tetraethyl leaded gasoline, (2) the banning of lead-containing solder to seal food and beverage containing cans, and (3) the application of a federal rule that limited the amount of lead allowed in paint intended for household use to less than 0.07% by weight. Continued surveillance by the CDC has shown that the prevalence of elevated BLLs has declined markedly and is now below 10% of preschoolers. Of these children, less than 10% have BLLs greater than 20?µg/dL. Children with levels high enough to be life threatening are rare, but deaths continue to occur. These estimates imply that there are still more than a half million U.S. children with elevated BLLs.

A closer analysis shows that the remaining cases of BLL elevations are not evenly distributed across the United States but vary considerably by state and county. Several factors have been identified that indicate increased risk of lead poisoning, including, in addition to preschool age, low socioeconomic status, living in older housing built primarily before 1960, urban location, and African-American race. The combination of these factors identifies a group of children of whom more than 20% still have elevated BLLs. Other high-risk groups include recent immigrants, including adoptees, from countries that still use leaded gasoline or ceramic ware with lead-containing glazes. Prevalence rates in many United States locations are unknown.

SOURCES OF EXPOSURE.

Lead poisoning may occur in utero because lead readily crosses the placenta from maternal blood. The spectrum of toxicity is similar to that experienced by children after birth. The source of maternal blood lead content is

either redistribution from endogenous stores, her skeleton, or newly acquired lead due to ongoing environmental exposure.

Although there are several hundred products that contain lead, such as batteries, cable sheathing, cosmetics, mineral supplements, plastics, and toys, the major source of exposure to U.S. children remains old lead-based paint; by estimates there are about 40 million households with some lead-based paint. As paint deteriorates it chalks, flakes, and turns to dust. Improper rehabilitation work of painted surfaces can result in dissemination of lead-containing dust throughout a home. The dust can coat all surfaces, including children's hands. All of these forms of lead can be ingested. If remodeling work is done by using heat to strip paint, then lead vapor concentrations in the room can reach levels sufficient to cause lead poisoning by way of inhalation.

Pathophysiology.

The non-nutritive hand-to-mouth activity of young children provides the pathway for lead to enter the body in the majority of children. In nearly all cases lead is ingested either as a component of dust licked off of surfaces or in swallowed paint chips. Less commonly, water contaminated by its flow through lead pipes or brass fixtures is drunk or food is contaminated by contact with lead-glazed ceramic ware. Cutaneous contamination with inorganic lead compounds, as are found in pigments, does not result in a substantial amount of absorption. In contrast, organic lead compounds such as tetraethyl lead may penetrate through skin.

Once lead is in the intestine the percentage absorbed depends on several factors: particle size, pH, other material in the intestine, and nutritional status of essential elements. Large paint chips are difficult to digest and mainly are excreted. Fine dust can be dissolved more readily, especially in an acid medium. Lead eaten on an empty stomach is better absorbed than if taken with a meal. The presence of calcium

and iron may decrease lead absorption by direct competition for binding sites. On the other hand, iron, and probably calcium, deficiency results in enhanced lead absorption, retention, and toxicity.

After absorption, lead is disseminated throughout the body by way of the blood. It circulates bound to erythrocytes; about 97% is bound on or in the red blood cell. The plasma fraction is too small to be measured by conventional techniques such as atomic absorption spectroscopy or anodic stripping voltammetry; it is, however, presumably the plasma portion that may enter cells and induce toxicity. In cells, lead has multiple effects. It binds to enzymes, particularly those with available sulfhydryl groups, changing the contour and diminishing function. The heme pathway, present in all cells, has three enzymes susceptible to lead inhibitory effects. The last enzyme in this pathway, ferrochelatase, enables protoporphyrin to chelate iron, thus forming heme. Protoporphyrin is readily measurable in red blood cells. Levels greater than 35?µg/dL are abnormal and are consistent with lead poisoning, iron deficiency, or recent inflammatory disease. Lack of heme affects multiple metabolic pathways. The accumulation of excess amounts of protoporphyrin and other heme precursors is toxic as well, independently of lead. Measurement of the erythrocyte protoporphyrin (EP) level is, therefore, a useful tool for monitoring biochemical lead toxicity. In general, EP levels begin to rise several weeks after BLLs have reached 20?µg/dL in a susceptible portion of the population and will be elevated in nearly all children with BLLs of more than 50?µg/dL. A decrease in EP levels also lags behind a decrease in BLLs by several weeks, because it depends on both cessation of further overproduction in marrow red cell precursors and cell turnover.

A second mechanism of lead toxicity is by way of its competition with calcium. Many calcium-binding proteins have a higher affinity for lead. Lead bound to these proteins may alter function, resulting in intracellular and intercellular communications breakdown. For example, neurotransmitter release is in part a calcium-dependent process that is adversely affected by lead.

Although these two mechanisms of toxicity may be reversible, a third way that lead may cause harm is by preventing the development of the normal tertiary structure in the brain. In immature mammals, the normal pruning process that results in elimination of multiple intercellular brain connections is inhibited by lead. This process is part of the timed developmental sequence that humans undergo as well. Failure to construct the appropriate tertiary brain structure during the first few years of life may, therefore, result in a permanent abnormality.

Clinical Manifestations.

The BLL is the best studied measure of lead in children. Subclinical and clinical findings correlate with BLLs in populations. However, there is considerable inter-individual variability in this relationship. For instance, lead encephalopathy is more likely to be observed in children with BLLs greater than 100?µg/dL. Yet, one child may have no symptoms with a BLL of 300?µg/dL and another will be in the intensive care unit on life support for cerebral edema.

Several subclinical effects of lead have been demonstrated in cross-sectional epidemiologic studies. Hearing and height were inversely related to BLLs in children. In neither case does the lead effect reach a level that would bring an individual child to medical attention. Rather, as BLLs increased in the study population, a little more sound, at all frequencies, was needed to reach hearing threshold. Likewise, children with higher BLLs were slightly shorter than those with lower levels; for every 10?µg higher the BLL, the children were 1?cm shorter.

In addition, a number of longitudinal studies have followed cohorts of children from birth for as long as 20 yr and examined the relationship between BLLs and cognitive test scores over time. These studies were designed to address the question of whether lead causes or is a marker of cognitive deficits. In general, BLLs, expressed as either a level obtained at around 2 yr of age or a measure that integrates multiple BLLs drawn from a subject over time, are inversely related to cognitive test scores. On average, for each 1?µg/dL elevation in BLL the cognitive score is approximately a quarter to half a point lower. However, this relationship is not based on concurrent testing of lead and cognition. Rather it is the BLLs from early childhood that are predictors of the cognitive test results performed years later. This implies that the cognitive effects of lead are permanent.

Data from two studies challenge this implication. In the first, scores on the Bayley Scale of Mental Development were obtained repeatedly every 6 mo for the first 2 yr of life. Results correlated inversely with cord BLL, a measure of in utero exposure, but not with BLLs obtained concurrently at the time of developmental testing. However, after 2 yr of age all other cognitive tests performed on the cohort over the next 10 yr correlated with the BLLs at age 2 yr but not with cord BLLs. Thus, the effects of prenatal lead exposure on brain function were superseded by early childhood events and later BLLs. The second line of evidence is from an intervention study in which moderately lead-poisoned children, with initial BLLs of 20–55?µg/dL, were aggressively managed over 6 mo. Components of treatment included education regarding sources of lead and its abatement, nutritional guidance, multiple home and clinic visits, and, for a subset, chelation therapy. Average BLLs declined, and cognitive scores were again inversely related to the change in BLL. For every 1?µg/dL decrease in BLL, cognitive scores were one quarter point higher.

Behavior is also disturbed by lead. Hyperactivity is noted in young school-aged children with histories of lead poisoning or with concurrent elevations in BLL. Older children with higher bone lead content are more likely to be aggressive and to have behaviors that are predictive of later juvenile delinquency. Whether the behavioral effects of lead are reversible has only been examined in a single small study. Seven-year-old

hyperactive children with BLLs in the 20s were randomized to receive a chelating agent (penicillamine), methylphenidate, or placebo. Teacher and parent ratings of behavior improved for the first two groups but not the placebo receivers. BLLs declined only in the chelated group.

Additional clinical signs and symptoms occur in the gastrointestinal and central nervous systems (CNS). Gastrointestinal symptoms include anorexia, abdominal pain, vomiting, and constipation, often occurring and recurring over a period of weeks. Children with BLLs of more than 20?µg/dL are twice as likely to have gastrointestinal complaints as those with lower BLLs. CNS symptoms are related to

increasing cerebral edema and increased intracranial pressure. Headaches, change in mentation, lethargy, seizures, and coma leading to death are rarely seen at levels below 100?µg/dL but have been reported in children with a BLL as low as 70?µg/dL. The last reported death attributable to lead poisoning in the United States was in 2000 in a child with a BLL over 300?µg/dL. There is no clear cutoff for the appearance of hyperactivity in relation to BLL, but it is more likely to be observed in children who have reached 20?µg/dL.

Although not usually causing symptoms in children, other organs are affected by lead as well. At high levels, over 100?µg/dL, renal tubular dysfunction is observed. Lead induces a reversible Fanconi syndrome. Also at such BLL elevations, red cell survival is shortened and may contribute to anemia, although most cases of anemia in lead-poisoned children are due to other factors, such as iron deficiency and hemoglobinopathies.

Diagnosis

SCREENING.

Approximately 99% of lead-poisoned children are identified by screening procedures rather than by clinical recognition of lead-related symptoms. Until 1997, universal screening by blood lead testing of all children at ages 12 and 24 mo was the standard. Because of the national decline in the prevalence of lead poisoning, this recommendation has been revised. Currently, targeted blood lead testing of high-risk populations is indicated. High risk is based on an evaluation of the likelihood of lead exposure. Departments of health are responsible for determining the local prevalence of lead poisoning as well as the percentage of housing built before 1950, the period of peak leaded paint use. When this information is available, informed screening guidelines for practitioners can be issued. For instance, in New York State, where a large percentage of housing is known to have been built before 1950, the Department of Health mandates that all children be tested for lead poisoning by blood analyses. In the absence of such data the practitioner should continue to test all children at 12 and 24 mo of age. In areas where the prevalence of lead poisoning and old housing is low, targeted screening may be performed based on a risk assessment. Three questions form the basis of a questionnaire (Box 703–1). Items that are pertinent to the locale or individual may be added. For example, if questioning determines that there is a lead-based industry in the child's neighborhood (e.g., a car battery factory) or that the child is a recent immigrant from a country that still uses leaded gasoline or the child has developmental delay, then blood lead testing would be appropriate. If feasible, venous sampling is always preferred to capillary sampling because the chances of false-positive and false-negative results are less.

INTERPRETATION OF BLOOD LEAD LEVELS.

The current cutoff of a BLL of 10?µg/dL is an arbitrary and probably temporary point based on knowledge accumulated before 1991. Levels as low as 5?µg/dL may affect cognitive function, and older data support biochemical effects of lead occurring below this threshold as well.

A screening value at or above 10?µg/dL requires repeat testing for a diagnosis and to determine the intervention. The timing for the repeat evaluation depends on the initial value (Table 703–1). If the diagnostic (second) test confirms that the BLL is elevated, then further testing will be required as per the recommended schedule (Table 703–2). **A confirmed venous BLL of 45?µg/dL or more requires prompt chelation therapy.**

Box 703-1. Minimum Personal Risk Questionnaire

1. Does the child reside in or visit regularly a house that was built before 1950 (include settings such as daycare, babysitters or relatives).
2. Does the child reside in or visit regularly a house built before 1978 with recent or ongoing (past 6 mo) renovation.
3. Does the child have a sibling or playmate with lead poisoning.

OTHER TOOLS FOR ASSESSMENT.

BLL determinations remain the gold standard for evaluating children, although techniques are available to measure lead in other tissues and body fluids. Experimentally, the method of x-ray fluorescence (XRF) allows direct and noninvasive assessment of bone lead stores. XRF methodology was used to evaluate a population that had long-term exposure to lead from a polluting battery recycling factory. The study found that the school-aged children had elevated bone lead levels but not BLLs. This is consistent with the slow turnover of lead in bone, measurable in years, in contrast to that in blood, measurable in weeks. It also indicates that children may have substantial lead in their bodies that will not be detected by routine blood lead testing. This stored lead may be released, resulting in toxic blood levels, if bone resorption rates suddenly increase, as occurs with immobilization of greater than a week and during pregnancy. Thus, children with histories of elevated BLLs are potentially at risk for recrudescence of lead toxicity long after ingestion has stopped and may pass this lead to the next generation. Currently, XRF methodology remains limited primarily for research uses.

Lead can also be measured in urine.

Spontaneous excretion of lead, even in children with high BLLs, is usually low. Lead excretion may be stimulated by treatment with chelating agents, and this property is the basis of their use as a component of lead treatment. Urinary lead excretion has also been used to develop a test to identify children with lead burdens responsive to chelation therapy, the Lead Mobilization Test. In one version, a standardized protocol is employed that includes a fixed dose of the drug (500?mg/M^2 of $CaNa_2$ EDTA given once intramuscularly, mixed 1:1 by volume with 1% procaine) followed by a timed urine collection of 6–8?hr that is analyzed for its lead content. Urine lead per dose of $CaNa_2$ EDTA greater than or equal to 0.6 or urine lead levels greater than or equal to 200?µg/volume identifies children most likely to respond to a full course of treatment with an enhanced lead diuresis. Practical (collecting urine

Data in part from Centers for Disease Control and Prevention: Screening Young Children for Lead Poisoning: Guidance for State and Local Public Health Officials.Atlanta, CDC, 1997.

on an infant for 6–8?hr in the office) and theoretical concerns (Is there a redistribution of lead after a single dose of chelating agent that may result in transient elevation in brain lead? Are there any data showing long term efficacy of children chelated on this basis?) have limited the use of this diagnostic test to a few experienced medical centers, and it is not recommended by the American Academy of Pediatrics.

Lead in hair is also measurable but is problematic, owing to concerns about contamination and interpretability.

Other tests are used as indirect assessments of lead exposure and accumulation. Radiographs of long bones may show dense bands at the metaphyses that may be difficult to distinguish from growth arrest lines but, if caused by lead, are indicative of months to years of exposure. For children with acute symptoms, when a BLL level result is not immediately available, a kidney-ureter-bladder view may be helpful; radiopaque flecks observed in the intestinal tract are consistent with very recent

ingestion of lead-containing plaster or paint chips. The absence of radiographic findings does not rule out lead poisoning.

Because BLLs reflect recent ingestion or redistribution from other tissues but do not necessarily correlate with the body burden of lead or lead toxicity in an individual child, tests of lead effects may also be useful. After several weeks of lead accumulation and a BLL greater than 20?µg/dL, increases in erythrocyte protoporphyrin (EP) levels greater than 35?µg/dL may occur. An elevated EP level, not attributable to iron deficiency or recent inflammatory illness, is both an indicator of lead effect but also a useful test for assessing the success of the treatment; levels will begin to decrease a few weeks after successful interventions that reduce lead ingestion and increase lead excretion. Because EP is light sensitive, whole blood samples should be covered in aluminum foil (or equivalent) until analyzed.

Treatment.

Once lead is in bone it is slowly released and is difficult to remove even with drugs. In addition, the cognitive/behavioral effects from lead may be irreversible. Thus, the main efforts in treating lead poisoning are to prevent it from occurring and to prevent further ingestion by already poisoned children. The main components of these efforts are the identification of environmental sources of lead exposure and their elimination, behavioral modification to reduce non-nutritive hand-to-mouth activity, and dietary counseling to ensure sufficiency of the essential elements calcium and iron. For the small minority of children in the United States with more severe lead poisoning, drug treatment is available that enhances lead excretion.

During health maintenance visits (see Chapter 5) a limited risk assessment is warranted that includes questions pertaining to the most common sources of lead exposure, namely, the condition of old paint, secondary occupational exposure via an adult living in the home, or proximity to an industrial source of pollution. If such a source is identified, its elimination will usually require assistance from public health and housing agencies as well as educational efforts aimed at the parents. Ideally, a family should move from a lead-contaminated dwelling until repairs are completed. In the interim, repeated washes of surfaces and the use of high-efficiency particle accumulator (HEPA) vacuum cleaners will help reduce exposure to lead-containing dust. Care in the selection of a contractor who is certified to perform lead abatement work is necessary. Sloppy work can cause dissemination of lead-containing dust and chips throughout a home or building and result in further elevation of a child's BLL. After the work is completed, dust wipe samples should be collected from floors and window sills and window wells to determine if the risk from lead has abated.

It is often observed that a single case of lead poisoning is discovered in a household with multiple family members, including other young children. This occurs despite a common source of exposure, such as peeling lead-based paint. The lack of accumulation in the other children, at least in part, is caused by differences in behavior. Parental efforts at reducing the hand-to-mouth activity of the affected child are necessary to decrease the risk of lead ingestion. Handwashing effectively removes lead; but in a home with lead-containing dust, lead rapidly accumulates on the child's hands after washing. Therefore, handwashing is best limited to the period immediately before nutritive hand-to-mouth activity is allowed to occur.

Because there is competition between lead and essential metals, it is reasonable to promote a healthy diet that is sufficient in calcium and iron content. The recommended daily intakes of these metals vary somewhat with age (see Chapter 40). In general, for children 1 yr of age and older a calcium intake of about 1?g/24?hr is sufficient. This is roughly the calcium content of a quart of milk (~1200?mg/qt) or calcium-fortified orange juice. Calcium absorption is vitamin D dependent. Although milk is vitamin D fortified, other nutritional sources of calcium are not. A multivitamin containing vitamin D may be prescribed for those children not drinking sufficient milk or who have inadequate sunshine exposure. Iron requirements also vary with age: 6?mg/24?hr for infants to 12?mg/24?hr for adolescents. It is more difficult to eat enough iron-containing foods to attain this intake than to ingest calcium, and iron deficiency is commonly observed in young lead-poisoned children. For children identified biochemically as being iron deficient, therapeutic iron at a daily dose of 5–6?mg/kg for 3 mo is appropriate. Iron absorption is enhanced when ingested with ascorbic acid (citrus juices). Whether doses of calcium and/or iron greater than the daily requirements offer any additional benefits to lead-poisoned children is under investigation but cannot be recommended at this time.

Drug treatment to remove lead is lifesaving for children with lead encephalopathy. Its role for nonencephalopathic children is to prevent symptom progression and further toxicity. Guidelines for selecting children for chelation are based on the BLL. A child with a venous BLL greater than or equal to 45?µg/dL should be treated. Four drugs are available in the United States: DMSA (succimer), $CaNa_2$ EDTA (versenate), BAL (dimercaprol), and penicillamine. DMSA and penicillamine can be given orally, whereas EDTA and BAL can only be administered parenterally. The choice of agent is guided by the severity of the lead poisoning, the effectiveness of the drug, and the ease of administration (Table 703–3). Children with BLLs between 44 and 70?µg/dL should be treated with a single drug, preferably DMSA. Those with BLLs of 70?µg/dL or greater require two-drug treatment: (1) $CaNa_2$ EDTA in combination with either DMSA or BAL for those without evidence of encephalopathy and (2) $CaNa_2$ EDTA and BAL for those with encephalopathy. Data on the combined treatment with $CaNa_2$ EDTA and DMSA for children with BLLs greater than 100?µg/dL are very limited.

Drug-related toxicities are generally minor and reversible. These include gastrointestinal distress, transient elevations in

TABLE 703-3 -- **Chelation Therapy**

Name	Synonym	Dose	Toxicity
Succimer	Chemet, DMSA	350?mg/m^2 /dose (***not 10?mg/kg)*** q8h, PO, for 5 days; then q12h for 14 days	Gastrointestinal distress, rashes; elevated LFTs, depressed WBCs

Edetate	$CaNa_2$ EDTA, versenate	1000–1500?mg/m^2 /24?hr; IV infusion, continuous or intermittent; > IM divided q6h or q12h. For 5 days.	Proteinuria, pyuria, increasing BUN/creatinine—all rare. >Hypercalcemia if too rapid an infusion. >Tissue inflammation if infusion infiltrates
BAL	Dimercaprol, British AntiLewisite	300–500?mg/m^2 /24 h; **IM only** divided q4h. For 3–5 days. Only for blood lead level =70.	Gastrointestinal distress, altered mentation; elevated LFTs, hemolysis if G6PD deficiency; no concomitant iron therapy
d-Pen	Penicillamine	10?mg/kg/24?hr for 2 wk increasing to 25–40?mg/kg/24?hr; oral, divided q12h. For 12–20 wk.	Rashes, fever; blood dyscrasias, elevated LFTs, proteinuria. >Allergic cross-reactivity with penicillin.

LFTs = Liver function tests; WBCs = white blood cells; BUN = blood urea nitrogen; G6PD = glucose-6-pyruvate dehydrogenase.

From Markowitz ME: Lead poisoning. Pediatr Rev 2000;21:327–35.

transaminase values, active urinary sediment, and neutropenia. The frequencies of these types of events are lowest for $CaNa_2$ EDTA and DMSA and highest for BAL and penicillamine. All of the drugs are effective in reducing BLLs when given in sufficient doses over the recommended duration of time. However, these drugs may also increase lead absorption from the intestine and should be administered to children in lead-free environments. Some authorities also recommend the administration of a cathartic immediately before or concomitant with the initiation of chelation to eliminate the presence of lead already in the intestine.

None of these agents will remove all lead from the body. Within days to weeks after completion of a course of therapy the BLL rises, even in the absence of new ingestion. The presumed source of this rebound in the BLL is bone. Chelation is again indicated if the BLL rebounds to 45?µg/dL or greater. Children with initial BLLs greater than 70?µg/dL are likely to require more than one course. A minimum of 3 days between courses is recommended, if possible, to prevent treatment-related toxicities, especially kidney injury. Serial x-ray fluorescent measurements of bone lead content have shown that chelation with $CaNa_2$ EDTA is associated with a decrease in bone lead levels; however, residual bone lead remains detectable even after multiple courses of treatment.

The indication for chelation therapy for children with BLL less than 45?µg/dL is less clear. Use of these drugs in children with BLLs between 20 and 44?µg/dL will result in transiently lowered BLLs, and in some this will be accompanied by reversal of lead-induced enzyme inhibition. However, very few of such children significantly increase their excretion of lead during chelation, raising the question of whether any long-term benefit is achieved. A study that enrolled 2-yr-old children with BLLs 20–44?µg/dL and randomized them to receive either DMSA or placebo found the following: BLLs decreased more in the first 6 mo after enrollment in the DMSA-treated group, but the levels converged by 1 yr of follow-up; cognitive test scores obtained at 4 yr of age were not statistically different between the groups. Thus, chelating all children with BLLs of 20–44?µg/dL is not recommended. However, it is possible that a subset of children may benefit. These might include children with persistently elevated BLLs. Another group may include children who can be shown to respond to a test dose of a chelating agent with an enhanced lead diuresis, an indication that the drug is effective at removing lead permanently from the body. Such children could be identified by administration of the Lead Mobilization Test. Data on cognitive outcomes are not available for either of these groups of children after chelation.

With successful intervention, BLLs decline, with the greatest fall in BLL occurring in the first 2 mo after therapy is initiated. Subsequently, the rate of change in BLL declines slowly, so that by 6–12 mo after identification the average child with moderate lead poisoning (BLL > 20?µg/dL) will have a BLL that is 50% lower. Children with more markedly elevated BLLs may take years to reach the acceptable threshold of 10?µg/dL even if all sources of lead exposure have been eliminated, behavior has been modified, and nutrition has been optimized. Thus, early screening remains the best way of avoiding the need for the treatment of lead poisoning.

704.1 Epidemiology and Approach to Management

Of the more than 2 million human poisoning exposures reported annually to the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers (AAPCC), more than 50% occurred in children 5 yr of age or younger. Almost all of these exposures are unintentional and reflect the propensity for children in this age group to put virtually anything in their mouths. See Chapters 57 and 701 .

More than 90% of toxic exposures in children occur in the home, and most involve only a single substance. Ingestion is the most common route of poisoning exposure (76% of cases), with

the dermal, ophthalmic, and inhalation routes each occurring in about 6% of cases. About 60% of cases involve nondrug products, most commonly cosmetics and personal care products, cleaning substances, plants, foreign bodies, and hydrocarbons. Pharmaceutical preparations comprise the remainder, with analgesics, cough and cold products, antimicrobial agents, and vitamins the most common categories. More than 75% of pediatric poisoning exposures can be managed without direct medical intervention, because either the product involved is not inherently very toxic or the quantity of the material involved is not sufficient to produce significant toxic effects. A partial list of nontoxic products commonly encountered by children is shown in Box 704–1 . Death due to unintentional poisoning in young children is uncommon owing to increased product safety measures (e.g., child-resistant packaging), increased poison prevention education, early recognition of exposure, and improvements in medical management.

Poison prevention education should be an integral part of all well-child visits, even before a child is mobile. Counseling parents and other caregivers about potential

poisoning risks, how to “poison-proof” a child's environment, and what to do if a poisoning occurs diminishes the likelihood of serious morbidity or mortality from an exposure. Poison prevention educational materials are available from both the American Academy of Pediatrics and regional poison control centers (1-800-222-1222 in the United States). See Chapter 5 .

Poisoning exposures in children 6–12 yr of age are much less common (4% of exposures). Toxic exposures in adolescents are primarily intentional (suicide or abuse) or occupational. Pediatricians should be aware of the signs of drug abuse or suicidal ideation in this population and should aggressively intervene.

MANAGEMENT PLAN FOR POISONING AND OVERDOSE

History.

Obtaining an accurate problem-oriented history is of paramount importance if a poisoning has occurred or is suspected. The following information should be obtained during the initial assessment:

DESCRIPTION OF TOXINS.

Product names (brand, generic, or chemical) and ingredients, along with their concentrations, may be obtained from labels. Because many brand names that sound alike have very different ingredients, it is important to be precise. If the ingredient information is not readily available on the product, consultation with a poison control center can usually provide this information rapidly. Several characteristic toxic syndromes are described (Table 704–1). These may assist in identifying the offending agent.

TABLE 704.1-1 -- **Toxic Syndromes**

Syndrome	Symptoms	Causes
Anticholinergic	Exocrine gland hyposecretion, thirst, flushed skin, mydriasis, hyperthermia, urinary retention, delirium, hallucinations, tachycardia, respiratory insufficiency	Belladonna alkaloids, jimsonweed, some mushrooms, antihistamines, tricyclic antidepressants, scopolamine
Cholinergic (muscarinic and nicotinic)	Exocrine gland hypersecretion, urination, nausea, vomiting, diarrhea, muscle fasciculations, miosis, weakness or paralysis, bronchospasm, tachycardia or bradycardia, convulsions, coma	Organophosphate and carbamate insecticides, some mushrooms, tobacco, black widow spider bites (severe)
Extrapyramidal	Tremor, rigidity, opisthotonos, torticollis, dysphonia, oculogyric crisis	Phenothiazines, haloperidol, metoclopramide
Hypermetabolic	Fever, tachycardia, hyperpnea, restlessness, convulsions, metabolic acidosis	Salicylates, some phenols, triethyltin, chlorophenoxy herbicides
Narcotic	Central nervous system depression, hypothermia, hypotension, hypoventilation, miosis	All narcotics, propoxyphene, heroin
Sympathomimetic	Excitation, psychosis, seizures, hypertension, tachypnea, hyperthermia, mydriasis	Amphetamines, phencyclidine, cocaine, crack cocaine, phenylpropanolamine, methylphenidate, theophylline, caffeine

Withdrawal	Abdominal cramps, diarrhea, lacrimation, sweating, “goose flesh,” yawning, tachycardia, restlessness, hallucinations	Cessation of alcohol, barbiturates, benzodiazepines, narcotics

Box 704.1-1. Common Nontoxic Products

Abrasives

Antacids

Antibiotics

Ballpoint pen inks

Bathtub floating toys

Bath oil (castor oil and perfume)

Body conditioners

Bubble bath soaps (detergents)

Calamine lotion

Candles (beeswax or paraffin)

Caps (toy pistols, potassium chlorate)

Chalk (calcium carbonate)

Children's toy cosmetics

Clay (modeling)

Contraceptive agents

Corticosteroids

Cosmetics

Crayons (marked A.P. or C.P., gel)

Corticosteroids

Cosmetics

Crayons (marked A.P. or C.P., gel)

Dehumidifying packets (silica or charcoal)

Deodorants–underarm

Fabric softeners

Fertilizers (if no insecticide or herbicides added)

Fishbowl additives

Glues and pastes

Golf ball (core may cause mechanical injury)

Grease

Hand lotions and creams

Hydrogen peroxide (medicinal 3%)

Incense

Indelible markers

Ink (black, blue–nonpermanent)

Iodophil disinfectants (unless allergic)

Laxatives

Lipstick

Lubricating oils (unless aspirated)

Magazines

Magic markers

Makeup

Matches

Mineral oil (unless aspirated)

Newspaper (chronic ingestion may result in lead poisoning)

Paint–indoor latex

Pencil lead (graphite, coloring)

Newspaper (chronic ingestion may result in lead poisoning)

Paint–indoor latex

Pencil lead (graphite, coloring)

Petroleum jelly (Vaseline)

Play-Doh

Polaroid picture coating fluid

Porous–tip ink marking pens

Putty

Rubber cement

Sachets

Shampoo

Shaving creams and lotions

Soap and soap products

Spackles

Suntan preparations

Sweetening agents (saccharin, aspartame)

Toothpaste (with and without fluoride)

Warfarin rodenticides (<0.5%)

Watercolor paints

Zinc oxide

MAGNITUDE OF EXPOSURE.

Attempt to determine how much of the substance has been ingested. This can often be accomplished by counting the number of tablets or measuring the volume of liquid remaining. Because the toxicity of most agents is dose related, knowing the age or weight of the child aids in assessment. For inhalation, ocular, or dermal exposures, the concentration of the offending agent and the length of contact time with the material should be determined.

TIME OF EXPOSURE.

For some products, toxic manifestations may be delayed for hours or days. Knowing the time lapse between exposure and the time to either medical

evaluation or the onset of symptoms may influence therapeutic intervention.

PROGRESSION OF SYMPTOMS.

Knowing the nature and progression of symptoms is helpful for assessing the need for immediate life support, the prognosis, and the type of intervention that may need to be performed.

MEDICAL HISTORY.

Underlying diseases may make a child more susceptible to the effects of a toxin. Concurrent drug therapy may also increase susceptibility, because certain drugs may interact with the toxin. Pregnancy is a common precipitating factor in adolescent suicide attempts and may influence the treatment plan.

DEMOGRAPHIC INFORMATION.

This is particularly important to know if a parent or caregiver telephones the physician's office with a poisoning situation. Obtain the caller's telephone number and street address to allow for follow-up or to dispatch emergency personnel in the event phone contact is broken.

Initial Medical Care.

If the patient is treated at home, follow-up assessment calls should be made approximately 0.5, 1, and 4?hr after exposure. Any change in the patient's condition may alter the decision to treat at home. Consultation with a poison control center for assistance in monitoring such patients should be considered. Poison control centers are staffed by nurses, pharmacists, and physicians specially trained to respond to and monitor poisoning exposures. If the patient requires hospital treatment, the probability of developing life-threatening symptoms dictates the mode of transportation used. After a decision to transport a patient is made, emergency department personnel should be notified so they can properly prepare. All product containers thought to be related to the exposure should be collected and transported with the patient. If the patient has vomited, the emesis should also be brought to the emergency department for possible toxicologic analysis.

Once the patient has arrived in the appropriate medical care setting, initial attention should focus on life support, with primary emphasis on cardiorespiratory care. Initial treatment of shock, dysrhythmias, and seizures is generally the same as for any other critically ill patient (see Chapter 57). Antidotes exist for only a few poisons (

Table 704–2).

Preventing Absorption.

Most toxins are rapidly absorbed from the gastrointestinal tract or through inhalation. Many may also be well absorbed upon dermal contact. Prompt action to remove the toxin and minimize contact with the absorptive surface is crucial and may prevent the development of major toxicity.

Dermal and ocular decontamination can be accomplished by flushing the affected area with tepid water. A minimum of 10?min is recommended for ocular exposures, although some chemicals, particularly alkaline corrosives, may require much longer periods of flushing. For dermal exposures, mild soap and water can be used.

For inhaled toxins, decontamination is generally accomplished by moving the patient to fresh air or, if necessary, administering oxygen. In addition to supportive care, a few specific antidotes are used for some specific inhaled toxins. These are listed in Table 704–2 .

Several procedures are used to prevent absorption of a toxin from the stomach and gastrointestinal tract, and each has limitations and risks. The decision to use one particular method over another should be based on whether the technique chosen is likely to be of sufficient value to merit the risk of the procedure. Timing is a limitation because many toxins are rapidly absorbed from the stomach. A decontamination procedure instituted after the drug is absorbed poses a risk to the patient with no potential for benefit. In general, most liquid drug products are almost completely absorbed within 30?min of ingestion, and most solid dosage forms within 1–2?hr. Gastrointestinal decontamination beyond this time is unlikely to be of value.

EMESIS.

The only emetic routinely used is syrup of ipecac, which contains two emetic alkaloids that work both in the central nervous system (CNS) and locally in the gastrointestinal tract to produce vomiting. The onset of emesis is usually 20–30?min after dosing, with vomiting occurring in 90–95% of patients. Several episodes of vomiting usually occur over a period of 1–2?hr. The recommended dose is 10?mL for infants 6–12 mo of age, 15?mL for children age 1–12 yr, and 30?mL for older children and adults. Ipecac should not be used in infants younger than 6 mo. Ipecac administration is followed by at least 8?oz of water or other clear fluid. At best, emesis with syrup of ipecac removes about one third of the stomach contents. Because of the delay in onset of emesis and poor yield, it should not be used as a general treatment for ingestions. Ipecac-induced emesis is contraindicated after the ingestion of caustics, hydrocarbons, and agents likely to cause the rapid onset of CNS or cardiovascular symptoms. The use of ipecac syrup has declined dramatically in the past 2 decades.

GASTRIC LAVAGE.

This technique involves placing a tube into the stomach to aspirate contents, followed by flushing with aliquots of fluid, usually normal saline. Although gastric lavage has been widely used for many years, objective data do not document its efficacy, particularly in children, in whom only small-bore tubes can be used. Lavage is time consuming and, even under the best of circumstances, removes only a fraction of gastric contents. It should only be used in older children and only in select situations.

ACTIVATED CHARCOAL.

The use of activated charcoal to prevent absorption of toxins has increased dramatically in the past 2 decades as data demonstrating its efficacy have accumulated. Activated charcoal is specially prepared to have a very large adsorptive surface area. Many, but not all, toxins are adsorbed onto its surface, preventing absorption from the gastrointestinal tract. Some toxins, including heavy metals, iron, lithium, hydrocarbons, cyanide, and low molecular weight alcohols, are not significantly bound to charcoal. In vitro, activated charcoal adsorbs about 1?g of toxin for each 10?g of charcoal; however, this relationship is generally not useful for clinical situations because the exact ingested dose is seldom known. The usual dose is 10–30?g for a child and 30–100?g for an adolescent or adult. Activated charcoal is commercially available mixed as a slurry in water or a solution of sorbitol, a cathartic. Flavoring may be added to improve palatability. In some serious poisonings, when life-threatening symptoms are present, repeated doses of activated charcoal may be useful to adsorb either toxin not bound by the first dose or toxin that may be recirculated through the gut. Under these circumstances, a cathartic should be used only with the first charcoal dose to prevent major fluid loss and dehydration. About 25% of patients receiving activated charcoal experience one episode of vomiting. Aspiration of activated charcoal into the lungs occasionally occurs. There is no evidence that aspiration of activated charcoal is more serious than aspiration of gastric contents alone. If charcoal is given through a gastric tube, placement of the tube should be carefully confirmed before activated charcoal is given, because instillation of charcoal directly into the lungs has disastrous effects.

CATHARTICS.

Cathartics are commonly used in conjunction with activated charcoal to hasten the clearance of the charcoal-toxin complex, although no evidence shows that this is of value. Commonly used cathartics are sorbitol (maximum dose, 1?g/kg), magnesium sulfate (maximum dose, 250?mg/kg), and magnesium citrate (maximum dose, 250?mL/kg). Cathartics should be used with care in young children because of the risk of dehydration and electrolyte imbalance.

WHOLE BOWEL IRRIGATION.

Whole bowel irrigation (WBI) involves instilling large volumes of a polyethylene glycol electrolyte solution (Colyte, GoLYTELY) into the stomach to cleanse the entire gastrointestinal tract. This technique has been

TABLE 704.1-2 -- **Common Antidotes for Poisoning**

Antidote	Use	Dose	Route	Adverse Effects/Warnings
N-Acetylcysteine (NAC, Mucomyst)	Acetaminophen; carbon tetrachloride and chloroform (experimental)	140?mg/kg loading, followed by 70?mg/kg q4h for 17 doses	PO	Nausea, vomiting IV form not available in USA
Atropine	Organophosphate and carbamate pesticides; bradycardia due to atrioventricular conduction defects	0.05?mg/kg repeated q5–10?min as needed. Dilute in 1–2?mL of NS for ET instillation.	IV/ET	Tachycardia, dry mouth, blurred vision, and urinary retention
BAL in oil (dimercaprol)	Arsenic, mercury, other metals	3–5?mg/kg/dose q4hr, for the first day; subsequent dosing depends on toxin	Deep IM	Local injection site pain and sterile abscess, nausea, vomiting, fever, salivation, nephrotoxicity
Benztropine (Cogentin)	Acute dystonic reactions	0.02–0.05?mg/kg/dose qd or bid (4?mg max)	IV/PO	Sedation, blurred vision, dry mouth, and tachycardia
Cyanide antidote kit	Cyanide	Amyl nitrite: 1 crushable ampule, inhale 30 sec of each min	Inhalation	Methemoglobinemi
	Hydrogen sulfide (nitrites only)	Sodium nitrite: 0.33?mL/kg of 3% solution if hemoglobin level not known, otherwise based on tables with product	IV	Methemoglobinemi
		Sodium thiosulfate: 1.6?mL (400?mg)/kg of 25% solution, may be repeated every 30–60?min to a maximum of 50?mL	IV	
Deferoxamine (Desferal)	Iron	Infusion of 15?mg/kg/hr (max 6?g/24?hr)	IV (preferred)	Hypotension (minimized by avoiding rapid infusion rates)
		IM: 90?mg/kg/dose q8h (max of 6?g/24?hr)	IM	
Digoxin-specific Fab antibodies (Digibind)	Digitalis glycosides (synthetic or natural)	One vial binds 0.6?mg of digitalis estimated from serum level (see table with product)	IV	Allergic reactions (rare), return of condition being treated with digitali glycoside
Dimercaptosuccinic acid (succimer, DMSA, Chemet)	Lead and probably mercury, arsenic, and perhaps other metals	10?mg/kg/dose q8h for 5 days, then 10?mg/kg q12h for 14 days	PO	Nausea and vomiting; repeated courses may be needed
Diphenhydramine (Benadryl)	Extrapyramidal symptoms, acute dystonic reactions, allergic reactions	5?mg/kg divide q8h; 300?mg/ 24?hr max	IV/PO	Sedation or paradoxical agitation, ataxia
EDTA, calcium (calcium disodium, Versenate)	Lead, manganese, nickel, zinc, and perhaps chromium	1–1.5?g/m^2 /24?hr in divided doses q12h for 5 days	IV	Nausea, vomiting, fever, hypertension arthralgias, allergic reactions, local inflammation, and nephrotoxicity (maintain adequate hydration)
Ethanol (ethyl alcohol)	Methanol, ethylene glycol	750?mg/kg loading dose followed by 80–150?mg/kg/hr infusion of 5% or 10% ethanol	IV/PO	Nausea, vomiting, sedation
Flumazenil (Romazicon)	Benzodiazepines	0.2?mg over 30 sec; if inadequate response, repeat q1min to 1?mg max	IV	Nausea, vomiting, facial flushing, agitation, headache dizziness, seizures Do not use for unknown or antidepressant ingestions *Note*: May not reverse respiratory depression
Fomepizole (4-methylpyrazole, Antizole)	Ethylene glycol; methanol	15?mg/kg load; 10?mg/kg q12h for 4 doses; 15?mg/kg q12h until level <20?mg/dL No specific dose for children.	IV	Infuse slowly over 30?min; increase doses to q4h if dialysis is concurrent
Glucagon	ß-Blockers, calcium channel blockers, hypoglycemic agents	0.05?mg/kg bolus followed by infusion of 0.05?mg/kg/hr	IV	Hyperglycemia, nausea, and vomiting

Methylene blue	Methemoglobinemia	0.1–0.2?mL/kg of 1% solution, slow infusion, may be repeated q30–60?min	IV	Nausea, vomiting, headache, dizziness
Naloxone (Narcan)	Narcotics Clonidine (inconsistent response)	0.01?mg/kg; if no effect, give 0.1?mg/kg; may be repeated as needed; may give continuous infusion	IV	Acute withdrawal symptoms if given to addicted patients
Physostigmine (Antilirium)	Anticholinergic agents	0.02?mg/kg; slow push; may repeat q5–10?min to 2?mg max	IV/IM	Bradycardia, asystole, seizures, bronchospasm, vomiting, headache *Note*: Do not use with cyclic antidepressants
Pralidoxime (2-PAM, Protopam)	Organophosphate insecticides	25–50?mg/kg over 5–10?min (max 200?mg/min); can be repeated after 1–2?hr then q10–12?hr as needed	IV/IM	Nausea, dizziness, headache, tachycardia, muscle rigidity, and bronchospasm (rapid administration)
Pyridoxine (vitamin B_6)	Isoniazid, *Gyromitra* mushrooms Ethylene glycol (investigational)	Isoniazid; dose = dose of isoniazid Mushrooms: 25?mg/kg	IV	Uncommon

successfully used to remove slowly absorbed products such as iron or sustained-release preparations. Whole bowel irrigation can be combined with the use of activated charcoal, if appropriate. It should be used with caution in young children because of the possibility of fluid and electrolyte imbalance.

Enhancing Elimination.

Enhancing excretion is useful for only a few toxins. Dialytic techniques are not useful for drugs that are either highly protein bound or have a large volume of distribution. These techniques are also invasive and associated with risk. Certain procedures can be used for very specific agents.

DIURESIS.

For most toxins, renal clearance is not proportionate to urine volume; thus diuresis alone does not increase elimination. Increasing the pH of the urine with intravenously administered bicarbonate increases the elimination of weak acids, such as salicylates and phenobarbital. Alternately, acidifying the urine to increase the elimination of weak bases such as amphetamine and phencyclidine is not clinically useful. This technique is termed *ion trapping*.

DIALYSIS.

Hemodialysis and peritoneal dialysis have been used successfully to treat poisonings by select agents. Although hemodialysis is generally more efficient at removing toxins, peritoneal dialysis is often easier to perform in young children and may be sufficient. Few drugs or toxins are removed by dialysis in amounts sufficient to justify the risks and difficulty of dialysis. Examples of toxins for which dialysis may be useful include methanol, ethylene glycol, and large symptomatic ingestions of salicylate or theophylline.

HEMOPERFUSION.

Hemoperfusion is a dialytic technique in which blood is passed through a column of activated charcoal or resin. It has been used successfully to treat large ingestions of salicylate, theophylline, and a few other selected agents. It is rarely used in small children because of the risks associated with its use.

Laboratory Evaluation.

For some intoxications (e.g., salicylates, acetaminophen, iron, methanol, ethylene glycol), blood levels are integral to the treatment plan. For other intoxicants, qualitative measurement may assist in establishing a diagnosis but is not likely to change treatment. Examples include opioid toxicity, in which definitive treatment is based on symptoms not levels, or cyanide, in which treatment must be started rapidly and would be significantly delayed if the physician were to wait for laboratory confirmation. Comprehensive qualitative “drug screens” vary widely in their ability to detect toxins and generally add little information, particularly if the agent is known and a patient's symptoms are consistent with that agent. If a drug screen is ordered, it is important to know the specific drugs that can be identified by the test. Although drug screens can be done on any body fluid, urine is generally the best sample. The best way to use the laboratory is to discuss the case with a poison control center, medical toxicologist, or laboratory technologist and to provide appropriate samples and clinical data so that the most appropriate tests can be performed and properly interpreted.

704.2 Acetaminophen

Acetaminophen is the most widely used analgesic and antipyretic, in part because of the finding of a relationship between Reye syndrome and salicylates. Consequently, acetaminophen is commonly available in the home, where it can be unintentionally ingested by young children or taken in an intentional overdose by adolescents.

Pathophysiology.

Acetaminophen toxicity results from the formation of a highly reactive intermediate metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). When therapeutic doses are administered, only a small amount (4%) of a dose is metabolized by hepatic cytochrome P450 enzymes to NAPQI, which is immediately conjugated with glutathione to form a harmless mercapturic acid conjugate. When hepatic stores of glutathione are depleted to less than 70% of normal, the NAPQI metabolite can combine with hepatic macromolecules to produce hepatocellular damage. The acute toxic dose of acetaminophen is generally considered to be more than 200?mg/kg in children younger than 12 yr. A single ingestion of more than 7.5?g is considered a minimum toxic dose in adolescents and adults. Repeated administration of acetaminophen at doses exceeding those recommended may lead to hepatic injury or failure in some children. Parents should be advised to follow closely the manufacturer's dosing guidelines and be aware of its presence in combination products.

Children younger than 6 yr are unlikely to develop significant toxicity after a single ingestion of even relatively large doses of acetaminophen. Nevertheless, at this time, children with a significant ingestion should have their plasma acetaminophen level measured and receive treatment with *N*-acetylcysteine (NAC) if the level falls within the toxic range on the nomogram. Adolescents have a higher incidence of toxic plasma levels after ingestion than do children. Even if a serious case of hepatotoxicity develops, the mortality rate is less than 0.5%. Patients who recover have no sequelae when observed 3–12 mo after the acute toxicity. Severely affected patients may require liver transplantation (see Chapter 349).

Clinical and Laboratory Manifestations.

If untreated, patients who have acutely overdosed pass through four stages of toxicity (Table 704–3). Because early symptoms are nonspecific, physicians may fail to diagnose the ingestion without a good history or high index of suspicion. If a toxic ingestion is suspected, a plasma acetaminophen level should be measured 4?hr or more after ingestion. Measurement earlier than 4?hr after ingestion may be useful to determine if an ingestion has occurred, but cannot be used to determine the

severity of an overdose. The level should be plotted on the Rumack-Matthew nomogram (Fig. 704–1) to determine whether antidotal treatment is indicated. The nomogram should only be used to evaluate the risk after acute exposure to regular release products. Liver function

TABLE 704.2-3 -- Stages in the Clinical Course of Acetaminophen Toxicity

Stage	Time After Ingestion	Characteristics
I	½–24?hr	Anorexia, nausea, vomiting, malaise, pallor, diaphoresis
II	24–48?hr	Resolution of above; right upper quadrant abdominal pain and tenderness; elevated bilirubin, prothrombin time, hepatic enzymes; oliguria
III	72–96?hr	Peak liver function abnormalities; anorexia, nausea, vomiting, malaise may reappear
IV	4 days–2 wk	Resolution of hepatic dysfunction or complete liver failure

studies including enzymes, bilirubin, and prothrombin time should be followed daily in all patients with acetaminophen levels falling within the toxic range on the nomogram.

Treatment.

After large acute overdose, when the need for antidotal treatment is anticipated and when treatment can be started

Figure 704.2-1 Rumack-Matthew nomogram for acetaminophen poisoning. Semilogarithmic plot of plasma acetaminophen levels versus time. *Cautions for the use of this chart*: (1) The time coordinates refer to time *after ingestion*. (2) Serum levels drawn before 4?hr may not represent peak levels. (3) The graph should be used only in relation to a single acute ingestion. (4) The lower *solid line* 25% below the standard nomogram is included to allow for possible errors in acetaminophen plasma assays and estimated time from ingestion of an overdose. (From Rumack BH, Hess AJ [eds]: Poisindex. Denver, 1995. Adapted from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. *Pediatrics* 1975;55:871.)

within 1–2?hr of the ingestion, activated charcoal administration should be considered. The antidote for acetaminophen poisoning is *N*-acetylcysteine (NAC or Mucomyst; see Table 704–2 for dosing). NAC serves as a precursor for glutathione synthesis, thus replenishing glutathione stores and preventing the reaction of NAPQI with hepatocytes. NAC therapy should be initiated as soon as possible after ingestion but may have value even if started 24–36?hr after the ingestion in severe cases. NAC is unpalatable and irritating to the gastrointestinal tract and should be diluted to a 5% solution with soda or fruit juice to minimize vomiting. Antiemetics may be used to control vomiting or NAC may be given directly into the stomach or upper intestine by tube. An intravenous preparation of NAC should soon be available in the United States; it is equally effective as oral NAC but given over a shorter time period. Physicians are encouraged to consult with a medical toxicologist or regional poison control center for cases involving subacute or chronic exposure or extended release products, because the Rumack-Matthew nomogram is not useful in making treatment decisions under these circumstances. **REFERENCES**

704.3 Salicylates

The incidence of salicylate poisoning has declined, particularly in young children, as the use of alternative antipyretics has increased. However, salicylate toxicity must still be considered in therapeutic situations as well as in cases of acute overdose. Methyl salicylate is the active ingredient in oil of wintergreen, a common component in rubefacients.

Pathophysiology.

Salicylates directly or indirectly affect most organ systems by uncoupling oxidative phosphorylation, inhibiting Krebs cycle enzymes, and inhibiting amino acid synthesis. Various complex metabolic abnormalities result. Salicylates also decrease platelet adhesiveness and increase pulmonary capillary permeability. The acute toxic dose of salicylates is generally considered to be greater than 150?mg/kg.

Clinical and Laboratory Manifestations.

The clinical presentation after acute poisoning differs significantly from chronic toxicity. Chronic toxicity results in signs and symptoms that are easily attributed to other causes, such as flu or other febrile illness. Young children are more susceptible to toxic effects because they are less able to buffer the acid load produced by salicylates.

After acute salicylate ingestion, nausea and vomiting occur secondary to gastric irritation. Salicylates directly stimulate the respiratory center, leading to hyperventilation and hyperpnea.

An increased respiratory rate results in respiratory alkalosis with compensatory alkaluria. Both potassium and sodium bicarbonate are excreted in the urine; however, early after exposure, the serum potassium concentration may be in the normal range. When sufficient potassium has been lost through the kidneys, an exchange of potassium for hydrogen ion occurs, and the urine becomes relatively acidic. This “paradoxical aciduria” occurs in the presence of a continued respiratory alkalosis. Dehydration and progressive metabolic acidosis, caused by the accumulation of lactic acid and other metabolic acids, eventually develop. Seriously poisoned patients are more than 5–10% dehydrated. Patients with chronic salicylate poisoning usually present with metabolic acidosis.

CNS changes are an important sign of serious toxicity. Agitation, restlessness, and confusion are common in children. Coma may develop secondary to cerebral edema. Pulmonary edema or hemorrhage may develop in more severe cases. Hyperglycemia or hypoglycemia, particularly in infants, has also been observed. Hepatotoxicity occurs after chronic exposure or very large acute ingestions. Death results from pulmonary edema and respiratory failure, cerebral edema, hemorrhage, severe electrolyte imbalance, or cardiovascular collapse.

Serial serum salicylate levels (obtained every 2–3?hr) should be monitored to evaluate for either continued absorption or impairment of excretion. The Done nomogram, once the standard tool for predicting salicylate toxicity after acute ingestion, is no longer used. After acute ingestion, patents with serum salicylate levels greater than 20?mg/dL should undergo continued observation and monitoring. Levels greater than 70?mg/dL may produce life-threatening effects. Patients with chronic salicylate toxicity may have a level within the therapeutic range (10–20?mg/dL). The level is low in relation to the severity of their illness, reflecting higher tissue concentrations of salicylate.

Urine pH and volume should be measured hourly in all seriously poisoned children. Plasma pH, glucose, potassium, and other electrolytes should be monitored at regular intervals. Clotting studies and liver function tests should be monitored in all severely poisoned patients.

Treatment.

Initial treatment should include gastric decontamination, preferably with activated charcoal, if the patient presents soon after an acute ingestion. Salicylate tablets occasionally form into bezoars, which may be suspected if salicylate levels continue to rise many hours after ingestion or are persistently elevated. Gastric decontamination is usually not useful after chronic exposure.

Initial therapy focuses on rehydration and correction of electrolyte abnormalities (see Chapter 48). Large quantities of potassium and bicarbonate may be needed if symptoms have been present for some time after an acute ingestion or in the case of chronic salicylate poisoning, because body stores of these electrolytes may be severely depleted.

Urinary excretion of unmetabolized salicylate becomes an important route of elimination in overdose. Urinary clearance is affected by urine pH. Because metabolic acidosis produces a more acidic urine, a higher percentage of filtered salicylate remains in the un-ionized form, which is reabsorbed. Urinary salicylate elimination can be increased using ion trapping, increasing urine pH to convert a greater percentage of salicylate to the ionized form, which is then excreted in the urine. Each 1-unit increase in urine pH increases urinary salicylate clearance 4-fold. Urine pH should be raised to at least 7–7.5, using intravenous bicarbonate. It is important to remember that it may be impossible to alkalize the urine without adequately replenishing tissue stores of potassium. Acetazolamide (Diamox) should not be used to achieve urine alkalization.

In severe cases of salicylate intoxication, dialysis may be required both to remove salicylate and to correct electrolyte abnormalities. Indications for extracorporeal removal include serum levels more than 90?mg/dL, changes in neurologic status, respiratory or cardiovascular instability, refractory metabolic acidosis, severe hypokalemia, or renal failure. Hemodialysis is preferred over either peritoneal dialysis or charcoal hemoperfusion.

704.4 Ibuprofen

Ibuprofen is involved in a growing number of unintentional and intentional overdoses because of wider distribution and its increased use as an analgesic and antipyretic. Serious effects after overdose of ibuprofen are rare, occurring in fewer than 0.3% of cases reported to the AAPCC TESS database.

Pathophysiology.

Prostaglandins are involved in a wide variety of physiologic processes. Ibuprofen inhibits prostaglandin synthesis, and this disruption produces the side effects reported with therapeutic use such as gastrointestinal irritation, reduced renal blood flow, and platelet dysfunction. The toxic mechanism of ibuprofen in acute overdose has not been well described. In children, doses less than 100?mg/kg do not cause toxicity, whereas doses greater than 400?mg/kg are capable of producing more serious effects, including seizures and coma.

Clinical and Laboratory Manifestations.

Symptoms usually develop within 4?hr of ingestion and resolve within 24?hr. Common effects include nausea, vomiting, epigastric pain, drowsiness, lethargy, and ataxia. Anion gap metabolic acidosis, coma, transient apnea, renal failure, hypotension, and seizures are rare. Other reported effects include nystagmus, diplopia, headache, tinnitus, and transient deafness.

Symptoms may correlate with ibuprofen blood levels; however, data are limited and the test is not readily available. Renal function studies and acid-base balance should be monitored after ingestion of large doses.

Treatment.

Good supportive care is essential because there is no antidotal therapy. Emesis is of little benefit, but activated charcoal can be administered. Extracorporeal removal methods have not been adequately evaluated and are not recommended.

704.5 Antidepressants

The tricyclic antidepressants (TCAs) and the selective serotonin reuptake inhibitors (SSRIs) represent the two most common classes of antidepressants of toxicologic significance. Tricyclic antidepressants include amitriptyline, nortriptyline, and sinequan. SSRI agents include fluoxetine, sertraline, paroxetine, and citalopram.

TRICYCLIC ANTIDEPRESSANTS

Pathophysiology.

These agents block the neuronal reuptake of norepinephrine, serotonin, and dopamine, in both the central and peripheral nervous systems. They also produce varying degrees of sedation, a-blocking, and anticholinergic effects. Inhibition of fast sodium channels in the myocardium leads to the development of cardiac dysrhythmias and myocardial depression. The potentially toxic dose of these agents in children ranges from 5–20?mg/kg.

Clinical and Laboratory Manifestations.

The primary organ systems affected are the CNS and cardiovascular systems. Symptoms can develop as early as 30?min after ingestion, with serious symptoms usually developing within 6?hr of ingestion. The pattern of toxicity in children is slightly different from that described for adolescents and adults in that CNS effects occur more frequently in children than do cardiovascular effects. Drowsiness, lethargy, or coma have been reported in as many as one third of pediatric cases. Coma, when it occurs, usually resolves in a few hours, but may last longer than 24?hr. Seizures develop in about 15% of cases and can occur without warning. They are usually brief and resolve without treatment. Adolescents with comparable blood TCA levels suffer more significant toxicity than younger children.

Tachycardia, likely secondary to the anticholinergic actions of TCA, is the most common cardiovascular effect but does not usually compromise blood pressure. Hypertension may occur soon after ingestion but rarely requires treatment. Hypotension is uncommon but is a poor prognostic sign. Other cardiac findings include slowing of myocardial conduction, multifocal premature ventricular contractions, and ventricular tachycardia, flutter, or fibrillation. In addition to widening of the QRS complex, QT prolongation occurs with T-wave flattening or inversion, ST segment depression, right bundle branch block, and complete heart block.

Hypoventilation with respiratory arrest may occur without warning. Other reported effects include hyperthermia, choreiform movements, agitation, and twitching. An anticholinergic syndrome including mydriasis, disorientation, hallucinations, urinary retention, and diminished bowel sounds may be present.

The electrocardiogram (ECG) should be closely monitored for QRS widening and QT and QTc prolongation. QRS duration and axis deviation and the level of consciousness have been suggested as predictors of potential toxicity. ECG changes may not be useful predictors of toxicity in younger children because of normal variation. Blood levels of TCAs are not helpful in assessing or predicting the severity of the exposure but may aid in establishing a diagnosis.

Treatment.

After general life support measures are instituted, including endotracheal intubation if indicated, efforts should be made to prevent absorption. Emesis is contraindicated because of the danger of aspiration from vomiting after the onset of CNS depression or seizures. Activated charcoal should be administered. Sodium bicarbonate in doses sufficient to achieve a serum pH of 7.45–7.55 should be administered to treat and prevent dysrhythmias. Lidocaine is used to treat dysrhythmias that are unresponsive to serum alkalization. Quinidine and procainamide should not be used because they further depress cardiac conduction. Hypotension may respond to standard fluid therapy, although vasopressors such as norepinephrine may be required. Severe, unresponsive hypotension is a poor prognostic sign. Hypertension usually is transient and does not require treatment. Seizures, if they require treatment, usually respond to benzodiazepine therapy. Physostigmine, once promoted as an “antidote” for TCA toxicity, is a dangerous agent that can cause seizures and dysrhythmias and should not be used. Because of the large volumes of distribution and high degree of plasma protein binding of TCAs, extracorporeal removal is not of value.

Asymptomatic children should be observed and the ECG monitored for at least 6?hr after exposure. If any manifestations of toxicity (e.g., a QRS interval > 0.10?msec, conduction defects, altered mental status, hypotension, or hypoventilation) develop, continue monitoring in an intensive care unit for 24?hr. Only completely asymptomatic children should be discharged after 6?hr of observation.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

These agents differ from TCAs in that they specifically inhibit reuptake of serotonin in the CNS. They have little or no effect on norepinephrine or dopamine reuptake and minimal, if any, anticholinergic or a-blocking effects.

Clinical Manifestations.

These drugs have a wide therapeutic index so toxic effects are mild. The usual onset of symptoms is within 3?hr, with resolution of symptoms within 24?hr in treated patients. Most cases in children remain asymptomatic. Drowsiness or hyperactivity, agitation, and tachycardia are the most commonly reported effects. Nausea,

vomiting, tremor, dizziness, and abdominal pain are less common. Life-threatening effects such as seizures and coma are rare but have been reported after very large ingestions. Cardiac conduction defects are not common. Adolescents have an increased incidence of symptoms, although they are still relatively minor. The toxic dose of these agents is not well defined.

A *serotonin syndrome* has been reported after accidental overdose of SSRIs as well as therapeutic use. It is an idiosyncratic reaction that includes confusion and disorientation, agitation, coma, hyperthermia, myoclonus, hyperreflexia, tremor, and muscle rigidity. Therapy is supportive, but awareness and recognition of the syndrome is important to prevent complications caused by inappropriate interventions.

Treatment.

Gastrointestinal decontamination with activated charcoal is preferred over ipecac-induced emesis because of the potential for CNS depression. There is no specific therapy other than general supportive care.

704.6 Clonidine

Clonidine was first introduced for use as an antihypertensive but has found use in ADHD and tic syndromes in children (see Chapter 28). Increased use for pediatric indications has resulted in an explosion of acute poisoning and therapeutic misadventures.

Pathophysiology.

The toxic effects of clonidine are a result of a_2 -adrenergic receptor inhibition in the CNS. Children are very sensitive to the toxic effects of clonidine, with as little as 0.1?mg reported to produce significant toxicity. Serious toxicity has developed after sucking or chewing on a new or discarded topical patch preparation.

Clinical and Laboratory Manifestations.

In clonidine naïve children, symptoms frequently develop within 1?hr of ingestion, thus rapid recognition and intervention is essential. Lethargy, miosis, bradycardia, and hypotension occur in all age groups. Apnea, respiratory depression, and coma are common findings in younger children. Serious symptoms usually resolve within

24?hr of ingestion. Serum clonidine levels are not readily available and not recommended.

Treatment.

Immediate recognition of an exposure with transfer to a health care facility is of paramount importance. Gastric decontamination is usually of little value owing to the small quantities usually ingested and the rapid onset of serious symptoms. Aggressive supportive care is imperative. The ECG, vital signs, and blood gases are monitored as symptoms dictate. Naloxone (see Table 704–2) has been used with mixed success to reverse CNS and respiratory depression; however, its use should not replace supportive care. Because the duration of effect of naloxone is shorter than that of clonidine, administration by continuous infusion may be necessary. Extracorporeal removal techniques are not of value.

704.7 Calcium Channel Blockers

Calcium channel blockers (CCBs) encompass a variety of chemical structures that produce various effects on the myocardium and the systemic vasculature. Specific agents include nifedipine, diltiazem, verapamil, amlodipine, and felodipine. They are available as regular-release and sustained-release preparations as well as in combination with diuretics and other antihypertensives. Their increasing therapeutic use has also increased the incidence of poisoning exposure.

Pathophysiology.

The toxic effects of these drugs are an extension of their therapeutic effect in that they slow sinoatrial and atrioventricular nodal conduction and depress myocardial contractility. Inhibition of calcium influx into vascular smooth muscle cells results in arterial dilation and lowered blood pressure. CCBs affect both myocardial tissue and vascular smooth muscle; therefore, in overdose, either cardiac dysrhythmias or hypotension may occur or both effects may be evident. CCBs have a narrow therapeutic index; thus, any dose greater than the usual maximum daily therapeutic dose should be considered potentially toxic.

Clinical and Laboratory Manifestations.

The onset of symptoms may occur within minutes of the ingestion of a regular release product or may be delayed several hours after the ingestion of a sustained-release product. Bradycardia and varying degrees of atrioventricular block are common. Hypotension develops secondary to dilation of vascular smooth muscle. Myocardial depression may lead to shock in severe cases. Confusion, agitation, or lethargy and possible coma may occur. Nausea and vomiting are common.

Careful blood pressure and electrocardiographic monitoring is essential. Although these agents block calcium channels, the serum calcium level is not affected. Hyperglycemia is also common, so serial serum glucose measurements should be followed. Blood levels of CCB are not readily available and are not useful in guiding therapy.

Treatment.

After appropriate supportive care has been instituted, absorption should be prevented using activated charcoal if appropriate. Whole bowel irrigation should be considered if a sustained-release product has been ingested. Bradycardia and conduction disturbances are frequently unresponsive to atropine and often require

the placement of a pacemaker. Isoproterenol may worsen hypotension and should not be used to treat bradycardia. Myocardial depression may contribute to hypotension and should improve if conduction disturbances are reversed. Hypotension may be treated with fluids and vasopressors. Because many CCBs are available as sustained-release formulations, toxic effects may be prolonged if adequate gastrointestinal decontamination has not been performed.

Intravenous calcium may reverse myocardial depression, but it is not consistently effective. Calcium chloride is preferred over calcium gluconate because it contains a greater amount of calcium per gram. Because the duration of action of calcium salts is much shorter than that of CCBs, administration by continuous infusion may be necessary (see Table 704–2). Hypercalcemia does not produce clinical effects and is not a concern.

Glucagon improves cardiac conduction and contractility by promoting calcium ion influx through calcium channels indirectly (see Table 704–2). Its efficacy in the treatment of CCB overdose is not consistent. Other inotropic agents such as amiodarone have also been used with mixed success. High-dose infusion of regular insulin and glucose therapy has demonstrated some effectiveness; however, its use in children has not been examined. Extracorporeal elimination methods are not useful for removing CCBs.

704.8 Iron

Iron is one of the most common causes of childhood poisoning death. Iron-containing products are common in many homes and often resemble candy. The potential severity of exposure is based on the amount of elemental iron ingested. The amount of elemental iron ingested is calculated on the basis of the number of tablets ingested and the percentage of elemental iron in the salt. Ferrous sulfate contains 20%, ferrous gluconate 12%, and ferrous fumarate 33% elemental iron. Multiple vitamin products containing iron list on the label the amount of iron per tablet as elemental iron.

Pathophysiology.

Iron is corrosive to the gastrointestinal mucosa. It also accumulates in the mitochondria and tissues to produce cellular damage and systemic toxicity. Iron causes venodilation and increased capillary permeability leading to hypotension. Reduced peripheral perfusion and mitochondrial damage result in lactic and citric acid accumulation, causing metabolic acidosis. Hepatic necrosis develops after serious poisoning, resulting in abnormal liver function tests and coagulopathies. Drowsiness and coma may develop as a result of hemodynamic instability or possibly a direct toxic effect of iron in the CNS. Greater than 60?mg/kg of elemental iron is generally considered a toxic dose.

Clinical and Laboratory Manifestations.

Nausea, vomiting, diarrhea, and abdominal pain are the hallmark of iron poisoning and usually develop within 30?min–6?hr after ingestion. Hematemesis and bloody diarrhea may develop in more serious poisonings. The gastrointestinal signs may subside over 6–12?hr; however, careful observation is warranted because systemic toxicity due to cellular damage may ensue, particularly in patients with severe gastrointestinal signs, early hypotension, or drowsiness. Gastric scarring and pyloric stenosis can develop 2–4 wk after a large ingestion or in instances when iron tablets remain in prolonged contact with the gastrointestinal mucosa. Stenosis may be symptomatic and occasionally requires surgical intervention.

Serum iron levels should be obtained and evaluated in the context of symptoms. Iron levels should be obtained about 4?hr after ingestion. Serum iron levels less than 500?µg/dL, measured 4–8?hr after ingestion, indicate a low risk of significant toxicity.

Levels greater than 500?µg/dL indicate significant toxicity is likely. Blood gas levels, serum glucose concentration, liver function tests, and coagulation studies should be monitored in patients with iron levels greater than 500?µg/dL.

Because iron is radiopaque, an abdominal radiograph may confirm the ingestion. Repeat radiographs may help with assessment of the efficiency of gastric decontamination methods. A negative result does not rule out iron ingestion because only undissolved tablets can be seen. Children's multiple vitamins are usually not visualized on radiography because of the low concentration of iron and the rapid dissolution of the tablets.

Treatment.

Good supportive and symptomatic care is essential in cases of iron poisoning. Ipecac-induced emesis may be used to remove tablets from the stomach. Gastric lavage is not recommended in young children because of its inefficiency, particularly because of the large size of many iron tablets. Activated charcoal does not adsorb iron and should not be used. Whole bowel irrigation may be of benefit. If tablets adhere to the gastric mucosa, removal by endoscopic or surgical intervention (gastrotomy) or aggressive whole bowel irrigation has been attempted with mixed success.

Oral bicarbonate (2%), dilute Phospho-Soda (1:4), and magnesium hydroxide (milk of magnesia) react with iron to form less soluble, poorly absorbed iron salts, but this technique is of questionable clinical benefit. Complexation of iron in the gastrointestinal tract using oral deferoxamine is expensive, may increase iron absorption, and is generally not recommended.

Deferoxamine is a specific chelator of iron and is the antidote for moderate to severe iron intoxication (see Table 704–2 for dosing). Indications for deferoxamine include a serum iron level greater than 500?µg/dL, regardless of symptoms, or moderate to severe symptoms regardless of the serum iron level. It should be administered as a continuous intravenous infusion, continued until a patient is symptom free. The deferoxamine-iron complex may color the urine reddish (vin rosé), although this is an unreliable indicator of iron excretion.

704.9 Caustics

Pathophysiology.

Caustics include acids and alkalis as well as a few common oxidizing agents such as bleach. Acids coagulate proteins, causing tissue necrosis. Alkalis digest and dissolve proteins, producing liquefaction necrosis with the risk of perforation if the injury is located in the intestinal tract. The severity of the chemical burn produced depends on the pH, the concentration of the agent, and the length of contact time. Agents with a pH below 2 or above 12 are most likely to produce significant injury.

Clinical Manifestations.

Ingestion of caustic materials may produce oral burns visualized as reddened areas or whitish plaques. Symptoms include pain, drooling, vomiting, or difficulty or refusal to swallow. Circumferential burns of the esophagus are prone to cause strictures on healing, which may require repeated dilation or surgical correction. Strong acids may sometimes produce scarring around the pylorus, leading to delayed onset of gastric obstruction. Caustics on the skin or in the eye can cause significant tissue damage.

Treatment.

Initial treatment of caustic exposure includes thorough removal of the product from the skin or eye by flushing with water. Contaminated clothing should also be removed. Ingested agents should be rinsed from the oral cavity. Emesis and lavage are contraindicated. Activated charcoal should not be used, because it does not bind these agents. Patients should be evaluated for evidence of esophageal burns and, if symptoms are present, oral fluids or solids should be withheld. The absence of visible oral injury does not preclude significant esophageal lesions. Endoscopy should be performed in symptomatic patients or those in whom injury is highly suspect on the basis of history. The use of corticosteroids and esophageal stents is controversial. Prophylactic antibiotics do not improve outcomes.

704.10 Methanol and Ethylene Glycol

Methanol is commonly found in windshield washer fluids, fuel additives, liquid fuel canisters, and industrial solvents. Ethylene glycol is commonly found in car radiator antifreeze. Both solvents are well absorbed via inhalation or after skin contact; however, accidental ingestion is the most common route of exposure in children. The pathophysiology, clinical effects, and treatment of both chemicals are similar. Although each parent compound is capable of producing mild toxicity, it is the metabolites of each product that are responsible for the serious clinical effects that can follow exposure.

METHANOL

Pathophysiology.

Methanol is metabolized in the liver by alcohol dehydrogenase to formaldehyde, which is further metabolized to formic acid by aldehyde dehydrogenase. Formic acid is metabolized through folate-dependent pathways to carbon dioxide and water. Toxicity is caused primarily by formic acid, which inhibits mitochondrial respiration. The development of serious toxic effects is delayed while formic acid is generated and accumulates in blood and tissues.

Clinical and Laboratory Manifestations.

Drowsiness, mild inebriation, and gastric irritation, including nausea and vomiting, develop early after ingestion. The onset of serious effects, including profound metabolic acidosis and visual disturbances, is delayed up to 24?hr. Visual disturbances include blurred or cloudy vision, constricted visual fields, decreased acuity, and the “feeling of being in a snowstorm.” Small children may not be able to describe these visual changes. Pupils may be dilated and unreactive to light, and retinal edema and optic disc hyperemia may be noted. Visual disturbances are usually reversible, but in

significant poisonings, blindness has occasionally been permanent. An anion-gap metabolic acidosis develops; thus, serum electrolytes, pH, and acid-base balance should be monitored.

Children are usually discovered with an open container of product soon after an exposure, and determining if a significant exposure has occurred is usually a problem. Methanol blood measurements are usually available and can rule out an exposure; however, levels do not correlate well with toxicity. Formic acid levels may correlate more closely with toxicity; however, these levels are not routinely available. If methanol levels are not available, estimation of an osmolar gap has been recommended as a surrogate. Serum osmolarity is measured by the freezing point depression method and compared with a calculated serum osmolarity. The osmolar gap can be used to estimate the serum methanol level using the following formula:

ETHYLENE GLYCOL

Pathophysiology.

Ethylene glycol is metabolized by alcohol dehydrogenase in the liver to glycoaldehyde, which is further converted to glycolic acid by aldehyde dehydrogenase. Glycolic acid is metabolized to glyoxylic acid and oxalic acid, which cause toxicity. The development of serious toxic effects is delayed while these acids are generated and accumulate in blood and tissues. Oxalic acid combines with serum and tissue calcium, causing hypocalcemia and the formation of calcium oxalate crystals.

Clinical and Laboratory Manifestations.

Ethylene glycol toxicity is described as occurring in three stages; however, there is considerable overlap in the stages. Early symptoms occur 1–12?hr after ingestion and include gastric irritation, with nausea and vomiting, and CNS effects, including drowsiness and inebriation. Metabolic acidosis begins to develop. From 12–24?hr after ingestion, cardiac dysrhythmias, muscle pain, and tetany due to hypocalcemia may occur. Later in the clinical course, cardiac failure, seizures, cerebral edema, and renal failure occur. Renal failure is caused by the deposition of calcium oxalate crystals in renal tubules.

Ethylene glycol blood levels are not readily available, and results do not correlate well with toxicity. Glycolic acid and glyoxylic acid levels may correlate more closely with toxicity, but these levels are not routinely available. Sodium fluorescein is an additive in many commercial antifreeze products. It is renally excreted and may be visualized in urine up to 6?hr after ingestion when illuminated with Wood's lamp. This simple test may be used to confirm ethylene glycol ingestion in children; however, a negative test does not preclude a possible ingestion. Ethylene glycol levels can be estimated from an osmolar gap. The serum osmolarity is measured by the freezing point depression method and is compared with a calculated serum osmolarity. The osmolar gap can be used to estimate the serum ethylene glycol level using the following formula:

Calcium oxalate crystals are commonly seen in urine on microscopy but may not be evident early after exposure. Electrolytes, including calcium, should be monitored, as well as the ECG and renal function studies.

Methanol and Ethylene Glycol Treatment.

Because methanol and ethylene glycol are rapidly absorbed, gastric decontamination is usually not of value. Activated charcoal does not bind either agent. Metabolic acidosis is treated with intravenous sodium bicarbonate at doses of 1–2?mEq/kg.

Ethanol is an antidote for both methanol and ethylene glycol poisoning because it is preferentially metabolized over methanol and ethylene glycol by alcohol dehydrogenase, thus preventing formation of toxic metabolites (see Table 704–2). The parent compounds are then excreted via the lungs and kidneys. Indications for ethanol therapy are a serum ethylene glycol level greater than 25?mg/dL or methanol level greater than 20?mg/dL, a significantly symptomatic patient, or ingestion of more than 0.4?mL/kg of 100% ethylene glycol or methanol. Assistance with ethanol dosing may be obtained through consultation with a medical toxicologist or poison control center. Fomepizole (see Table 704–2) is a potent competitive inhibitor of alcohol dehydrogenase that has been approved for use in both methanol and ethylene glycol poisoning. Like ethanol, it inhibits metabolism of methanol or ethylene glycol. Ease of dosing and lack of side effects are major advantages of fomepizole over ethanol. The high cost is a disadvantage. There is also very limited experience with this agent in children.

Hemodialysis effectively removes ethylene glycol, methanol, and their acid metabolites. It is also useful for correcting severe metabolic acidosis. The indications for hemodialysis are refractory metabolic acidosis, renal failure, or ethylene glycol or methanol blood levels exceeding 50?mg/dL. Both ethanol and fomepizole are removed by dialysis; thus, dosing of either must be increased during dialysis.

704.11 Hydrocarbons

Hydrocarbons include a wide array of chemical substances found in thousands of commercial products. Many factors determine whether a particular product and exposure will produce systemic toxicity, local toxicity, or both.

Pathophysiology.

The most important toxic effect of hydrocarbons is aspiration pneumonitis (see Chapter 385). Aspiration usually occurs at the time of ingestion, when coughing and gagging are common, but can be secondary to vomiting that commonly occurs after ingestion. The propensity of a hydrocarbon to cause aspiration pneumonitis is inversely proportional to its viscosity. Compounds with low viscosity, such as mineral spirits, naphtha, kerosene, gasoline, and lamp oil, spread rapidly across surfaces and cover large areas of the lungs when aspirated. Only small quantities (<1?mL) of low viscosity hydrocarbons need be aspirated to produce significant injury. Pneumonitis does not result from dermal absorption of hydrocarbons or from ingestion in the absence of aspiration.

Hydrocarbons can be absorbed after ingestion, inhalation, or dermal contact. Most hydrocarbons have anesthetic properties and can cause transient CNS depression. Several chlorinated solvents, most notably carbon tetrachloride, can produce hepatic toxicity. A few hydrocarbons have also been associated with renal toxicity. Benzene is known to cause cancer in humans after long-term exposure. The malignancy most commonly associated with benzene is acute myelogenous leukemia. Methylene chloride, found in some paint removers, is metabolized to carbon monoxide. Nitrobenzene, aniline, and related

compounds can produce methemoglobinemia. Methemoglobin can be determined in the laboratory; its presence is also suggested if a drop of blood applied to filter paper remains brown as it dries. Methemoglobinemia is treated with the antidote methylene blue (see Table 704–2).

A number of volatile hydrocarbons, including toluene, propellants, refrigerants, and volatile nitrites, are commonly abused by inhalation. Some of these substances can sensitize the myocardium with the risk of dysrhythmias and sudden death. Chronic abuse of these agents can lead to cerebral atrophy, neuropsychological changes, peripheral neuropathy, and renal disease (see Chapter 105). All volatile hydrocarbons are lipid solvents and can cause defatting of the skin, producing local irritation or, with prolonged exposure, chemical burns.

Clinical and Laboratory Manifestations.

Transient, mild CNS depression is common after hydrocarbon ingestion. Aspiration is characterized by coughing, which usually is the first clinical finding. Chest radiographs may be normal for as long as 8–12?hr after aspiration. Respiratory symptoms may remain mild or may rapidly progress to respiratory failure. Fever occurs and may persist for as long as 10 days after aspiration. Accompanying leukocytosis may be misleading because, in most cases of aspiration pneumonitis, no bacteria are present in the lungs. Chest radiographs may remain abnormal long after a patient is clinically normal and should not be used to guide acute treatment. Pneumatoceles may appear on the chest radiograph 2–3 wk after exposure. See Chapter 385 .

Treatment.

Emesis is contraindicated because of the risk of aspiration. Likewise, gastric lavage is contraindicated, except under special circumstances, because of the risk of vomiting and aspiration. Activated charcoal also is not useful, because it does not bind the common hydrocarbons. If hydrocarbon-induced pneumonitis develops, respiratory treatment is supportive. Corticosteroids should be avoided, because they are not effective and may be harmful. Prophylactic antibiotics should not be given because bacterial pneumonia occurs in only a very small percentage of cases. Respiratory failure has been successfully treated with both standard ventilation and with extracorporeal membrane oxygenation (ECMO).

704.12 Cholinesterase-Inhibiting Insecticides

The most commonly used insecticides are either organophosphates or carbamates. Both of these classes are inhibitors of cholinesterase enzymes. Nerve agents used in warfare are organophosphates. Most pediatric poisonings occur as the result of accidental exposure to insecticides in and around the home or farm.

Pathophysiology.

Both organophosphates and carbamates bind to cholinesterase enzymes, preventing the degradation of acetylcholine, resulting in its accumulation at nerve synapses. Enzymes affected include acetylcholinesterase or red blood cell cholinesterase, pseudocholinesterase (found in plasma), and neurotoxic esterase (found in the nervous system). If left untreated, organophosphates form a permanent bond to these enzymes, inactivating them. This process, called aging, occurs over the 2–3 days after exposure. Weeks to months are required for the body to regenerate inactivated enzymes. In contrast, carbamates form a temporary bond to the enzymes, allowing regeneration of the enzymes over several hours.

Clinical and Laboratory Manifestations.

Clinical manifestations of organophosphate and carbamate toxicity relate to the accumulation of acetylcholine at peripheral nicotinic and muscarinic synapses and in the CNS. Muscarinic signs and symptoms include diaphoresis, emesis, urinary and fecal incontinence, tearing, drooling, bronchorrhea and bronchospasm, miosis, and hypotension and bradycardia. Nicotinic signs and symptoms include muscle weakness, fasciculations, tremors, hypoventilation, hypertension, tachycardia, and dysrhythmias. CNS effects include malaise, confusion, delirium, seizures, and coma. Symptoms caused by carbamate toxicity are usually less severe than those seen with organophosphates. A commonly used acronym for the most common symptoms is SLUDGE, which stands for **s**alivation, **l**acrimation, **u**rination, **d**efecation, **g**astrointestinal cramps, and **e**mesis.

Red blood cell cholinesterase and pseudocholinesterase levels can be readily measured in the laboratory. They may be useful in documenting an exposure but do not correlate well with symptoms. Significant symptoms do not generally occur until measured enzyme levels fall below 25% of normal. Red blood cell cholinesterase, although more difficult to measure, is a better reflection of the enzyme activity in the nervous system.

Treatment.

Basic decontamination should be done on exposed persons. Activated charcoal can be used for gastric decontamination. Basic supportive care should be provided, including fluid and electrolyte replacement and intubation with artificial ventilation if necessary. Two antidotes are useful to treat poisoning with cholinesterase inhibitors: atropine and pralidoxime (2-PAM) (see Table 704–2). Atropine, which blocks the acetylcholine receptor, is useful for both organophosphates and carbamates. It is most effective at reversing the muscarinic and CNS effects. Often, large doses of atropine must be administered by continuous infusion. Pralidoxime chemically breaks the bond between the organophosphate and the enzyme, liberating the enzyme and degrading the organophosphate. Pralidoxime is only effective if used before the bond "ages" and becomes permanent. Pralidoxime is not necessary for carbamate poisonings because the bond between the insecticide and the enzyme degrades spontaneously. For significant organophosphate poisonings both antidotes are used and large doses of atropine may be necessary to achieve adequate reversal of symptoms. Without treatment, symptoms of organophosphate poisoning may persist for weeks, requiring continuous supportive care. Even with treatment, neurologic symptoms may occur and may persist.

704.13 Toxic Gases

Although many industrial and naturally occurring gases pose a health risk by inhalation, only two, carbon monoxide (CO) and hydrogen cyanide, are considered in detail here. CO is a colorless, odorless gas produced during the combustion of any carbon-containing fuel. Hydrogen cyanide, as well as cyanide salts, is used in many industrial processes. It is also produced during combustion of many plastics and fabrics and is released during the metabolism of some chemicals, including the solvent acetonitrile and the drug nitroprusside.

Chlorine, chloramine, and hydrogen chloride are severe lung irritants and may cause a chemical pneumonitis. Nitrogen, propane, and methane are examples of simple asphyxiants.

CARBON MONOXIDE

Pathophysiology.

CO toxicity develops through at least three mechanisms. First, it binds to hemoglobin, displacing oxygen, with an affinity for hemoglobin that is about 250 times that of oxygen. Second, CO impairs the ability of hemoglobin to release oxygen to tissues. Finally, CO also binds to cytochrome oxidase in tissues, impeding oxygen utilization. Although the relative contribution of each of these mechanisms to carbon monoxide toxicity is unclear, the net result is tissue hypoxia.

Clinical and Laboratory Manifestations.

Symptoms of CO poisoning are generally proportionate to the concentration of carboxyhemoglobin in the blood. Carboxyhemoglobin levels can be measured in almost all hospital laboratories. Early symptoms are nonspecific and include headache, malaise, and nausea, which are often confused with the flu. At higher exposure levels, headaches become severe and dizziness, visual changes, and weakness may be present. Children may experience syncopal episodes as a first symptom. At high concentrations, coma, seizures, respiratory instability, and death may occur.

Treatment.

In addition to general supportive care, treatment of CO poisoning requires the administration of high concentrations of oxygen. High concentrations of oxygen shorten the half-life of CO in the blood and tissues. Severely poisoned patients benefit from hyperbaric oxygen therapy. After a significant exposure, some patients may experience delayed-onset neurotoxicity, which may be permanent. Aggressive early treatment of patients with significant symptoms may diminish the risk of neurologic sequelae.

HYDROGEN CYANIDE

Pathophysiology.

Cyanide produces toxicity by interfering with oxygen use in the cytochrome oxidase system, resulting in cellular hypoxia.

Clinical and Laboratory Manifestations.

Clinical symptoms occur rapidly after significant exposure and include headache, agitation and confusion, loss of consciousness, convulsions, and cardiac dysrhythmias. Severe metabolic acidosis occurs rapidly. Death may occur. Cyanide levels can be measured in the blood, but tests are not readily available and levels do not correlate well with symptoms. Severe metabolic acidosis in a patient with suspected cyanide exposure (e.g., fire victims) should be assumed to be cyanide poisoning.

Treatment.

The cornerstone of treatment is rapid administration of high concentrations of oxygen, together with the use of the Lilly Cyanide Antidote Kit. The kit includes nitrites (amyl nitrite and sodium nitrite) used to produce methemoglobin, which reacts with cyanide, forming cyanomethemoglobin. The kit also contains sodium thiosulfate, which is given to hasten the metabolism of cyanomethemoglobin to hemoglobin and the less toxic thiocyanate. Hydroxocobalamin (vitamin B_{12a}), which reacts with cyanide to produce cyanocobalamin (vitamin B_{12}), is an alternative antidote, but is not currently available in the United States.

704.14 Plants

Exposure to plants, both inside the home and outside in backyards and fields, is one of the most common causes of unintentional poisoning in children. Fortunately, ingestion of most plant parts (leaves, seeds, flowers) results in mild, self-limiting effects. The treatment is symptomatic and supportive. Box 704–2 contains a list of plants considered to be nontoxic. This means that the inherent toxicity of the product is so low that the ingestion of small to moderate quantities of plant material is unlikely to produce toxic symptoms. Table 704–4 contains information describing the effects after exposure to some toxic plants commonly found in and around the home and yard.

The potential toxicity of a particular plant is highly variable, depending on the part of the plant involved (flowers are generally less toxic than the root or seed), the time of year, the growing conditions of the plant, and the route of exposure. Assessment of the potential severity after a plant exposure is also complicated by the difficulty in properly identifying the plant. Many plants are known by several common names, and the common name of the same plant may vary between communities. Poison control centers have access to individuals able to assist in the proper identification of plants. They also keep current on the common poisonous plants in their service area and the seasons in which they are more abundant; thus, consultation with a poison control center is recommended if a potentially toxic plant is involved in the exposure. The literature describing plant exposure is often extrapolated from animal data or based on isolated case reports and thus is limited.

Gastrointestinal decontamination for potentially toxic ingestions includes the use of activated charcoal. Treatment is supportive and symptomatic.

TABLE 704.14-4 -- Common Poisonous Plants

Common Plant Name	Toxic Constituent	Symptoms or Special Treatment

Black nightshade Climbing nightshade Deadly nightshade Horse nettle Jimsonweed Potato/tomato (foliage & sprouts)	Anticholinergic alkaloids such as atropine and solanine	Anticholinergic syndrome; gastroenteritis
Asparagus fern Caladium Dumbcane Elephant ear Jack-in-the-pulpit Peace lily Philodendron Pothos Rhubarb (leaves) Skunk cabbage	Calcium oxalate crystals	Irritation and edema of mucous membranes, edema, gastroenteritis; large ingestions may cause hypocalcemia
Christmas pepper Hot pepper	Capsicum	Irritation and burning sensation of skin and mucous membranes
Foxglove Lily-of-the-valley Oleander	Cardiac glycosides	Irritation of mucous membranes, cardiac toxicity; severe intoxication may require dioxin-specific FAB fragments
Water hemlock	Cicutoxin	Grand mal seizures
Fall crocus	Colchicine	Gastroenteritis, cardiotoxicity
Poison hemlock	Conine	Salivation, nausea, vomiting, diarrhea, seizures, coma, respiratory paralysis

Cherry, apple, peach, apricot, chokecherry (seeds, pits, leaves)	Hydrocyanic acid-containing glycosides	Very large amounts may cause dyspnea, seizures, coma
Morning glory (seeds)	Lysergic acid monoethylamide	Gastroenteritis, hallucinations
Amaryllis Daffodil Narcissus (bulb)	Lycorine	Vomiting, diarrhea
Tobacco Cardinal flower	Nicotine	Salivation, gastroenteritis
May apple	Podophylloresin	Vomiting, diarrhea, drowsiness, peripheral neuropathy
Pokeweed (leaves, root)	Podophyllotoxin-like resins	Vomiting, sweating, colic, drowsiness
Castor bean (chewed seeds)	Ricin	Burning sensation of mouth, throat; gastroenteritis, hepatotoxicity, seizures
Yew	Taxine	Vomiting, abdominal pain, respiratory depression
Euphorbia Spurges	Unknown acrid principle	Mucous membrane irritation
Mistletoe (berries)	Viscotoxin, phoratoxin, lectins	Gastroenteritis, cardiovascular collapse

Chapter 705 - Nonbacterial Food Poisoning

Denise A. Salerno
Stephen C. Aronoff

705.1 Mushroom Poisoning

Consumption of wild mushrooms, a favorite pastime in Europe, is increasingly popular in the United States, with concomitant increases in fatal cases of mushroom poisoning.

Four clinical syndromes and seven classes of toxins are associated with wild mushroom poisoning. The clinical syndromes are divided according to the predominant system involved and the rapidity of onset of symptoms. The toxins produced by wild mushrooms are categorized as follows: cyclopeptides, monomethylhydrazine, muscarine, coprine, ibotenic acid, psilocybin, and unknown. Additionally, the edible wild mushroom *Tricholoma equestre* has been associated with delayed rhabdomyolysis, although the toxin has not been identified.

GASTROINTESTINAL: DELAYED ONSET

Amanita Poisoning.

Poisonings by species of *Amanita* and *Galerina* account for 95% of the fatalities due to mushroom intoxication, although the mortality rate for this group is 5–10%. Most species produce two classes of cyclopeptide toxins: (1) phalloidins, which are heptapeptides believed to be responsible for the early symptoms of *Amanita* poisoning; and (2) amanitotoxin, which is an octapeptide that inhibits RNA polymerase and subsequent production of messenger RNA. Cells with high turnover rates, such as those in the gastrointestinal mucosa, kidneys, and liver, are the most severely affected.

Histopathologically, Amanita poisoning causes cellular necrosis, which may occur throughout the gastrointestinal tract, the most heavily exposed site. Acute yellow atrophy of the liver and necrosis of the proximal renal tubules are found in lethal cases.

The *clinical course* produced by poisoning with *Amanita* or *Galerina* species is

biphasic, after an initial 6–12?hr latent period. Nausea, vomiting, and severe abdominal pain ensue 6–24?hr after ingestion. Profuse watery diarrhea follows shortly

---

thereafter and may last for 12–24?hr. During this time, as much as 9?L of fluid may be lost. From 24–48?hr after poisoning, jaundice, hypertransaminasemia (peaking at 72–96?hr), renal failure, and coma occur. Death occurs 4–7 days after the ingestion. A prothrombin time less than 10% of control is a poor prognostic factor.

Treatment of *Amanita* poisoning is both supportive and specific. Fluid loss from severe diarrhea during the early course of the illness is profound, requiring aggressive therapy for correction of this loss. In the late phase of the disease, management of renal and hepatic failure is also necessary.

Specific therapy for *Amanita* poisoning is designed to remove the toxin rapidly and to block binding at its target site. Oral activated charcoal and lactulose combined with fluid and electrolyte replacement are recommended as part of the initial treatment of children with *Amanita* poisoning. Forced diuresis should be avoided because this increases renal exposure. Intravenous penicillin G (250?mg/kg/24?hr) administered as a continuous infusion combined with silibinin, the water-soluble form of the flavolignone silymarin (in an intravenous dosage of 20–50?mg/kg/24?hr), acts synergistically to inhibit binding of both toxins and to interrupt enterohepatic recirculation of amanitotoxin. Hemodialysis and hemoperfusion are also recommended as part of the initial treatment for intoxicated children. Orthotopic liver transplantation is recommended for children in whom severe hepatic failure develops (see Chapter 349).

Monomethylhydrazine Intoxication.

Species of *Gyromitra* contain monomethylhydrazine (CH_3NHNH_2), which inhibits central nervous system (CNS) enzymatic production of ?-aminobutyric acid (GABA). Monomethylhydrazine also oxidizes iron in hemoglobin, resulting in methemoglobinemia. Children with *Gyromitra* poisoning develop vomiting, diarrhea, hematochezia, and abdominal pain within 6–24?hr of ingestion of the toxin. Symptoms of CNS depression and seizures develop later in the clinical course. Hemolysis and methemoglobinemia are potential life-threatening complications of monomethylhydrazine poisoning. Severe methemoglobinemia may require dialysis.

Hypovolemia due to gastrointestinal fluid losses and seizures require supportive intervention. Pyridoxal phosphate, the coenzyme that catalyzes the production of GABA, can reverse the effects of monomethylhydrazine when administered in high doses. Pyridoxine hydrochloride (25?mg/kg) is administered intravenously at a frequency dependent on clinical improvement. Parenteral administration of methylene blue is indicated if the methemoglobin concentration exceeds 30%. Blood transfusions may be required for significant hemolysis.

AUTONOMIC NERVOUS SYSTEM: RAPID ONSET

Muscarine Poisoning.

Mushrooms of the genera *Inocybe* and, to a lesser degree, *Clitocybe* contain muscarine or muscarine-related compounds. These quaternary ammonium derivatives bind to postsynaptic receptors, producing an exaggerated cholinergic response.

The *clinical manifestations* are characterized by the following hypercholinergic response: the onset of symptoms is rapid (30?min–2?hr after consumption) and consists of diaphoresis, excessive lacrimation, salivation, miosis, urinary and fecal incontinence, and vomiting. Respiratory distress caused by bronchospasm and increased bronchopulmonary secretions is the most serious complication. The symptoms subside spontaneously within 6–24?hr.

Atropine sulfate, the *specific antidote*, is administered intravenously (0.01?mg/kg; max 2?mg). This is repeated until the pulmonary symptoms resolve or the patient becomes overtly tachycardic.

Coprine Ingestion.

Coprinus atramentarius and *Clitocybe clavipes* contain coprine. Like disulfiram (Antabuse), coprine inhibits the metabolism of acetaldehyde after ethanol ingestion. The clinical manifestations result from accumulation of acetaldehyde.

Coprine intoxication becomes apparent after ethanol ingestion and may occur up to 5 days after consuming the mushroom. Hyperemia of the face and trunk, tingling of the hands, metallic taste, tachycardia, and vomiting occur acutely. Hypotension may result from intense peripheral vasodilation.

The syndrome is typically self-limited and lasts only several hours. No specific antidote is available. If hypotension is severe, vascular re-expansion with isotonic parenteral solutions may be required. Small oral doses of propranolol have also been suggested.

CENTRAL NERVOUS SYSTEM: RAPID ONSET

Ibotenic Acid and Muscimol Intoxication.

Although *Amanita muscaria* and *Amanita pantherina* may contain muscarine (see earlier), the toxins responsible for the CNS symptoms after ingestion of these mushrooms are muscimol and ibotenic acid. Muscimol, a hallucinogen, and ibotenic acid, an insecticide, have anticholinergic effects. From 30?min–3?hr after ingestion, CNS symptoms appear; obtundation, alternating lethargy and agitation, and, occasionally, seizures ensue. Nausea and vomiting are uncommon. If large amounts of muscarine are contained in the mushroom, symptoms of cholinergic crisis may also occur.

Specific therapy must be carefully selected. If an exaggerated cholinergic response is observed, atropine should be administered. Because ingestions of *A. muscaria* are frequently associated with anticholinergic findings, the acetylcholinesterase inhibitor physostigmine is used to reverse the delirium and coma. Seizures can be controlled with diazepam. Early treatment with ipecac (if the patient is conscious) and close observation are all that is required in most cases.

Indole Intoxication.

Mushrooms belonging to the genus *Psilocybe* (“magic mushrooms”) contain psilocybin and psilocin, two psychotropic compounds. Within 30?min after ingestion, patients experience euphoria and hallucinations, often accompanied by tachycardia and mydriasis. Fever and seizures have also been observed in children with psilocybin poisoning. These symptoms are short lived, usually lasting 6?hr after consumption of the mushroom. Severely agitated patients may respond to diazepam.

GASTROINTESTINAL: RAPID ONSET

Many mushrooms from various genera produce local gastrointestinal manifestations. The causative toxins are diverse and largely unknown. Within 1?hr of ingestion, patients develop acute abdominal pain, nausea, vomiting, and diarrhea. Symptoms may last from hours to days, depending on the species of mushroom.

Treatment is mainly supportive. Children with large fluid losses may require parenteral fluid therapy. It is imperative to differentiate ingestion of mushrooms of this class from ingestions of *Amanita* and *Galerina* species containing cyclopeptide toxins.

705.2 Solanine Poisoning

Solanine is a mixture of several related toxins found in “greened” and sprouted potatoes. Potatoes exposed to light and allowed to sprout produce a number of alkaloid glycosides containing the cholesterol derivative solanidine. Two of these glycosides, a-solanine and a-chaconine, are found in highest concentration in the peels of greened potatoes and in the sprouts. The solanine alkaloids bind to serum cholinesterase, suggesting a possible pathophysiologic mechanism.

Clinical manifestations of solanine intoxication occur within 7–19?hr after ingestion. The most common symptoms are vomiting and diarrhea; in more severe instances of poisoning, fever, generalized abdominal pain, coma, and hypovolemic shock occur.

Treatment of solanine poisoning is largely supportive. In the most severe cases, symptoms resolve within 11 days. Atropine treatment has not been evaluated.

705.3 Seafood Poisoning

Ciguatera Fish Poisoning.

Major outbreaks of ciguatera fish poisoning have been reported in Florida, Hawaii, the Caribbean, South Pacific, and the Virgin Islands; however, with modern methods of transportation, the illness now occurs worldwide. Grouper is the most frequently identified source of the toxin, followed by snapper, kingfish, amberjack, dolphin, eel, and barracuda. Poisoning has also been associated with farm-raised salmon.

The source of this poisoning is the dinoflagellate *Gambierdiscus toxicus*, a microscopic unicellular organism found along coral reefs that produces high concentrations of ciguatoxin and maitotoxin. The toxins are passed along the food chain from small herbivorous fish that consume the dinoflagellate from the coral reefs to larger predatory fish and then to humans. These toxins are harmless in fish but produce distinct clinical symptoms in humans.

Ciguatoxin-1, a lipid with a molecular weight of approximately 1.1?kd, is odorless, colorless, tasteless, and is not destroyed by cooking or freezing. Ciguatoxin-1 increases the sodium permeability of excitable membranes, an action that is inhibited by calcium and tetrodotoxin.

The onset of *clinical manifestations* of ciguatoxin poisoning is rapid, usually occurring within 2–30?hr after ingesting contaminated fish. The illness is often biphasic. The earliest symptoms are diarrhea, vomiting, and abdominal pain; the second phase includes intense itching, rash on palms and soles, myalgias, and circumoral or extremity dysesthesias. The dysesthesia is characterized by reversal of hot and cold sensation. Tachycardia, bradycardia, and hypotension occur infrequently. Ciguatera fish poisoning is diagnosed based on clinical presentation, and the diagnosis is confirmed by testing the ingested fish for toxin.

Treatment of ciguatera fish poisoning is supportive. Gastric lavage is recommended to remove any remaining toxin. Intravenous fluids may be required for severe diarrhea, and parenteral administration of calcium can be used to treat hypotension. In a few patients with coma or prolonged symptoms, mannitol given within 24?hr of the onset of symptoms has successfully reversed the neurologic manifestations of intoxication. However, further studies are needed before a recommendation for mannitol therapy can be made. Gabapentin has reportedly been successful in treating the neurologic symptoms in a few patients. Most cases are self-limited; neurologic symptoms may last months. Death occurs in less than 0.1% of cases.

Scombroid (Pseudoallergic) Fish Poisoning.

Epidemics have been associated with ingestion of members of the Scombresocidae or Scombridae families, notably albacore, mackerel, tuna, bonita, and kingfish. Nonscombroid fish and marine mammals, such as mahi-mahi (dolphin) and bluefish, have also been linked to outbreaks of poisoning.

Scombrotoxin, either histamine or the product of the action of the toxin on fish flesh, is responsible for the clinical syndrome. Histidine is found in high concentrations in the flesh of scombroid fish; the action of bacterial decarboxylases during putrification converts the histidine to histamine. Fish containing more than 20?mg of histamine per 100?g of flesh are toxic. In patients receiving isoniazid, a potent histaminase blocker, ingestion of fish flesh containing a lower concentration of histamine may be toxic.

The onset of *clinical manifestations* is acute and occurs within 10?min–2?hr after ingestion. The most common symptoms and signs include diarrhea, flushing, diaphoresis, urticaria, nausea, and headache. Abdominal pain, tachycardia, oral burning, dizziness, respiratory distress, and facial swelling also occur. The illness is usually self-limited, terminating within 8–10?hr.

Treatment is mainly supportive. Gastric lavage decreases continued absorption of histamine. With severe diarrhea, fluid replacement may be necessary. Antihistamines have been variably successful. Four patients with severe toxicity treated with cimetidine (a histamine blocker) responded rapidly. Because data are limited, cimetidine or ranitidine should be reserved for severe cases.

Paralytic Shellfish Poisoning.

Filter-feeding mollusks, such as the black mussel and sea scallop, may become contaminated during dinoflagellate blooms or “red tides.” The dinoflagellate *Ptychodiscus brevis* is often responsible for these red tides and contains several potent neurotoxins. Paralytic shellfish poisoning is a distinctive neurologic illness caused by 20 closely related heat-stable paralytic shellfish toxins. Saxitoxin is the most potent of the neurotoxins responsible for paralytic shellfish poisoning. This toxin prevents nerve conduction by inhibiting the sodium-potassium pump. Other toxins may be bioconverted to less toxic compounds. Consumption of bivalves, such as mussels, scallops, and clams, is the usual pathway of intoxication, although crustacea and fish have been implicated as well.

The onset of *clinical manifestations* of paralytic shellfish poisoning occurs rapidly, 30?min–2?hr after ingestion. Abdominal pain and nausea are common. Paresthesias are common and occur circumorally, in a stocking-glove distribution, or both. Perioral numbness or tingling, diplopia, ataxia, dysarthria, and the sensation of floating occur less commonly. Hot-cold reversal in temperature sensation is not unusual. In severe cases, respiratory failure from diaphragmatic paralysis may result.

No antidote for paralytic shellfish poisoning is known. Supportive care, including mechanical ventilation, may be needed. Although the symptoms are usually self-limited and short-lived, weakness and malaise may persist for weeks after

ingestion.

Diarrhetic Shellfish Poisoning.

Several outbreaks of diarrhetic shellfish poisoning have been reported in Europe after consumption of mussels, cockles, and other shellfish. The dinoflagellates *Dinophysis* and *Prorocentrum* produce okadaic acid and its derivatives, the dinophysistoxins. These compounds inhibit protein phosphatases. The intracellular accumulation of phosphorylated proteins causes increased fluid secretion by gut cells via calcium influx, mediated by cyclic adenosine monophosphate and prostaglandins.

Clinically, patients develop severe diarrhea. Care is supportive and directed at rehydration. The illness is self-limited, and recovery occurs in 3–4 days; few patients require hospitalization.

Amnesic Shellfish Poisoning.

This entity was first reported in 1987 in Canada after a group of people developed severe gastroenteritis as well as neurologic symptoms, including memory loss, after eating mussels from Prince Edward Island. Subsequent cases have been identified after eating shellfish from the United States, Spain, and the United Kingdom. The responsible toxin, domoic acid, comes from a diatom, *Pseudo-nitzschia multiseries*, and is a potent glutamate agonist, disrupting neurochemical transmission in the brain. It also binds to glutamate receptors, which increase calcium influx, producing neuronal swelling in the hippocampal area of the brain and death.

The initial *clinical manifestations* are gastrointestinal. Memory loss is closely related to advanced age. Those patients younger than age 40 yr are more likely to only suffer from diarrhea, whereas those older than 50 yr suffer from short-term memory loss lasting months to years.

Chapter 706 - Biologic and Chemical Terrorism

Theodore J. Cieslak
Fred M. Henretig

The events of September 11, 2001, and the subsequent outbreak of anthrax cases originating from exposure to contaminated mail should leave little doubt as to the ability of terrorists to execute an attack using biologic or chemical "weapons of mass destruction." Therefore, it is imperative that pediatricians be familiar with the clinical manifestations of diseases induced by biologic and chemical agents, many of which can be successfully treated if diagnoses are made early, therapy initiated promptly, and preventive measures instituted.

Etiology.

Hundreds of biologic and chemical agents could theoretically be adapted for sinister use by terrorists. Attempts to ascertain which agents are most likely to be employed are fraught with difficulties. First, such analysis often depends on accurate intelligence, which is likely to be problematic. Second, many terrorists may choose to use weapons of opportunity, that is, agents that for some reason are readily available to some member of the terrorist group. Finally, the motives of terrorists are often obscure and difficult to predict. With these considerations in mind, a working group convened by the Centers for Disease Control and Prevention (CDC) elected to concentrate response efforts not necessarily on those agents most likely to be used but, rather, on those agents that, if used, would constitute the gravest potential threats to public health and security.

In the case of biologic agents, the CDC working group divided pathogens and toxins into three categories, with category A including diseases caused by those six agents posing the greatest threat. Viral hemorrhagic fevers are discussed in Chapter 246 . This chapter focuses on the remaining diseases in category A: anthrax, plague, tularemia, smallpox, and botulism. In the case of chemical agents, a vast array of potentially harmful chemicals might conceivably be released by terrorists. Tank cars full of flammable industrial gases and liquids, corrosive industrial acids and bases, poisonous compounds such as cyanides and nitriles, pesticides, dioxins, and explosives traverse our railways and roads daily. In this chapter, however, the focus is on four classes of "military-grade" chemicals with a history of use in warfare, or manufactured specifically for use as weapons. These include the organophosphate-based nerve agents, vesicants, "blood agents" (cyanides), and

certain “pulmonary agents.”

Epidemiology and Pediatric-Specific Concerns.

Large-scale attacks on civilian targets will almost certainly involve pediatric victims. Furthermore, pediatric patients may be more susceptible than adults to the effects of certain biologic and chemical agents. Thinner skin makes dermally active chemical agents, such as mustard, of greater risk to children than adults. A larger surface area per unit volume further increases the problem. Similarly, a small relative blood volume makes children more susceptible to the volume losses associated with enteric infections such as cholera and to gastrointestinal intoxications such as might be seen with exposure to the staphylococcal enterotoxins. A relatively high minute ventilation compared with adults increases the threat of agents delivered by way of the inhalational route. The fact that children live closer to the ground compounds this effect when heavier-than-air chemicals are involved. An immature blood-brain barrier may heighten the risk of central nervous system toxicity from nerve agents. Finally, developmental considerations make it less likely that a child would readily flee an area of danger, thereby increasing exposure to these various adverse effects. Also see Chapter 701 .

In certain instances, children appear to have a unique susceptibility to potential agents that might be used by terrorists. Although adults generally suffer only a brief self-limited incapacitating illness after infection with Venezuelan equine encephalitis (VEE) virus, for example, young children are more likely to experience seizures, permanent neurologic sequelae, and even death. In the case of smallpox, waning immunity may disproportionately affect children. Vaccine-induced immunity to smallpox probably diminishes significantly after 3–10 yr. Although most adults are considered susceptible to smallpox, given that routine civilian immunization ceased in the early 1970s, older adults may enjoy some residual protection from death, if not from the development of disease. Today's children are among the first to grow up in a world without any individual or herd immunity to smallpox.

Children also may experience unique disease manifestations not seen in adults. In a study of melioidosis cases among children in Thailand, suppurative parotitis was observed as a characteristic presentation; this condition is not generally seen in adults with *Burkholderia pseudomallei* infection.

Pediatricians are likely to experience unique problems in managing childhood victims of biologic or chemical attack. Many of the drugs useful in treating such casualties are unfamiliar to pediatricians or have relative contraindications in childhood. The fluoroquinolones and tetracyclines are often mentioned as agents of choice in the treatment and prophylaxis of anthrax, plague, tularemia, brucellosis, and Q fever. Both are often avoided in children, although the risk of morbidity and mortality from biologic agent–induced diseases far outweighs the minor risks associated with short-term use of these agents. For example, ciprofloxacin received, as its first licensed pediatric indication, U.S. Food and Drug Administration (FDA) approval for use in the prophylaxis of anthrax after inhalational exposure (i.e., terrorism). Doxycycline is now licensed specifically in children for the same indication. Similarly, immunizations potentially useful in preventing biologic agent–induced diseases are often not approved for use in pediatric patients. The current anthrax vaccine is licensed only for those between 18–65 yr of age. The plague vaccine, currently out of production and probably ineffective against inhalational exposures, was only approved for 18–61 yr olds. The smallpox vaccine, a live vaccine employing vaccinia virus, can lead to fetal vaccinia and demise when given to pregnant women.

Moreover, many otherwise useful pharmaceuticals are not available in pediatric dosing regimens. The military distributes nerve agent antidote kits (NAAKs) consisting of autoinjectors designed for the rapid administration of atropine and pralidoxime. Many emergency departments and some ambulances stock these kits. The doses of agents contained in the NAAK are calculated for soldiers but are far in excess of those appropriate for young children. Similarly, although physical protection would not likely be useful in a civilian setting, it is noteworthy that commercially available devices such as gas masks are not typically available in pediatric sizes.

Finally, there may not be adequate numbers of pediatric hospital beds. In the event of a large-scale terrorist attack, as in the case with any large disaster, excess hospital bed capacity could potentially be provided at civilian and Department of Veterans Affairs hospitals under the auspices of the national disaster medical system. The system makes no specific provision for pediatric beds.

Clinical Manifestations.

In the event of a terrorist attack, clinicians may be called on to make prompt diagnoses and render rapid life-saving treatment before the results of confirmatory diagnostic tests are available. Thus, although each potential agent of terrorism produces its own unique clinical manifestations, it is useful to consider their effects in terms of a limited number of distinct clinical syndromes. This will facilitate clinicians making prompt, rational decisions regarding empirical therapy. In general, casualties from a terrorist attack will develop symptoms immediately on exposure to an agent (or within the first several hours after exposure) or they will develop symptoms slowly over a period of days to weeks. In the former case, the sinister nature of the event is often obvious and the etiology more likely to be conventional or chemical in nature. Biologic agents, however, differ from conventional, chemical, and nuclear weapons (see Chapter 700) in that they have inherent incubation periods. Because of this, patients are likely to present far removed in time and place from the point of an unannounced exposure to a biologic agent. Thus, whereas traditional first responders such as firemen and paramedics may be at the forefront of a conventional or chemical terrorism response, the primary care physician is likely to constitute the first line of defense against the effects of a biologic agent.

With these considerations in mind, casualties can be categorized as either immediate or delayed in presentation. Within each of these categories, patients can be further classified as having primarily respiratory, neuromuscular, or dermatologic manifestations (Table 706–1). A limited number of agents may cause each particular syndrome, permitting institution of empiric therapy targeted at a short list of potential etiologies.

SUDDEN-ONSET NEUROMUSCULAR SYNDROME: NERVE AGENTS.

The rapid onset of neuromuscular symptoms after an exposure should lead the clinician to consider nerve agent intoxication. The nerve agents (tabun, sarin, soman, and “VX”) are organophosphate analogues of common pesticides that act as potent inhibitors of the enzyme acetylcholinesterase. They are hazardous via ingestion, inhalation, or cutaneous absorption.

The inhibition of cholinesterase by these compounds results in the accumulation of acetylcholine at neural and neuromuscular junctions, causing excess stimulation. The resultant cholinergic syndrome involves central, nicotinic, and muscarinic effects. Central effects include altered mental status progressing rapidly to lethargy and coma, as well as ataxia, convulsions, and respiratory depression. Nicotinic effects include muscle fasciculations and twitching, followed by weakness progressing to flaccid paralysis as the muscles fatigue. Muscarinic effects include miosis, visual blurring, profuse lacrimation, and watery rhinorrhea. Bronchospasm and increased bronchial secretions lead to cough, wheezing, dyspnea, and cyanosis. Cardiovascular manifestations include bradycardia, hypotension, and atrioventricular block. Flushing, sweating, salivation, nausea, vomiting, diarrhea, abdominal cramps, and urinary incontinence are also seen. In the absence of prompt intervention, death can quickly result from a combination of central effects and respiratory muscle paralysis.

DELAYED-ONSET NEUROMUSCULAR SYNDROME: BOTULISM.

The delayed onset (hours to days after exposure) of neuromuscular symptoms is characteristic of botulism. Botulism occurs after exposure to one of seven related neurotoxins produced by certain strains of *Clostridium botulinum*, a strictly anaerobic spore-forming gram-positive bacillus commonly found in soil. Naturally occurring botulism (see Chapter 193) usually follows ingestion of preformed toxin (food poisoning) or results from intestinal toxin production (infantile form). Nonetheless, an aerosol exposure would likely result in a case of clinical botulism indistinguishable from that caused by natural exposures.

After exposure to botulinum toxin, clinical manifestations begin with bulbar palsies, causing patients to complain of ptosis, photophobia, and blurred vision from difficulty in accommodation. Symptoms can progress to include dysarthria, dysphonia, and dysphagia and, finally, a descending symmetric paralysis. Sensation and sensorium are not typically affected. In the absence of intervention, death often results from respiratory muscle failure.

TABLE 706-1 -- **Diseases Caused by Agents of Chemical and Biologic Terrorism, Classified by Syndrome**

	Neuromuscular Symptoms Prominent	**Respiratory Symptoms Prominent**	**Dermatologic Findings Prominent**
Sudden-onset	Nerve agents	Chlorine >Phosgene >Cyanide	Mustard >Lewisite
Delayed-onset	Botulism	Anthrax >Plague >Tularemia	Smallpox

SUDDEN-ONSET RESPIRATORY SYNDROME: CHLORINE, PHOSGENE, AND CYANIDE.

The acute onset of respiratory symptoms shortly after exposure should cause the clinician to consider a range of potential chemical agents. Nerve agents may, of course, affect respiration, but these effects are usually secondary to respiratory muscle paresis rather than pulmonary pathology per se. Moreover, this distinction should be readily evident clinically, because the nerve agent casualty will have generalized muscle involvement. In contrast, the toxic inhalants chlorine and phosgene produce respiratory distress without muscle involvement.

Chlorine is a dense, acrid, yellow-green gas that is heavier than air. After mild to moderate exposure, ocular and nasal irritation occur, followed by cough, a choking sensation, bronchospasm, and substernal chest tightness. Pulmonary edema, mediated by hydrochloric acid and free oxygen radical generation, follows moderate to severe exposures within 30?min to several hours. Hypoxemia and hypovolemia secondary to pulmonary edema are responsible for death in fatal cases.

Phosgene, like chlorine, is a common industrial compound that was used as a weapon on the battlefields of World War I. Its odor is sometimes said to resemble that of “new-mown hay.” Similar to chlorine, phosgene is also thought to generate hydrochloric acid, contributing particularly to upper airway, nasal, and conjunctival irritation. Acylation reactions caused by the effects of phosgene on the pulmonary alveolar-capillary membrane lead to pulmonary edema. Phosgene lung injury may also be mediated, in part, by an inflammatory reaction associated with leukotriene production. Patients with mild to moderate exposures to phosgene may be asymptomatic, potentially causing victims to remain in a contaminated area. Pulmonary edema occurs 4–24?hr post exposure and is dose dependent, with heavier exposures causing earlier symptoms. Dyspnea may precede radiologic findings. In severe exposures, pulmonary edema may be so marked as to result in hypovolemia and hypotension. As in the case of chlorine, death results from hypoxemia and asphyxia.

Cyanide is a cellular poison with protean manifestations. Initially, however, cyanide toxicity is most likely to present as tachypnea and hyperpnea, progressing rapidly to apnea in cases with significant exposure. The efficacy of cyanide as a chemical terrorism agent is limited by its volatility in open air and relatively low lethality compared with nerve agents. Released in a closed room, however, cyanide could have devastating effects. Cyanide inhibits cytochrome a_3 , interfering with normal mitochondrial oxidative metabolism and leading to cellular anoxia and lactic acidosis. In addition to respiratory distress, early findings among cyanide victims include tachycardia, flushing, dizziness, headache, diaphoresis, nausea, and vomiting. With greater exposure, seizures, coma, apnea, and cardiac arrest may follow within minutes. An elevated anion gap metabolic acidosis is typically present, and decreased peripheral oxygen utilization leads to an elevated mixed venous oxygen

saturation value.

DELAYED-ONSET RESPIRATORY SYNDROME: ANTHRAX, PLAGUE, AND TULAREMIA.

A delayed onset of respiratory symptoms (days after exposure) is characteristic of several infectious diseases that might be adapted for sinister use by terrorists. Among these are anthrax, plague, and tularemia.

Anthrax is caused by infection with the gram-positive spore-forming rod *Bacillus anthracis*. Its ability to form a spore enables the anthrax bacillus to survive for long periods in the environment and enhances its potential as a weapon.

The vast majority of naturally occurring anthrax cases are cutaneous, acquired by close contact with the hides, wool, bone, and other by-products of infected cattle, sheep, and goats. Cutaneous cases also may result from the intentional deployment of anthrax-contaminated fomites. Cutaneous anthrax is, however, quite amenable to therapy with a variety of antibiotics and is readily recognizable to experienced clinicians in endemic areas; it is thus rarely fatal. Common in parts of Asia and sub-Saharan Africa, only two cases of cutaneous anthrax had occurred in the United States in the 9 yr that preceded the cases in 2001. Gastrointestinal anthrax, which has never been described in the United States, can occur after the ingestion of contaminated meat. In the past, inhalational anthrax, or woolsorter's disease, was an occupational hazard of abattoir and textile workers. Now eliminated as a naturally occurring disease in the United States, it is this inhalational form of anthrax that poses the greatest threat. Following an inadvertent release in 1979 from a bioweapons facility at Sverdlovsk in the former Soviet Union, 66 of 77 known adult victims of inhalational anthrax died. In the bioterrorism attacks involving contaminated letters in the United States, 6 of 11 patients with inhalational anthrax have survived. Whether improved intensive care modalities, changes in antibiotic therapy, or earlier recognition accounts for this improved mortality rate remains to be determined.

Symptomatic inhalational anthrax typically begins 1–6 days after exposure, although incubation periods up to several weeks in length have been reported. The disease begins as a flulike illness, characterized by fever, myalgia, headache, and cough. A brief intervening period of improvement sometimes follows, but rapid deterioration then ensues; high fever, dyspnea, cyanosis, and shock mark this second phase. Hemorrhagic meningitis occurs in up to 50% of cases. Chest radiographs obtained late in the course of illness may reveal a widened mediastinum or prominent mediastinal lymphadenopathy; pleural effusions may also be seen. Gram stains of peripheral blood may demonstrate the organism at this stage. Prompt treatment is imperative; death occurs in as many as 95% of inhalational anthrax cases if such treatment is begun more than 48?hr after the onset of symptoms.

Whereas inhalational anthrax is a disease primarily of mediastinal lymphatic tissue, exposure to aerosolized **plague** bacilli typically leads to a primary pneumonia. Endemic plague is usually transmitted via the bites of fleas and is discussed in Chapter 186.3 . The causative organism of all forms of human plague, *Yersinia pestis*, is a bipolar-staining, gram-negative facultative intracellular bacillus. An ability to survive within the macrophage aids its dissemination to distant sites after inoculation or inhalation. “Buboes,” markedly swollen, tender regional lymph nodes in the distribution of a bite, are the hallmark feature of bubonic plague. Fever and malaise are typically present, and septicemia often develops as bacteria gain access to the circulation. Petechiae, purpura, and overwhelming disseminated intravascular coagulopathy (DIC) commonly occur, and 80% of bubonic plague victims will ultimately have positive blood cultures. Testimony to the extreme infectivity and lethality of plague is the fact that the “Black Death” eliminated one third of the population of Europe during the Middle Ages. The potential of bubonic plague as a weapon also was appreciated, as evidenced by its use in 1346 by invading Tatars against the garrison at Kaffa in the Ukraine.

Intentional aerosol dissemination of *Y. pestis* would likely result in a preponderance of pneumonic plague cases. Pneumonic plague may also arise secondarily after seeding of the lungs of septicemic patients. Symptoms include fever, chills, malaise, headache, and cough. Chest radiographs may reveal a patchy consolidation, and the classic clinical finding is one of blood-streaked sputum. DIC and overwhelming sepsis typically develop as the disease progresses. Untreated pneumonic plague has a fatality rate approaching 100%.

Tularemia is a highly infectious disease caused by the gram-negative coccobacillus *Francisella tularensis*. Naturally occurring tularemia is discussed in Chapter 189 . The high degree of infectivity of *F. tularensis* (fewer than 10 organisms are thought necessary to produce infection via inhalation) as well as its survivability in the environment, contributes to its inclusion on the

list of agents of concern. Several clinical forms of endemic tularemia are known, but inhalational exposure in a terrorist attack would likely lead to a plaguelike primary pneumonia or to typhoidal tularemia, manifest as a variety of nonspecific symptoms including fever, malaise, and abdominal pain.

SUDDEN-ONSET DERMATOLOGIC SYNDROME: MUSTARD AND LEWISITE.

The development of skin lesions shortly after exposure is characteristic of the chemical vesicants. These compounds, often referred to as blistering agents, are cellular poisons and include the alkylating agent mustard and the organic arsenical lewisite. Tissue injury to rapidly reproducing cells begins within minutes of contact with these agents. In the case of mustard, clinical effects typically become evident several hours after exposure. In contrast, patients exposed to lewisite will feel immediate pain. In addition to cutaneous vesicle formation, the eyes and respiratory tract are also injured. Moreover, mustard exposure may lead to bone marrow suppression and both mustard and lewisite may produce significant gastrointestinal symptoms.

DELAYED-ONSET DERMATOLOGIC SYNDROME: SMALLPOX.

The appearance of an exanthem, days to weeks after exposure, is likely to be a presenting feature of smallpox. Smallpox, caused by the variola virus, a member of the orthopoxvirus family, has an incubation period of 7–17 days. This would likely

permit the wide dispersal of asymptomatic exposed persons, thus contributing to the spread of an outbreak. During the incubation period, virus replicates in the upper respiratory tract. A primary viremia ensues, during which time seeding of the liver and spleen occurs. A secondary viremia then develops, the skin is seeded, and the classic exanthem of smallpox appears.

Symptoms of smallpox begin abruptly during the phase of secondary viremia and include fever, rigors, vomiting, headache, backache, and extreme malaise. Within 2–4 days, macules appear on the face and extremities and then progress in synchronous fashion to papules, pustules, and finally scabs. As the scabs separate, survivors are often left with disfiguring, de-pigmented scars. The synchronous nature of the rash and its centrifugal distribution distinguish smallpox from chickenpox, which has a centripetal distribution. In the past, smallpox had a 30% mortality rate, with death typically resulting from visceral organ involvement.

Diagnosis.

In some cases, the terrorist nature of a chemical or biologic attack may be obvious. This might be especially true in the case of a chemical attack when victims succumb in close temporal and geographic proximity to a dispersal device. Alternatively, terrorists may announce their attack. In other instances, however, the clinician may need to rely on epidemiologic clues to suspect an intentional release of chemical or biologic agents. The presence of large numbers of victims clustered in time and space should raise the clinician's index of suspicion, as should cases of unexpected death or unexpectedly severe disease. Diseases unusual in a given locale, in a given age group, or during a certain season likewise warrant further investigation. Simultaneous outbreaks of a disease in noncontiguous areas should cause one to consider an intentional release, as should outbreaks of multiple diseases in the same area. Conversely, even a single case of rare disorders such as anthrax or certain viral hemorrhagic fevers would be suspicious, and a single case of smallpox would almost certainly be the result of an intentional release. Finally, large numbers of dying animals might provide evidence of an unnatural aerosol release, as would evidence of a disparate attack rate between those known to be indoors and outdoors at a given time.

In a mass casualty setting, diagnoses may, of necessity, be made largely on clinical grounds. The diagnosis of nerve agent intoxication, for example, is based primarily on clinical recognition and the response to antidotal therapy. In addition, several simple rapid detection devices developed for military use are able to detect the presence of nerve agents. Some of these are commercially available and are stocked in certain emergency departments and public safety vehicles. “M8” and “M9” test papers, for example, detect nerve agents and mustard and are interpreted by means of a simple color change. Measurements of acetylcholinesterase in plasma or erythrocytes of nerve agent victims may be helpful in long-term prognostication, but correlation between cholinesterase levels and clinical effects is often poor, and the test is rarely available emergently.

Botulism should be suspected clinically among patients presenting with a symmetric, descending, flaccid paralysis. Although the differential diagnosis of botulism includes other uncommon neurologic disorders such as myasthenia gravis and the Guillain-Barré syndrome, the presence of multiple casualties with similar symptoms should facilitate discovery of a botulism outbreak.

Initially, the diagnosis of *cyanide poisoning* will also likely be made on clinical grounds in the face of the appropriate toxidrome. An unusually high anion gap metabolic acidosis and a greater than expected oxygen concentration in venous blood lend support to the clinical diagnosis. Elevated blood cyanide concentrations can confirm the clinical suspicion.

Anthrax should be suspected on finding gram-positive bacilli in skin biopsy material (in the case of cutaneous disease), blood smears, pleural fluid, or spinal fluid. Chest radiographs demonstrating a widened mediastinum in the context of fever and constitutional signs, and in the absence of another obvious explanation (e.g., blunt trauma or postsurgical infection), should also lead one to consider the diagnosis. Confirmation can be obtained by blood culture. State health laboratories and federal facilities at the CDC and at the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) can confirm a diagnosis of anthrax by polymerase chain reaction and immunohistochemical assay.

A diagnosis of *plague* can similarly be suspected on finding bipolar “safety-pin”–staining bacilli in Gram or Wayson stains of sputum or aspirated lymph node material; confirmation is obtained by culturing *Y. pestis* from blood, sputum, or lymph node aspirate. The organism grows on standard blood or MacConkey TRA agars, but it is often misidentified by automated systems. *F. tularensis* grows poorly on standard media; its growth is enhanced on media containing cysteine. Because of its extreme infectivity, however, many laboratories prefer to make a diagnosis serologically using an enzyme-linked immunosorbent assay.

Smallpox should be suspected on clinical grounds and can be confirmed by culture or electron microscopy of scabs or vesicular fluid, although the manipulation of clinical material from suspected smallpox victims should be attempted only at public health laboratories able to employ maximum biocontainment precautions. Similar caution should be exercised with specimens from patients with various viral hemorrhagic fevers, a diagnosis that should be considered in those presenting with fever and a bleeding diathesis.

Prevention.

Preventive measures should be considered in both a pre-exposure and a postexposure context. Pre-exposure protection against a chemical or biologic attack may consist of physical, chemical, or immunologic measures. Physical protection against primary attack often involves gas masks and protective suits; such equipment is used by the military and by certain hazardous materials response teams, but it is unlikely to be available to civilians at the precise moment when a release might occur. Medical personnel, however, must understand the principles of physical protection as they apply to infection control and the spread of contamination.

Pneumonic plague is spread through respiratory droplets. Droplet precautions, including the use of simple surgical masks,

are thus warranted when caring for patients with plague. *Smallpox* is transmitted by droplet nuclei. Airborne precautions, including (ideally) a high-efficiency particulate air (HEPA) filter mask are warranted when caring for smallpox victims. Similarly, *viral hemorrhagic fever* patients should, in general, be managed using contact precautions. Most other biologic agent victims can be safely cared for while employing standard precautions. In the case of chemical agents, residual *mustard* or *nerve agent* on the skin or clothing of victims might potentially pose a hazard to medical personnel. Such victims, whenever possible, should thus have their clothing removed and be “decontaminated” using copious amounts of water before extensive medical care is rendered. Most other chemical agents are volatile enough that spread of agent among patients or from patient to caregiver is unlikely.

Pre-exposure chemical prophylaxis might conceivably be used on the basis of credible intelligence reports. For example, should officials deem that the threatened release of a specific biologic agent appears imminent, antibiotics might be distributed to a population preemptively. Obviously, opportunities to employ such a strategy are likely to be quite limited.

Licensed *vaccines* exist against anthrax and smallpox. Widespread use of either vaccine, however, is likely to be problematic, especially in children. The anthrax vaccine is licensed only for those persons age 18 yr and older. Moreover, the vaccine is given as a six-dose series over 18 mo and requires annual booster doses. These issues, coupled with a limited supply, make civilian employment of the current anthrax vaccine on a large scale unlikely.

Significant obstacles also exist to the widespread employment of smallpox vaccine, although public health officials have contemplated the resumption of a smallpox vaccination campaign. Whereas smallpox vaccine (prepared from vaccinia virus, an orthopoxvirus related to variola) was used safely and successfully in the past in even the youngest infants, it has a relatively high rate of serious complications in certain patients. Fetal vaccinia and demise can occur when pregnant women are vaccinated. Likewise, vaccinia gangrenosa, an often-fatal complication, can occur when immunocompromised persons are vaccinated. Another serious complication, eczema vaccinatum, occurs in those with pre-existing dermatoses. A severe vaccine-related encephalitis was well known during the era of widespread vaccination; because this occurs only in primary vaccinees, it would disproportionately affect pediatric patients. Autoinoculation can occur when virus present at the site of vaccination is manually transferred to other areas of skin or to the eye. Young children would presumably be at greater risk for such inadvertent transmission.

To manage these complications, vaccinia immune globulin (VIG) should be available when undertaking a vaccination campaign. VIG (0.6?mg/kg IM) may be given to vaccine recipients who experience severe complications or to significantly immunocompromised individuals exposed to smallpox, in whom vaccination would be unsafe. Stocks of current vaccine and of VIG are controlled by the CDC, and production of a new vaccine and VIG preparation has begun. In addition to a potential role in pre-exposure prophylaxis, it is thought that vaccination may be effective in postexposure prophylaxis if given within the first 4 days or so after exposure.

Anthrax vaccine might similarly be employed in a postexposure setting. Some authorities recommend three doses of this vaccine as an adjunct to postexposure chemoprophylaxis after documented exposure to aerosolized anthrax spores. Nonetheless, postexposure administration of oral antibiotics constitutes the mainstay of management for asymptomatic victims believed to have been exposed to anthrax, as well as to other bacterial agents such as plague and tularemia. Appropriate prophylactic regimens for various biologic exposures are provided in Table 706–2 .

Treatment.

Recommended therapies for overt diseases caused by various chemical and biologic agents are provided in Tables 706–2 and 706–3 . It is quite likely, however, that the clinician attending to victims will need to make therapeutic decisions before the results of confirmatory diagnostic tests are available and in situations where the diagnosis is not known with certainty. In such cases, it is useful to note that many diseases and symptoms caused by chemical and biologic agents will resolve spontaneously, with only supportive care required. Chlorine and phosgene exposures can thus be successfully managed by providing meticulous attention to oxygenation and fluid balance. Mustard victims may require intensive multisystem support, but no specific antidote or therapy is available. Similarly, many viral diseases such as smallpox, most viral hemorrhagic fevers, and the equine encephalitides are managed supportively.

In addition to ensuring adequate oxygenation, ventilation, and hydration, the clinician may, in certain instances, need to provide specific empirical therapies on an urgent basis. Patients suffering from the sudden onset of severe neuromuscular symptoms may have nerve agent intoxication and should be promptly given atropine (0.05?mg/kg) for its antimuscarinic effects. Although atropine relieves bronchospasm and bradycardia, reduces bronchial secretions, and ameliorates the gastrointestinal effects of nausea, vomiting, and diarrhea, it does not improve skeletal muscle paralysis. Pralidoxime (also known as 2-PAM) cleaves the organophosphate moiety from cholinesterase and regenerates intact enzyme if “aging” has not occurred. The effect is most prominent at the neuromuscular junction and leads to improved muscle strength. Its prompt use (at a dose of 25?mg/kg) as an adjunct to atropine is recommended in all serious cases.

Both atropine and pralidoxime should ideally be administered intravenously in severe cases, although the intraosseous route may be acceptable. Some experts recommend that atropine be given intramuscularly in the presence of hypoxia to avoid arrhythmias associated with intravenous administration. Many EMS systems now stock military autoinjector kits consisting of atropine and 2-PAM for intramuscular injection. Kits containing pediatric doses are currently not available, although military kits (with 2?mg of atropine and 600?mg of pralidoxime) might be used in children older than 2–3 yr of age. Animal studies support the routine prophylactic administration of anticonvulsant doses of benzodiazepines, even in the absence of observable convulsive activity.

Delayed neuromuscular symptoms in the setting of terrorism might be due to botulism. Supportive care, with meticulous attention to ventilatory support, is the mainstay of botulism treatment. Such support may be necessary for several months,

making the management of a large-scale botulism outbreak especially problematic in terms of medical resources. A licensed trivalent (types A, B, E) equine botulinum antitoxin is available through the CDC. Administration of this antitoxin is unlikely to reverse disease in symptomatic patients but may prevent further progression. A test dose should be administered before therapy, and patients reacting to this test dose should be desensitized. An investigational heptavalent despeciated (Fab_2) antitoxin, also produced in horses, is available through USAMRIID on a compassionate use protocol. In addition, a pentavalent (types A–E) investigational product, Botulism Immune Globulin Intravenous (Human), is available through the California Department of Health Services (510-540-2646), specifically for the treatment of infant botulism.

The rapid onset of respiratory symptoms may signal an exposure to chlorine, phosgene, cyanide, or a number of other toxic industrial chemicals. Although the mainstay of therapy in virtually all of these exposures consists of removal to fresh air and intensive supportive care, cyanide intoxication often requires the administration of specific antidotes, given in two stages.

TABLE 706-2 -- Critical Biologic Agents of Terro

Disease	Etiology	Clinical Findings	Incubation Period	Diagnostic Samples	Diagnostic Assay
Anthrax	*Bacillus anthracis*	Inhalational: febrile prodrome with rapid progression to mediastinal lymphadenitis, medastinitis (chest x-ray: +/- infiltrates, widened mediastinum, pleural effusions); sepsis; shock; meningitis	1–5 days (up to 6 wk?)	Blood >CSF >Pleural fluid	Culture >Gram stain >ELISA >PCR
		Cutaneous: papule progressing to vesicle, to ulcer, then to depressed black eschar, with marked edema		Skin biopsy	Immunohisto-chemical assay
Plague	*Yersinia pestis*	Febrile prodrome with rapid progression to fulminant pneumonia with bloody sputum, sepsis, DIC	2–3 days	Blood, sputum, lymph node aspirate	Culture >Gram or Wright-Giemsa stain >ELISA, IFA Ag-ELISA
Smallpox	Variola virus	Febrile prodrome; synchronous vesicopustular eruption, predominately on face and extremities	7–17 days	Pharyngeal swab, scab material	ELISA, PCR Virus isolation
Tularemia	*Francisiella tularensis*	Pneumonic: abrupt onset of fever, fulminant pneumonia (chest x-ray: prominent hilar adenopathy)	2–10 days	Blood, sputum, serum	Culture Serology: agglutination
		Typhoidal: fever, malaise, abdominal pain		Tissue	EM

Botulism	*Clostridium botulinum* toxin	Afebrile; descending flaccid paralysis; cranial nerve palsies, sensation and mentation intact	1–5 days	Nasal swab?	Mouse bioassay, Ag-ELISA
Viral hemorrhagic fevers	Arenaviradae (e.g., Lassa fever) Filoviradae (Ebola, Marburg)	Febrile prodrome; rapid progression to shock, purpura, bleeding diathesis	4–21 days	Serum, blood	Viral isolation Ag-ELISA RT-PCR Serology: Ab-ELISA

CSF = cerebrospinal fluid; ELISA = enzyme- linked immunosorbent assay; Ag = antigen; PCR = p
DIC = disseminated intravascular coagulation; IFA = immunofluorescent assay; EM = electron mic
investigational new drug; RT = reverse transcriptase.

**Brief definition of isolation precautions:*
> Standard: handwashing; gloves, masks, eye protection, face shields and nonsterile, fluid-resistant gowns for blood, body fluid exposure; appropriate handling of patient care equipment, linens, etc.; avoidance of needle-stick, sharps injury.
> Airborne: standard, + private, negative-pressure room with external exhaust or HEPA-filtered recirculated air; special "fitted" and "sealing" respirator masks (e. g., N95)
> Droplet: standard, + private room, "routine" mask within 3 feet of patient
> Contact: standard, + private room; gloves at all times; handwashing after glove removal; gowns at all times, removed before leaving patient's room.
> Adapted from American Academy of Pediatrics. Infection control for hospitalized children. In Pickering LK (editor): 2000 Redbook: Report of the Committee on Infectious Diseases, *25th ed. Elk Grove Village, IL. American Academy of Pediatrics, 2000, pp 127– 37.*
†CDC recommended one or two additional antibiotics for inhalational anthrax in Fall 2001 outbreak: rifampin, vancomycin, penicillin or ampicillin, clindamycin, imipenem, or clarithromycin. Recommendations in future outbeaks may evolve rapidly, and frequent consultation with local health departments and CDC (1-770-488-7100; www.bt.cdc.gov) is encouraged.
‡ Amoxicillin, 80?mg/ kg/ day divided q8h can be substituted if strain proves susceptible.
§ Streptomycin, 15?mg/kg IM q12h may be substituted if available.
Laboratory must be notified that tularemia is suspected.

TABLE 706- 3 -- Critical Chemical Agents of Terrorism

Agent	Toxicity	Clinical Findings	Onset	Decontamination*
Nerve agents: Tabun, Sarin, Soman, VX	Anticholinesterase: Muscarinic, nicotinic and CNS effects	Vapor: miosis, rhinorrhea, dyspnea Liquid: Diaphoresis, vomiting Both: coma, paralysis, seizures, apnea	Seconds: vapor Minutes–hours: liquid	Vapor: fresh air, remove clothes, wash hair Liquid: remove clothes, copious washing skin, hair with soap and water, ocular irrigation
Vesicants:		Skin: erythema, vesicles	Hours	Skin: soap and water
Mustard	Alkylation	Eye: inflammation Respiratory tract: inflammation		Eyes: water (only effective if done within minutes of exposure)
Lewisite	Arsenical		Immediate pain	

Pulmonary agents: chlorine, phosgene	Liberate HCL, Alkylation	Eyes, nose, throat irritation (especially chlorine) Respiratory: bronchospasm, pulmonary edema (especially phosgene)	Minutes: eyes, nose, throat irritation, bronchospasm; Hours: pulmonary edema	Fresh air Skin: water
Cyanide	Cytochrome oxidase inhibition: cellular anoxia, lactic acidosis	Tachypnea, coma, seizures, apnea	Seconds	Fresh air Skin: soap and water

ABCs = airway, breathing, and circulatory support; BAL = British antilewisite; CNS = central nervou system; Hgb = hemoglobin concentration; est. = estimated hemoglobin concentration; max = maxi min = minimum; prn = as needed.

Adapted from Henretig FH, Cieslak TJ, Eitzen EM. Biological and chemical terrorism.J Pediatr 200 141(3): 311– 26. Used with permission.

**Decontamination, especially for patients with significant nerve agent or vesicant exposure; should be performed by health care providers garbed in adequate personal protective equipment. For emergency department staff, this consists of nonencapsulated, chemically resistant body suit, boots, and gloves with a full face air purifier mask/ hood.*

† Intraosseous route is likely equivalent to intravenous.

‡ Atropine might have some benefit via endotracheal tube or inhalation, as might aerosolized ipratropium.

§ Pralidoxime is reconstituted to 50?mg/ mL (1?g in 20?mL water) for IV administration, and the total dose infused over 30?min, or may be given by continuous infusion (loading dose 25?mg/ kg over 30?min, then 10?mg/ kg/ hr). For IM use, it might be diluted to a concentration of 300?mg/ mL (1g added to 3?mL water— by analogy to the US Army's Mark 1 autoinjector concentration), to effect a reasonable volume for injection. Each Mark 1 kit holds two autoinjectors, one each of atropine 2?mg (0.7?ml) and pralidoxime 600?mg (2?ml); while not approved for pediatric use, they might be considered as initial treatment in dire (especially prehospital) circumstances, for children with severe, life- threatening nerve agent toxicity who lack intravenous access, and for whom more precise, mg/ kg IM dosing would be logistically impossible. Suggested dosing guidelines are offered; note potential excess of intial atropine and pralidoxime dose for age/ weight, though within general guidelines for recommended total over first 60– 90?min of therapy of severe exposures:

A methemoglobin-forming agent such as sodium nitrite is administered first, because methemoglobin has high affinity for cyanide and causes it to dissociate from cytochrome oxidase. Nitrite dosing in children should be based on body weight to avoid excessive methemoglobin formation and nitrite-induced hypotension. For the same reasons, nitrites should be infused slowly over 5–10?min. A sulfur donor, such as sodium thiosulfate, is given next. This compound is used as a substrate by the hepatic enzyme rhodanese, which converts cyanide to thiocyanate, a less toxic compound excreted in the urine. Thiosulfate treatment itself is efficacious and relatively benign and, thus, may be used alone for mild to moderate cases. Sodium nitrite and sodium thiosulfate are packaged together in standard antidote kits, along with amyl nitrite, a sodium nitrite substitute that can be inhaled in prehospital settings where intravenous access is not available.

In cases in which the delayed onset of respiratory symptoms is potentially due to a terrorist attack, consideration should be given to the empirical administration of an antibiotic effective against anthrax, plague, and tularemia. Ciprofloxacin (10–15?mg/kg IV q12hr) or doxycycline (2.2?mg/kg IV q12hr) are reasonable choices. Although naturally occurring strains of *B. anthracis* are usually quite sensitive to penicillin G, these agents are chosen because penicillin-resistant strains of *B. anthracis* exist. Moreover, ciprofloxacin and doxycycline are effective against almost all known strains of *Y. pestis* and *F. tularensis*. Concerns about inducible ß-lactamases in *B. anthracis* have led some experts to recommend one or two additional antibiotics in patients with inhalational anthrax. Rifampin, vancomycin, penicillin or ampicillin, clindamycin, imipenem, and clarithromycin are reasonable choices based on in vitro sensitivity data. Because *B. anthracis* relies on the production of two protein toxins, edema toxin and lethal toxin, for its virulence, drugs that act at the ribosome to disrupt protein synthesis (e.g., clindamycin and the macrolides) provide a theoretical advantage. Ciprofloxacin or doxycycline monotherapy is probably adequate in cases of cutaneous anthrax.

In patients in whom a diagnosis of plague or tularemia is established, streptomycin (15?mg/kg IM q12hr) or gentamicin (2.5?mg/kg IV/IM q8hr) is the preferred choice for therapy. In addition to doxycycline and ciprofloxacin, chloramphenicol (25?mg/kg IV q6hr) is an acceptable alternative. The latter should be employed in the 6% of pneumonic plague cases with concomitant meningitis. To be effective, therapy for pneumonic plague must be initiated within 24?hr of the onset of symptoms.

The management of vesicant-induced injury is similar to that required in burn victims and is largely symptomatic. Mustard victims will benefit from the application of soothing skin lotions such as calamine and the administration of analgesics. Early

intubation of severely exposed patients is warranted to guard against edematous airway compromise. Oxygen and mechanical ventilation may be needed, and meticulous attention to hydration is of paramount importance. Lewisite victims can be managed in much the same manner as mustard victims. In addition, dimercaprol (British anti-Lewisite [BAL]) in oil, given intramuscularly, may help ameliorate the systemic effects of lewisite.

The management of symptomatic smallpox victims is also largely supportive, with attention to pain control, hydration status, and respiratory sufficiency again being of primary importance. The parenteral antiviral compound cidofovir, licensed for the treatment of cytomegalovirus retinitis in HIV-infected patients, has in vitro efficacy against variola and other orthopoxviruses. Its utility in treating smallpox victims is untested. Moreover, in the face of a large outbreak of disease, large-scale parenteral use of this drug would be problematic.

Chapter 707 - Animal and Human Bites

Charles M. Ginsburg

It has been estimated that there are nearly 100 million dogs and cats in the United States, and all have the potential to inflict injury to a child. Animal bite injuries account for between 0.7–1% of visits to hospital emergency departments and free-standing emergency centers in the United States. The precise number of individuals who sustain a bite injury who seek medical attention in medical offices and primary care clinics has been estimated to exceed the number who seek care in emergency facilities.

Epidemiology.

During the past 3 decades, there have been approximately 20 deaths per year in the United States from dog-inflicted injuries; 65% of these occurred in children who were younger than 11 yr of age. The breed of dog involved in the attacks on children varied; however, rottweilers, pit bulls, and German shepherds accounted for more than 50% of all fatal bite-related injuries. Unneutered male dogs account for approximately 75% of attacks; nursing dams often inflict injury to humans when children attempt to handle one of their puppies.

The majority of dog-related attacks occur in children between the ages of 6–11 yr of age, and males are attacked more often than females (1.5:1). Approximately two thirds of the attacks occur around the home, 75% of the biting animals are known by the child, and almost one half of the attacks are said to be unprovoked. By contrast, the 450,000 reported cat bites per year occur primarily in females and almost all are inflicted by known household animals. Rat bites and gerbil bites are not reportable conditions; therefore, there is a paucity of information available on the epidemiology of these injuries and the incidence of infection after rodent-inflicted bites or scratches.

Few data exist on the incidence and demographics of human bite injuries in pediatric patients; however, preschool-age and early school-age children appear to be the age groups at greatest risk to sustain an injury from a bite by a human. Human bites are the leading cause of injury in daycare centers in the United States.

Clinical Manifestations.

Dog bite–related injuries can be divided into three, almost equal categories: abrasions, puncture wounds, and lacerations with or without an associated avulsion of tissue. The most common type of injury from cat and rat bites is a puncture wound. Human bite injuries are of two types, an occlusional injury that is incurred when the upper and lower teeth come together on a body part and, in older children and young adults, a clenched-fist injury that occurs when their fist, usually on their dominant hand, comes in contact with the tooth of another individual.

Diagnosis.

Management of the victim of a bite should begin with a thorough history and physical examination. Careful attention should be paid to the circumstances surrounding the bite (type of animal, domestic or sylvatic, provoked or unprovoked, and location of the attack), a history of drug allergies, and the

immunization status of the child and animal. During physical examination, meticulous attention should be paid to the type, size, and depth of the injury; the presence of foreign material in the wound; the status of underlying structures; and, in instances where the bite is on an extremity, the range of motion of the affected area. A diagram of the injury(s) should be recorded in the patient's medical record. A radiograph of the affected part should be obtained if there is likelihood that a bone or joint could have been penetrated or fractured or if foreign material is present. The possibility of a fracture or penetrating injury of the skull should be considered in individuals, particularly infants, who have sustained dog bite injuries to the face and head.

Complications.

Infection is the most common complication of bite injuries, regardless of the species of biting animal. The decision to obtain material for culture from a wound depends on the species of the biting animal, the length of time that has transpired since the injury, the depth of the wound, the presence of foreign material contaminating the wound, and whether there is evidence of infection. Although potentially pathogenic bacteria have been isolated from up to 80% of dog bite wounds that are brought to medical attention within 8?hr after the bite, the infection rate for wounds receiving medical attention in less than 8?hr is small (2.5%–20%). Thus, unless they are deep and extensive, dog bite wounds that are less than 8?hr in duration do not need to be cultured unless there is evidence of contamination, early signs of infection, or the patient is immunocompromised. Species of *Capnocytophaga canimorsus*, uncommon pathogens in bite-inflicted injuries, have been isolated from nearly 5% of infected wounds in immunocompromised patients. By contrast, the infection rate in cat bite wounds that receive early medical attention is at least 50%; therefore, it is prudent to obtain material for culture from all but the most trivial cat-inflicted wounds and all other animal bite wounds that are not brought to medical attention within 8?hr, regardless of species of the biting animal.

The rate of infection after rodent bite injuries is not known. The majority of the oral flora of rats is similar to that of other mammals; however, approximately 50% and 25% of rats harbor strains of *Streptobacillus moniliformis* and *Spirillum minus*, respectively, in their oral flora. Each of these agents have the potential to cause infections manifested by fever, rash, and other systemic symptoms (i.e., **rat-bite fever**). In addition, *S. minus* is responsible for **sodoku,** which is characterized by fever, ulcerative lesions at the wound site, lymphadenopathy, and rash occurring days to weeks after the primary wound has healed.

All human bite wounds, regardless of the mechanism of injury, should be regarded as high risk for infection and cultured. Because of the large incidence of anaerobic infection after bite wounds, it is important to obtain material for anaerobic as well as aerobic cultures.

Treatment.

After the appropriate material has been obtained for culture, the wound should be anesthetized, cleaned, and vigorously irrigated with copious amounts of normal saline. Irrigation with antibiotic-containing solutions provides no advantage over irrigation with saline alone and has the potential to cause local irritation of the tissues. Puncture wounds should be thoroughly cleansed and gently irrigated with a catheter or blunt-tipped needle; however, high-pressure irrigation should not be employed. Avulsed or devitalized tissue should be débrided and any fluctuant areas incised and drained.

Much controversy and few data exist to determine whether bite wounds should undergo primary closure or delayed primary closure (3–5 days) or be allowed to heal by secondary intention. Factors to be considered are the type, size, and depth of the wound; the anatomic location; the presence of infection; the time interval from the injury; and the potential for cosmetic disfigurement. Surgical consultation should be obtained for all patients with deep or extensive wounds, those involving the bones and joints, and infected wounds that require open drainage. Although there is general agreement that infected wounds and those that are greater than 24?hr of age should not be sutured, there is disagreement and varying clinical experience about the efficacy and safety of closing wounds that are younger than 8?hr of age with no evidence of infection. All hand wounds are at high risk for infection, particularly if there has been disruption of the tendons or penetration of the bones; therefore, delayed primary closure is recommended for all but the most trivial bite wounds of the hands. In contrast to hand wounds, facial lacerations are at smaller risk for secondary infection because of the more luxuriant blood supply to this region. Many plastic surgeons advocate primary closure of facial bite wounds that have been brought to medical attention within 6?hr and have been thoroughly irrigated and debrided.

There are few studies that unequivocally demonstrate the efficacy of antimicrobial agents for prophylaxis of bite injuries; there is, however, a general consensus that antibiotics should be administered to all victims of human bites and all but the most trivial of dog, cat, and rat bite injuries, regardless of whether there is evidence of infection. The bacteriology of bite wound infections is primarily a reflection of the oral

flora of the biting animal and, to a lesser extent, a reflection of the skin flora of the victim. Because each of the multitude of aerobic and anaerobic bacterial species that colonize the oral cavity of the biting animal has the potential to invade local tissue, multiply, and cause tissue destruction, the majority of bite wound infections are polymicrobial. Evidence suggests that there may be as many as five different species isolated from infected dog bite wounds.

Despite the large degree of homology in the bacterial flora of the oral cavity between humans, dogs, and cats, important differences exist between the biting species, and this is reflected in the type of wound infections that occur. The predominant bacterial species isolated from infected dog bite wounds are *Staphylococcus aureus* (20–30%), *Pasteurella multocida* (20–30%), *Staphylococcus intermedius* (25%), and *C. canimorsus*; approximately one half of dog bite wound infections contain mixed anaerobes. Similar species are isolated from infected cat bite wounds; however, *P. multocida* is the predominant species in at least 50% of cat bite wound infections. At least 50% or rats harbor strains of *Streptobacillus moniliformis* in their oropharynx, and approximately 25% harbor *S. minor*, an aerobic gram-negative organism. In human bite wounds, nontypable strains of *Haemophilus influenzae, Eikenella corrodens, S. aureus*, a-hemolytic streptococci, and ß-lactamase–producing aerobes (about 50%) are the predominant species. Clenched fist injuries are particularly prone to infection by *Eikenella* (25%) and anaerobic bacteria (50%).

The choice between an oral and parenteral antimicrobial agent should be based on the severity of the wound, the presence and degree of overt infection, signs of systemic toxicity, and the immune status of the patient. Amoxicillin-clavulanate is an excellent choice for empirical oral therapy for human and animal bite wounds because of its activity against the majority of strains of bacteria that have been isolated from infected bite injuries. Similarly, ticarcillin-clavulanate or ampicillin and sulbactam are preferred for patients who require empirical parenteral therapy. Procaine penicillin remains the drug of choice for prophylaxis and treatment of rat-inflicted injuries. First-generation cephalosporins have limited activity against *P. multocida and E. corrodens* and, therefore, should not be used for prophylaxis or empirical initial therapy of bite wound infections. The therapeutic alternatives for penicillin-allergic patients are limited because the traditional alternative agents are generally inactive against one or more of the multiple pathogens that cause bite wound infections. Although erythromycin is commonly recommended as an alternative agent for penicillin-allergic patients who have suffered dog and cat bites, it has incomplete activity against strains of *P. multocida* and *S. moniliformis*

and is not effective against *E. corrodens*. Similarly, clindamycin and the combination trimethoprim-sulfamethoxazole have limited activity against strains of *P. multocida* and anaerobic bacteria, respectively. Azithromycin and the newer ketolide antibiotics may be considered because they have activity against aerobic and anaerobic bacteria that are present in infected bite wounds. Tetracycline is the drug of choice for penicillin-allergic patients who have sustained rat bite injuries.

Although the occurrence of tetanus after human or animal bite injuries is extremely rare, it is important to obtain a careful immunization history and to provide tetanus toxoid to all patients who are incompletely immunized or those in whom it has been longer than 10 yr since their last immunization. The need for postexposure rabies vaccine in victims of dog and cat bites is dependent on whether the biting animal is known to have been vaccinated and, most importantly, on the local experience with rabid animals in the community (see Chapter 251). The local health department should be consulted for advice in all instances where the vaccination status of the biting animal is unknown and instances where there is known endemic rabies in the community. Postexposure prophylaxis for hepatitis B should be considered in the rare instance in which an individual has sustained a human bite from an individual who is at high risk for hepatitis B.

All but the most trivial bite wounds of the hand should be immobilized in a position of function for 3–5 days, and patients with bite wounds of an extremity should be instructed to keep the affected extremity elevated for 24–36?hr or until the edema has resolved. All bite wound victims should be re-evaluated within 24–36?hr after the injury.

Prevention.

It is not possible to prevent mammalian bite injuries; however, it is possible to reduce the risk of injury with anticipatory guidance. Parents should be routinely counseled during prenatal visits and routine health maintenance examinations about the risks of having potentially biting pets in the household; all should be cautioned against harboring exotic animals for pets. Additionally, parents should be made aware of the proclivity of certain breeds of dogs to inflict serious injuries and the protective instincts of nursing dams. All young children should be closely supervised, particularly when in the presence of animals and, from a very early age, taught to respect animals and to be aware of their potential to inflict injury.

Basic safety tips that should be taught to all children include the following:

- Do not disturb any animal that is sleeping or eating.
- Do not approach an unfamiliar animal.
- Do not disturb a dam that is caring for or feeding her puppies.
- Never run from a unaccompanied dog.
- Remain still if an unfamiliar animal approaches.
- Always allow a dog to see and sniff you before touching it.

Reduction of human bite injuries, particularly in daycare centers and schools, can be achieved by good surveillance of the children and having adequate supervisory personnel to child ratios.

Chapter 708 - Envenomations

Steve Holve

The vast majority of bites and stings by spiders, snakes, and other venomous animals cause little more than local pain and do not require medical attention. However, pediatricians should be prepared to identify and treat those few individuals who present with severe envenomation. Children, unfortunately, are at greater risk for severe reactions because of their smaller volume for venom distribution.

Symptoms of envenomation may be either IgE mediated, such as anaphylaxis in response to Hymenoptera stings, or venom mediated, as with the bites of poisonous spiders or snakes or the sting of scorpions. Immediate hypersensitivity reactions are treated emergently as indicated in Chapter 137 on anaphylaxis. In moderate and severe envenomation, species-specific antivenin has been shown to ameliorate symptoms and prevent death, but the use of antivenin carries significant risks. Appropriate assessment of the risk:benefit ratio in the use of antivenin is therefore the most important skill a physician can possess in treating envenomation.

ANTIVENINS

Animal venoms are species-specific mixtures of polypeptides, proteolytic enzymes, glycoproteins, and vasoactive substances. In theory, for every venom an antivenin can potentially be produced. In the United States, only four antivenins approved by the Food and Drug Administration (FDA) are commercially available. For pit viper bites, horse serum–derived antivenin (Crotalidae), polyvalent, is available as well as a newly licensed sheep serum product, Crotalidae Polyvalent Immune Fab (ovine). In addition, horse serum–produced antivenin is available for coral snake *(Micrurus fulvius)* bites and black widow spider *(Latrodectus mactans)* bites. Other antivenins to more unusual species of snakes or scorpions are often available through local zoologic societies or the nearest poison control center.

All antivenins are animal-derived immunoglobulins that work by direct binding and neutralization of the proteins in venom. The animal origin of these products exposes patients to large amounts of foreign proteins that may cause both immediate and delayed hypersensitivity reactions.

Immediate hypersensitivity reactions (see Chapter 137), may be life threatening, and the incidence after administration of equine antivenin may be as high as 5–10%.

Given the risk of anaphylaxis, antivenin should be given only in a setting in which full resuscitative measures including oxygen, endotracheal intubation, and epinephrine are available. Patients should be asked about medication allergies and previous exposure to antivenins. Skin testing using 0.02?mL of a 1:10 dilution of antivenin should be performed before intravenous infusion of antivenin. This testing should be performed only if antivenin is to be given, because fatal anaphylactic reactions have been reported with skin testing alone. A negative skin test response is reassuring, but the false-negative rate may be as high as 20%. Conversely, a positive skin test result does not preclude the use of antivenin, because the false-positive rate may be as high as 50%, but it does alert a clinician to the higher probability of a severe allergic reaction. In such instances, pretreatment with intravenous administration of diphenhydramine, 1?mg/kg,

---

and methylprednisolone, 1–2?mg/kg, is required. Some toxicologists recommend pretreatment for all patients receiving antivenin.

If signs of immediate hypersensitivity develop during administration of antivenin, the infusion should be stopped until the patient is stabilized. If the severity of envenomation warrants continued infusion of antivenin, it may be resumed at a slower rate or simultaneously with administration of epinephrine. In such instances, consultation with the nearest toxicologist at a poison control center is advisable.

Delayed hypersensitivity or *serum sickness* (see Chapter 138) develops in up to 65% of patients who receive equine-derived antivenin and in 15% of patients who receive ovine-derived products. Serum sickness results from deposition of antigen-antibody complexes on endothelial surfaces. It usually develops 5–21 days after exposure and may last for weeks. It is most commonly manifested as urticaria, pruritus, arthralgia, and malaise but rarely may present as immune complex glomerulonephritis, neuritis, or myocarditis. Intradermal skin tests have not been shown to predict the risk of serum sickness accurately. Prophylactic use of antihistamines and corticosteroids may reduce the risk of serum sickness and is definitely of benefit if symptoms develop.

SNAKEBITE

Of the more than 3,000 known species of snakes, only 200 are poisonous to humans. Of poisonous snakes, 90% are members of one of three families: the Hydrophidae, or poisonous sea snakes; the Elapidae, which includes the cobras, mambas, and coral snakes; and the Viperidae, or true vipers.

In the United States, 95% of poisonous snakebites are by the Crotalidae, or pit vipers, which are a subfamily of the true vipers. Pit vipers may be identified by their triangular heads, elliptical eyes, and the identifiable pit between the eyes and nose (Fig. 708–1). Members of the pit viper family in this country include the rattlesnakes, cottonmouths, and copperheads.

The other native poisonous snakes in the United States are the coral snakes, which are found in Texas and the Southeast and are members of the Elapidae family. Coral snakes are small and

Figure 708-1 Identification of venomous snakes. (Modified from Rosen P, et al [editors]: *Emergency Medicine*, 3rd ed. St. Louis, CV Mosby, 1992.)

have a small, rounded head and brightly colored bands of black and red separated by more narrow yellow bands. The rhyme “red on yellow, kill a fellow; red on black, venom lack” serves to differentiate the coral snake from the similar-appearing but nonpoisonous scarlet king snake.

Epidemiology.

Approximately 45,000 snakebites are reported in the United States each year; only 8,000 are inflicted by venomous snakes. Most snakebites are in young males and involve alcohol intoxication and a history of the victim's foolishly trying to capture or play with the snake. Despite these many bites, only 12–15 deaths are recorded each year. Unfortunately, children, because of their smaller body mass for venom distribution, are far more likely to have a serious systemic reaction to envenomation and account for more than half of the fatalities.

Pathogenesis.

Snake venom is a mixture of polypeptides, proteolytic enzymes, and toxins, which are species specific. Venom from the Elapidae and the Hydrophidae is primarily neurotoxic and has a curare-like effect by blocking neurotransmission at the neuromuscular junction. Death due to envenomation results from respiratory depression. Crotalidae venom is cytolytic, causing tissue necrosis, vascular leak, and coagulopathies. Death from pit viper bites results from hemorrhagic shock, adult respiratory distress syndrome, and renal failure.

Clinical Manifestations.

Pit viper bites usually occur on the extremities; pain and swelling occur at the site within minutes. As the venom moves proximally, edema and ecchymosis advance and, in severe cases, bulla formation and tissue necrosis ensue. Systemic symptoms include nausea, vomiting, diaphoresis, weakness, tingling around the face, and muscle fasciculations. Rarely, patients may present in shock with generalized edema or cardiac arrhythmias. Complex clotting abnormalities often occur.

Bites of most Elapidae, including the coral snakes, are minimally painful because the venom has no cytotoxin. However, lack of immediate symptoms should not be mistaken for the absence of serious envenomation. The venom of the coral snake is primarily neurotoxic, and symptoms can rapidly progress in a few hours from mild drowsiness to cranial nerve palsies, weakness, and death from respiratory failure.

Treatment.

The first task is to determine if the bite was by a poisonous snake and if envenomation occurred. If the snake has been killed, it should be brought to the

emergency department for identification. More than 80% of snakebites in the United States are by nonpoisonous snakes; these bites cause minimal pain and no swelling and require only local wound care.

If the bite is by a venomous snake, immediate care is directed toward decreasing lymphatic flow to limit the spread of venom into the circulation. Immobilization of the extremity, pressure at the site of envenomation, and a proximal tourniquet accomplish this goal. The tourniquet should be loose enough to insert a finger and allow arterial blood flow, because ischemia only exacerbates local tissue damage. Similarly, applying ice to the bite site or using excision and suction is believed to cause more tissue damage than benefit and should be avoided.

On arrival at the emergency department, the patient should have a large-bore intravenous line inserted and blood for baseline laboratory studies should be obtained. Initial blood tests should include type and crossmatch because a progressive coagulopathy may make later typing impossible. Other needed tests include complete blood cell and platelet counts; prothrombin and partial thromboplastin times; fibrinogen and fibrin degradation products; and blood urea nitrogen, creatinine, and creatine phosphokinase levels. These studies need to be repeated at

intervals, depending on the severity of envenomation. Baseline vital signs and measurement of the circumference of the bitten extremity should be obtained, and demarcation of ecchymosis and swelling should be marked on the limb so progression can be monitored. The wound should be cleansed and tetanus toxoid given if appropriate.

The decision to use antivenin depends on the severity and progression of symptoms. In general, rattlesnake envenomation requires antivenin and copperhead bites do not, with cottonmouth bites falling between these extremes. The severity of envenomation is commonly graded on a four-point scale (Table 708–1). Most pit viper envenomations cause symptoms within 2?hr and almost always within 6?hr; if symptoms are not present, the bite may be presumed to have been “dry” and a grade 0 envenomation. A grade 1 envenomation with only localized swelling requires nothing more than pain control and careful observation. Unfortunately, children, because of their smaller size, are far more likely to have severe envenomation, and more than 75% of children have a grade 2 or 3 envenomation, which requires antivenin.

Antivenin is most effective if delivered within 4?hr of the bite and is of little value if administration is delayed beyond 12?hr. As discussed earlier, antivenin poses a small but significant risk of an immediate hypersensitivity reaction with an apparent greater risk in equine-derived products compared with ovine-derived antivenin. Antivenin (Crotalidae) polyvalent is administered in increments of 5 vials and repeated as needed to neutralize circulating venom, as measured by normalization of clotting parameters and a halt in the progression of swelling of the affected limb. Children often require more antivenin than a similarly envenomated adult because of their small volume-to-venom ratio. The recently licensed Crotalidae Polyvalent Immune Fab (ovine) appears to have the advantage of rarely causing immediate hypersensitivity and far less risk of serum sickness but has a shorter half-life and may require re-dosing. The choice of antivenin product, the rapidity of administration, and the volume of antivenin administered are best decided in consultation with a toxicologist.

Any person who has been bitten by a coral snake should be administered 3 to 5 vials of antivenin (*M. fulvius*) prophylactically. After being bitten by a coral snake, victims may be asymptomatic for hours before suffering paralysis and respiratory failure. Antivenin is effective only if given before symptoms develop and is ineffective in reversing them once they have occurred.

Prognosis.

Despite the potential for mortality and severe morbidity with poisonous snakebites, both can be minimized by early and judicious use of appropriate antivenin. Even extremities with marked tissue necrosis will return to full function with the resolution of swelling, and only rarely is delayed skin grafting required.

ARACHNID ENVENOMATION

The arachnids contain the largest number of known venomous species. More than 20,000 venomous spiders have been identified, but most are of no danger to humans because they lack either potent venom or fangs capable of penetrating the human skin. In the United States, the only significant morbidity is caused by spiders in two genera, *L. mactans* (the black widow spider) and *Loxosceles* (the fiddleback or brown recluse spider).

TABLE 708-1 -- **Classification of Envenomation Severity**

Grade	Description
Grade 0	No envenomation
Grade 1	Minimal envenomation (local swelling and pain without progression)
Grade 2	Moderate envenomation (swelling, pain, or ecchymosis progressing beyond the site of injury; mild systemic or laboratory manifestations)
Grade 3	Severe envenomation (marked local response, severe systemic findings, and significant alteration in laboratory findings)

Latrodectism.

The black widow is found throughout the United States, though more commonly in

the South. The black widow is glossy black and has bright red or orange markings on the ventral surface of the abdomen, although only the species *L. mactans* has the classic hourglass markings. Females have a body length of 1.5?cm and a leg span of 4–5?cm. Males of the species are approximately half the size of females and pose no threat to humans because their fangs are too short to penetrate the skin. The black widow is commonly found in protected places such as under rocks or in woodpiles, outhouses, and stables.

PATHOGENESIS.

The venom of the black widow contains a potent neurotoxin, a-latrotoxin, which binds to presynaptic neuronal membranes, causing dramatic release of acetylcholine and norepinephrine at the neuromuscular junction. The outpouring of these neurotransmitters results in excessive muscle depolarization and autonomic hyperactivity.

CLINICAL MANIFESTATIONS.

The bite causes both local and systemic effects. A pinprick sensation is usually felt at the bite, which develops into a pale area of 2–3?mm with a red border. Within an hour, dull, crampy pain is felt around the site and gradually extends throughout the body. In the past, it was claimed that upper extremity bites present with chest tightness and grunting respirations whereas lower extremity bites present with abdominal pain and boardlike rigidity; however, either may occur regardless of bite location. In addition to the severe muscle cramping, most children have nausea, vomiting, and diaphoresis, along with agitation and hypertension. In extremely rare instances, symptoms may progress to respiratory arrest and death.

Because of presentation with a painful, boardlike abdomen, a bite from the black widow spider can mimic acute appendicitis or peritonitis. A key point in the differential diagnosis is that most patients with black widow bites are hypertensive and agitated and tend to move about, seeking a comfortable position, whereas patients with a surgical abdomen are often hypotensive and try to lie still and avoid movement. Many past reports of deaths from black widow bites were related to patients' mistakenly taken to surgery for a presumed acute abdomen. Therefore, obtaining an accurate history and making the correct diagnosis are the most important steps in managing black widow spider bites.

TREATMENT.

Muscle cramping and agitation are the main causes of discomfort and can usually be well controlled with intravenous opiates for pain and benzodiazepines for muscle relaxation. Calcium infusions and dantrolene were previously used for muscle cramping; however, neither is efficacious and they are no longer recommended.

Use of antivenin versus symptomatic treatment in black widow bites is determined by the knowledge that without treatment all symptoms will resolve in 24–48?hr but that symptoms can be excruciating. Conservative measures should be tried first before using antivenin if satisfactory pain control is not achieved. A decision tree for treatment is shown in Figure 708–2 .

If antivenin is used, an intradermal test dose should be given and all precautions as listed in the earlier antivenin section should be followed. The risk of anaphylaxis is less than that associated with snake antivenin and is less than 1%. One vial of antivenin is usually sufficient, and symptoms of envenomation subside rapidly within 1–3?hr. As with other antivenin products, serum sickness may develop in 5–21 days.

Figure 708-2 Decision process for treating pediatric black widow spider envenomation. (Courtesy of Robin Woestman, Loma Linda Children's Hospital, Loma Linda, CA.)

Loxoscelism.

Although the bite of a number of spiders can result in mild tissue reactions, only species of the genus *Loxosceles* can cause significant skin necrosis. Members of this genus are commonly known as the “fiddleback spider” because of the brown violin-shaped marking on the thorax or as the “brown recluse spider” because of their predilection for living in dark, undisturbed places such as woodpiles, closets, and basements.

EPIDEMIOLOGY.

All species are dull colored and have a small body measuring 1?cm and legs extending up to 5?cm. The species with the most potent bite, *Loxosceles reclusa*, is found most commonly in the river country of mid America but is also found in the South. Other less potent *Loxosceles* species are found throughout the United States, although their numbers decrease with more northern latitudes.

CLINICAL MANIFESTATIONS.

The venom of the brown recluse contains hyaluronidase, or spreading factor, and sphingomyelinase D, a protein that lyses cell walls. The bite is often unnoticed or felt only as a pinprick. It typically occurs when a spider is unknowingly trapped against the skin while the victim is putting on clothes; thus, the bite is often on the upper arm, lateral thorax, inner thigh, or rarely on the hands or face. Within 2?hr, a painful, sinking blue macule with a halo of inflammation occurs at the bite site, followed by systemic symptoms that include fever, chills, nausea, and vomiting. In a minority of cases, but more commonly in small children, hemolysis can occur. The hemolysis is presumed secondary to toxin action because Coombs test results are negative and the coagulation system is not activated as measured by platelet counts, fibrin split products, and prothrombin time. In extremely rare instances, massive hemolysis can occur and may lead to disseminated intravascular coagulopathy or renal failure.

In addition to systemic symptoms of the bite, a hemorrhagic blister forms within 1–2 days. As the blister sloughs, it leaves the characteristic necrotic ulcer of brown recluse spider bites. Most ulcers remain at 1–2?cm but can enlarge up to 15?cm in

diameter and involve the full thickness of the skin and some underlying tissue.

TREATMENT AND PROGNOSIS.

The outcome in brown recluse spider bites is excellent, and most bites resolve with supportive care alone. Patients with systemic symptoms or significant hemolysis should be admitted to the hospital for pain control and monitoring. Hydration and maintenance of urine output are essential if there is significant hemoglobinuria. Treatment of the ulcerative skin lesions is also supportive, with local wound care. Pain usually subsides in a few days, although complete skin healing requires weeks. Hyperbaric oxygen to promote wound healing, dapsone for leukocyte inhibition, and cyproheptadine, a platelet aggregation inhibitor, all have been recommended to prevent enlargement of skin ulcers; however, none has proven beneficial. In rare instances, large necrotic ulcers require delayed skin grafting.

SCORPION BITES

More than 1,000 species of scorpions are found worldwide; all of them are capable of delivering venom through a stinger located at the end of a six-segment tail. Of medical importance are the small number of species that belong to the family Butidae, which produce venom that is neurotoxic to humans. Among the most toxic species are those of the *Buthus (Leiurus)* in India and the Middle East, *Tityus* in Brazil and Trinidad, and *Centruroides* in Mexico and the desert Southwest of the United States. The majority of stings, even by toxic species, cause only a painful local reaction. However, given their small size, infants and young children who are stung are at risk for severe autonomic dysfunction, multisystem organ failure, and even death.

Pathogenesis.

Scorpion venoms vary by species, but all have hyaluronidase, serotonin, histamine releasers, and neurotoxins, of which the latter are the most important component. These neurotoxins can bind to the presynaptic membranes, causing release of acetylcholine and stimulation of both the sympathetic and parasympathetic nervous systems.

Clinical Manifestations.

The only medically significant scorpion species in the United States is *Centruroides elixicada*, which is found in the Southwest. Most stings cause an immediate local reaction that can vary from mild burning to severe pain. Severe envenomation causes autonomic dysfunction within a few hours of the sting. Symptoms include agitation, irritability, salivation, blurred vision, and tremulousness with signs of hypertension, tachycardia, tachypnea, and nystagmus. Rarely, in small children or infants, respiratory failure, convulsions, or coma may occur. In these cases, if a history of a sting is not elicited, a diagnosis of encephalitis may be entertained and the correct diagnosis of scorpion envenomation obscured by the fact that children with severe *Centruroides* envenomation may have mild cerebrospinal fluid pleocytosis.

Envenomation by other scorpion species may have specific features. Stings by *Tityus* species in South America are a major cause of pancreatitis, and envenomation by *Buthus* can cause severe hypertension, direct toxic myocarditis, and life-threatening myocardial ischemia.

Treatment.

Localized pain can be treated with application of ice and analgesics; pain usually markedly diminishes within 24?hr. For *C. elixicada*, severe envenomation with autonomic instability requires hospital admission for sedation and observation. Symptoms usually resolve within 24–48?hr. If cardiopulmonary compromise occurs, consideration should be given to administering

---

antivenin. *Centruroides*-specific antivenin is not FDA approved but is available by contacting the Arizona Poison Control Center at (520) 626-6016. It is prepared from goat serum and poses the same small risk of immediate anaphylaxis and later serum sickness as other antivenins produced from horse serum. The use of antivenin, if warranted, leads to complete resolution of symptoms within 1–2?hr. Antivenin for other scorpion species is available in countries where those species are found or through zoologic societies.

HYMENOPTERA STINGS

The insect order of Hymenoptera includes the ants, bees, and wasps, which are characterized by the presence of a stinger at the end of the abdomen through which venom is injected. They are found throughout the United States and worldwide.

Hymenoptera venom, a mixture of proteins and vasoactive substances, is not very potent; most stings cause only local reactions that can be treated with application of cold compresses and analgesics. However, 1–4% of the population is sensitized to Hymenoptera venom and is at risk for immediate hypersensitivity reactions. Each year, 50–150 people in the United States die of anaphylaxis caused by Hymenoptera stings.

Any Hymenoptera envenomation that presents as urticaria, angioedema, wheezing, or hypotension should be treated aggressively for an immediate hypersensitivity reaction with intravenous fluids, oxygen, and epinephrine (see Chapter 137). In the past, any child who sustained a Hymenoptera sting and who had a systemic reaction and a positive result of a skin prick test with Hymenoptera venom was advised to have desensitization with venom-specific immunotherapy. Reports suggest that the clinical course of most children with venom sensitivity is much less severe than previously thought. Fewer than 20% of children with systemic reactions from an initial sting will have systemic reactions with subsequent stings. Evaluating IgE levels, radioallergosorbent testing (RAST), or results of skin prick tests with Hymenoptera venom are not predictive of future systemic reactions.

Children with large local reactions should receive corticosteroids and antihistamines. Children who have systemic reactions including wheezing do not require venom

immunotherapy but should carry an emergency kit with epinephrine. Children who have had a life-threatening immediate hypersensitivity reaction should carry an epinephrine kit with them at all times and should undergo venom immunotherapy. More than 95% of these patients have lifelong protection after 3–5 years of immunotherapy.

MARINE ENVENOMATION

Stingrays.

Although found only in tropical and subtropical waters, stingrays cause more human envenomations than any other marine vertebrate. The stinging spines on their whiplike tails are retroserrated, and therefore they commonly cause a jagged laceration along with envenomation.

Minor punctures may resemble cellulitis, whereas more severe envenomations may cause marked tissue destruction and necrosis. Regardless of the appearance of the lesion, stingray envenomation is intensely painful for 24–28?hr. Systemic manifestations include nausea and vomiting and, more rarely, paralysis, hypotension, bradycardia, and seizures.

Treatment begins with thorough cleaning of the wound and tetanus prophylaxis. Because stingray toxins are heat labile, immersion in hot water denatures the protein elements of the venom and decreases pain. Additional analgesia should be provided as needed. Superinfection with aerobic and anaerobic organisms, including *Vibrio* species, is common, and antibiotic prophylaxis should be considered.

Scorpionfish.

Members of the family Scorpaenidae include the zebrafish, scorpionfish, and stonefish; all have venomous spines that become erect on stimulation. Envenomation by the Scorpaenidae causes immediate pain that may last for hours or days. Victims may suffer intense local tissue destruction in which superinfections are common. Systemic manifestations include vomiting, abdominal pain, headache, delirium, seizures, and cardiorespiratory failure. Therapy is similar to that for stingray envenomations. Envenomations with severe systemic symptoms benefit from antivenin administration.

Coelenterate Envenomations.

Members of the phylum Cnidaria are common to the oceans of the world. Cnidarian species all share a common anatomic feature: minuscule capsules (cnidae) that contain a highly folded tubule that everts on contact, thereby injecting the venom.

Envenomation causes an immediate stinging sensation that may be associated with paresthesias, pruritus, and local edema. In more severe envenomations, systemic signs may include nausea and vomiting, myalgias, headache, and, more rarely, seizures, coma, and cardiorespiratory collapse. Most lethal envenomations have been attributed to the Pacific box jellyfish, *Chironex fleckeri*, which is indigenous to the waters off Australia, and the Atlantic Portuguese man-of-war, *Physalia physalis*.

Treatment of these envenomations begins in the ocean; the wounds should be rinsed in seawater because fresh water may lyse venom-producing cells (nematocysts), leading to further envenomation. Irrigation of the sting site with vinegar, rubbing alcohol, or baking soda is beneficial because it inhibits nematocyst discharge. Visible tentacle fragments should be removed with forceps, and microscopic fragments may be removed by gently shaving the affected area. Antihistamines and corticosteroids are indicated for swelling and urticaria.

Seabather's Eruption.

Seabather's eruption is an intensely pruritic vesicular or maculopapular eruption that primarily affects the skin surfaces covered by swimwear. It is caused by exposure to the larvae of two species of the phylum Cnidaria: the sea anemone, *Edwardsiella lineata*, which is found off the coast of the northeastern United States; and the thimble jellyfish, *Linuche unguiculata*, which is the principal cause of seabather's eruption in Florida and the Caribbean.

Epidemics of seabather's eruption occur during summer months in which there are large quantities of larvae in the water. An intensely pruritic rash begins within 4–24?hr of exposure and may persist for days or weeks. Associated symptoms may include fever, chills, headache, malaise, conjunctivitis, and urethritis. Antihistamines are the mainstay of treatment, although corticosteroids, either applied topically or given systemically, may be beneficial in severe cases.

Part 33 - Laboratory Medicine, Drug Therapy, and Reference Tables

Chapter 709 - Laboratory Testing in Infants and Children

John F. Nicholson
Michael A. Pesce

Because of genetic heterogeneity, biologic and environmental variability, and inhomogeneity of subclinical health status, normal values for many laboratory tests do not show a gaussian bell-shaped distribution curve. As a result, the population mean and the standard deviation (SD) are frequently less useful than the range of normal values, generally given as the 95% normal range, that is, the range of values obtained in testing a normal population minus the lowest 2.5% and the highest 2.5%. The serum sodium concentration in children, which is tightly controlled physiologically, has a distribution that is essentially gaussian; the mean value ±2 SD gives a range very close to that actually observed in 95% of children (Table 709–1). Alternatively, the serum creatine kinase level, which is subject to diverse influences and is not actively controlled, does not show a gaussian distribution, as evidenced by the lack of agreement between the range actually observed and that predicted by the mean value ±2 SD.

A refinement of referencing that is used with increasing frequency is reporting the value obtained together with the percentile of normal values into which the value obtained falls. This method is useful when one is testing for risk factors such as in determination of serum cholesterol. A further modification that is necessary for many tests performed in infants and children is calculating the age-related adjustment of the normal range. Both age adjustment and the use of percentiles are illustrated in the normal values for serum cholesterol in Table 726–6. A final modification needed

for reporting normal ranges is referencing to the Tanner stage of sexual maturation, which is most useful in assessing pituitary and gonadal function.

Accuracy and Precision of Laboratory Tests.

Technical accuracy is an important consideration in interpreting the results of a laboratory test. Because of improvements in methods of analysis and elimination of analytic interferences, the accuracy of most tests is limited primarily by their precision. **Accuracy** is a measure of the nearness of the test result to the actual value, whereas **precision** is a measure of the reproducibility of a result. No test can

TABLE 709-1 -- **Gaussian and Nongaussian Laboratory Values in 458 Normal Schoolchildren Aged 7–14 Yr**

	Serum Sodium (mM/L)	Serum Creatine Kinase (U/L)
Mean	141	68
SD	1.7	34
Mean ± 2?SD	138–144	0–136
Actual 95% range	137–144	24–162

SD = standard deviation.

be more accurate than it is precise. Analysis of precision by repetitive measurements of a single sample gives rise to a gaussian distribution with a mean and SD. The estimate of precision is the coefficient of variation (CV):

The CV is not likely to be constant over the full range of values obtained in clinical testing, but it is about 5% in the normal range. The CV is generally not reported but is always known by the laboratory. It is particularly important in assessing the significance of changes in laboratory results. For example, a common situation is the need to assess hepatotoxicity incurred as a result of administration of a therapeutic drug and reflected in the serum alanine aminotransferase (ALT) value. If serum ALT increases from 25?U/L to 40?U/L, is the change significant? The CV for ALT is 7%. Using the value obtained plus or minus 2 × CV to express the extremes of imprecision, it can be seen that a value of 25?U/L is unlikely to reflect an actual concentration greater than 29?U/L, and a value of 40?U/L is unlikely to reflect an actual concentration of less than 34?U/L. Therefore, the change in the value as obtained by testing is likely to reflect a real change in circulating ALT levels. Continued monitoring of ALT is indicated even though both values for ALT are within normal limits. “Likely” in this case is only a probability. Inherent biologic variability is such that the results of two successive tests may suggest a trend that will disappear on further testing.

The precision of a test may also be indicated by providing confidence limits for a given result. Ordinarily, 95% confidence limits are used, indicating that it is 95% certain that the value obtained lies between the two limits reported. Confidence limits are calculated using the mean and SD of replicate determinations:

where t is a constant derived from the number of replications. In most cases t = 2.

Sensitivity, Accuracy, and Testing Purpose.

There are some circumstances in which sensitivity and accuracy of an analysis are reduced or increased as functions of clinical purpose. For example, ion exchange chromatography of plasma amino acids for the diagnosis of inborn errors of metabolism is usually performed at a sensitivity that allows measurement of all the amino acids with a single set of standards. The range of values is roughly 20–800?µmol/L, and accuracy is poor at values of 20?µmol/L or less. The detection of homocysteine in this type of analysis suggests an inborn error of methionine metabolism. Adjusting the analysis to achieve greater sensitivity, one can accurately measure homocysteine in normal plasma (3–12?µmol/L). This more sensitive test is used in the assessment of cobalamin status and in the analysis of risk factors for atherosclerotic cardiovascular disease.

Predictive Value of Laboratory Tests.

Predictive value (PV) theory deals with the usefulness of tests as defined by their sensitivity

(ability to detect a disease) and specificity (ability to define absence of a disease).

The problems addressed by PV theory are false-negative and false-positive test results. Both are major considerations in interpreting screening tests in general and neonatal screening tests specifically.

Testing for human immunodeficiency virus (HIV) seroreactivity serves to illustrate some of these considerations. If it is assumed that approximately 1,100,000 of 284,000,000 residents of the United States are infected with HIV (prevalence = 0.39%) and that 90% of those infected demonstrate antibodies to HIV, we can consider the usefulness of a simple test with 99% sensitivity and 99.5% specificity. If the entire population of the United States were screened, it would be possible to identify most of those infected with HIV.

There will be 119,900 false-negative test results. Even with a 99.5% specificity, the number of false-positive test results would be larger than the number of true-positive results:

There will be 281,480,000 true-negative results.

Given the high cost associated with follow-up of false-positive test results, the anguish produced by a false-positive result, and the lack of effective therapy, it is easy to see why universal screening for HIV seropositivity received a low priority immediately after the introduction of testing for HIV infection.

By contrast, we can consider the screening of 100,000 individuals from groups at increased risk for HIV in whom the overall prevalence of disease is 10%, all other considerations being unchanged.

These two hypothetical testing strategies illustrate that the diagnostic efficiency of testing heavily depends on the prevalence of the disease being tested for, even if the test is a superior one such as the test for HIV antibodies. Because the treatment of pregnant women infected with HIV is effective in preventing vertical transmission of the infection, screening has now been expanded to all pregnant women. The proven effectiveness of current therapy to prevent neonatal infection has intensified screening for HIV early in pregnancy even though the risk of maternal infection is relatively low.

Neonatal Screening Tests.

Almost all the diseases detected in neonatal screening programs have a very low prevalence, and the tests are, for the most part, quantitative rather than qualitative. In general, the strategy is to use the initial screening test to separate a highly suspect group of patients from normal infants (i.e., to increase the prevalence) and then to follow this suspect group aggressively. This strategy is illustrated by a scheme used in screening newborns for congenital hypothyroidism, the prevalence of which is 25/100,000 liveborn infants. The initial test performed is for thyroxine in whole blood, and infants with the lowest 10% of test results are considered suspect. If all infants with hypothyroidism were in the suspect group, the prevalence of disease in this group would be 250/100,000 infants. The original samples obtained from the suspect group are retested for thyroxine and are tested for thyroid-stimulating hormone. This second round of testing results in an even more highly suspect group composed of 0.1% of the infants screened and having a prevalence of hypothyroidism of 25,000/100,000 subjects. This final group is aggressively pursued for further testing and treatment. Even with a 1,000-fold increase in prevalence, 75% of the population aggressively tested is euthyroid. The justifications advanced for the program are that treatment is easy and effective and that the alternative if undetected and untreated—long-term custodial care—is both unsatisfactory and expensive.

At its inception neonatal screening was driven by the selection of genetic diseases whose clinical manifestations developed postnatally such as phenylketonuria, galactosemia, and homocystinuria. The diseases could be treated effectively by simple means instituted shortly after birth. The screening tests are microbiologic assays that are disease specific.

Tandem mass spectrometry (MSMS) is a technically advanced method in which many compounds are initially separated by molecular weight. Each compound is then fragmented to allow identification. The process requires roughly 2?min per sample and can detect 20 or more inborn errors of metabolism. The effects of prematurity, neonatal illness, and of intensive neonatal management on metabolites in blood complicate interpretation of results. The predictive value of a positive screening result is likely to be less than 10%; that is, 90% of positive results are not indicative of a genetic disorder of metabolism. Nonetheless, MSMS permits diagnoses to be made before clinical illness develops. MSMS is not directed toward diseases defined as treatable but toward all the diseases, each of which is rare, that the technique can identify (Box 709–1). As of this writing at least 19 states use MSMS for neonatal screening, 4 more are in the process of implementing MSMS, and at least 10 more states are considering its use.

More common diseases have also become targets for neonatal screening programs. Congenital hypothyroidism was selected for screening because of its frequency and its ease of treatment. Sickle cell disease, easily detected, can be treated more effectively if diagnosed before clinical signs appear. Results of neonatal screening for cystic fibrosis (CF) show that there are clear benefits from preclinical diagnosis but also that there are some inherent difficulties of genetic screening for complex autosomal recessive diseases that

Phenylketonuria

Hyperphenylalaninemia

Tyrosinemia

are common and caused by a rather large number of mutations of a single gene. The definitive diagnostic test for CF is the measurement of concentrations of sodium and chloride in sweat, a test that is not practical during the first weeks of life. Neonates with CF generally have elevations in whole blood trypsinogen. This allows the definition of a group of neonates with high risk for CF. Performance of DNA analysis for common mutations that cause CF can reduce the suspect group to achieve a higher likelihood of disease among them and a manageable number of infants on whom to perform sweat tests. The problems include (1) uncommon mutations are not included in the screening panel (thus cases of CF caused by them can be missed); (2) common mutations that cause clinically innocent elevations of whole blood trypsinogen in heterozygous neonates will be false positives that will alarm parents; and (3) CF with normal sweat test results is rare but is likely to be missed. Congenital adrenal hyperplasia, another common disorder, is now included in neonatal screening programs. In this instance, the most common disorders are not life threatening but the life-threatening disorders commonly threaten life in the neonatal period.

The expansion of the menu of screening tests presents a significant additional cost to society in that screening programs generally attempt to identify all affected neonates and, in so doing, follow-up a significant percentage of false-positive screening results. The fact that an infant is called back suggests that the infant is “not right” to the parents. This suggestion is not automatically dismissed when the initial screening result is determined to be a false positive. For this reason, screening programs engender substantial need for effective counseling for parents whose infants are called back for follow-up testing.

Testing in Differential Diagnosis.

The use of laboratory tests in differential diagnosis satisfy PV theory because a correct differential diagnosis should result in a relatively high prevalence of the disease under consideration. An example of testing in differential diagnosis is the measurement of urinary vanillylmandelic acid (VMA) for diagnosis of neuroblastoma.

A simple spot test for VMA is not useful in general screening programs because of the low prevalence of neuroblastoma (3 cases/100,000) and the low sensitivity of the test (69%). Even though the specificity of urinary VMA is 99.6%, testing of 100,000 children would produce 2 true-positive test results, 400 false-positive results, and 1 false-negative result. The PV of a positive result in this setting is 0.5%, and the PV of a negative result is 99.99%, not much different from the assumption that neuroblastoma is not present at all. Testing for urinary VMA in a 3-yr-old child with an abdominal mass, however, gives a useful result because the prevalence of neuroblastoma is at least 50% in 3-yr-old children with abdominal masses. If 100 such children are tested and the prevalence of neuroblastoma in the group is assumed to be 50%, a satisfactory PV is obtained.

Here a test with a low sensitivity is powerful in differential diagnosis because the PV of a positive result is almost 100% in the setting of high prevalence.

SEROLOGIC TESTS FOR LYME DISEASE.

Using laboratory testing as a means to refine a differential diagnosis poses problems, as exemplified by serologic testing for Lyme disease, which is a tick-borne infection by *Borrelia burgdorferi* that has various manifestations in both early and late stages of infection (see Chapter 204). Direct demonstration of the organism is difficult, and serologic test results for Lyme disease are not reliably positive in young patients presenting early with erythema chronicum migrans. These results become positive after a few weeks of infection and remain positive for years. In an older population being evaluated for late-stage Lyme disease, some individuals will have recovered from either clinical or subclinical Lyme disease and some will have active Lyme disease, with both groups having true-positive serologic test results. Of those individuals without Lyme disease, some will have true-negative serologic test results but a significant percentage will have antibodies to other organisms that cross-react with *B. burgdorferi* antigens.

This set of circumstances gives rise to a number of problems. First, the protean nature of Lyme disease makes it difficult to ensure a high prevalence of disease in subjects to be tested. Second, the most appropriate antibodies to be detected are imperfectly defined, leading to a wide variety of entry tests with varying rates of false positivity and false negativity. Third, the natural history of the antibody response to infection and the difficulty of demonstrating the causative organism directly combine to make the laboratory diagnosis of early Lyme disease difficult. Fourth, in the diagnosis of late-stage Lyme disease in older subjects, the laboratory diagnosis is plagued by misleading positive (either false-positive or true-positive but not clinically relevant) results of the entry test, typically an enzyme-linked immunosorbent assay, that uses whole *B. burgdorferi* organisms. A review of 788 patients referred to a specialty clinic with the diagnosis of Lyme disease revealed that the diagnosis was correct in 180 patients, that 156 patients had true seropositivity without active Lyme disease, and that 452 had never had Lyme disease, even though 45% of them were seropositive by at least one test before referral.

The two-step approach, similar to that used in HIV testing, is commonly used: (1) a screening test that has high sensitivity (e.g., ELISA) and excellent negative predictive value; followed by (2) a confirmatory test for verification of positive screening tests that is very specific (e.g., Western blot to detect antibodies to selected bacterial antigens). Negative screening tests and negative verification tests are reported as negative. Positive verification tests are reported as positive. However, standardization of the testing

TABLE 709-2 -- Laboratory Profile as a Review of Systems

Laboratory Test	Assessment Facilitated by Tests
Complete blood cell count and platelets	Nutrition, status of formed elements
Complete urinalysis	Renal function/genitourinary tract inflammation
Albumin and cholesterol	Nutrition
ALT, bilirubin, GGT	Liver function
BUN, creatinine	Renal function, nutrition
Sodium, potassium, chloride, bicarbonate	Electrolyte homeostasis
Calcium and phosphorus	Calcium homeostasis

ALT = alanine aminotransferase; GGT = ?-glutamyltransferase; BUN = blood urea nitrogen.

procedures is difficult in North America where only one pathogenic strain of *B. burgdorferi* is found and is more difficult elsewhere in the Northern Hemisphere where as many as three pathogenic strains are present. Identification of microbial DNA in body fluids by polymerase chain reaction is definitive but invasive.

LABORATORY SCREENING AS A REVIEW OF SYSTEMS.

Screening profiles (Table 709–2), used as a technical review of systems or to establish a baseline, facilitate patient care in specific circumstances, including the following: (1) an illness is clearly present, but a specific diagnosis is elusive; (2) a patient requires intensive care for any clinical problem; and (3) treatment is indicated

that employs a new drug in postmarketing evaluation or a drug known to have systemic adverse effects.

RISK FACTORS AND PREDICTIVE VALUE.

When a given laboratory value within the spectrum of the reference range is considered a risk factor, it is generally true that, in the absence of clinical manifestations, the value has no predictive worth as an indicator of disease and has little worth in predicting the likelihood of future disease in any individual case.

Chapter 710 - Reference Ranges for Laboratory Tests and Procedures

John F. Nicholson
Michael A. Pesce

Introduction

In the following tables, the reference ranges apply to infants, children, and adolescents when possible. For many analyses, however, separate reference ranges for children and adolescents are not well delineated. When interpreting a test result, the reference range supplied by the laboratory performing the test should always be used. Refer to Figures 710–1 and 710–2 for estimations related to dosages.

In preparing the reference range listings, a number of abbreviations, symbols, and codes were used (Table 710–1).

Figure 710-1 Nomogram for estimation of surface area. The surface area is indicated where a straight line that connects the height and weight levels intersects the surface area column; or, if the patient is roughly of average size, from the weight alone (*enclosed area*). (Nomogram modified from data of E. Boyd by CD West.) (See also Briars G, Bailey B: Surface area estimation: Pocket calculator v nomogram. *Arch Dis Child* 1994;70:246.)

		Therapeutic	2–12?µg/mL	
		Toxic	>20	
Diazepam	S,P(H,E) at trough	Therapeutic	100–1,000?ng/mL	×3.512
		Toxic	>5,000	
Digitoxin	S,P(H,E)	Therapeutic	20–35?ng/mL	×1.307
	6?hr post dose	Toxic	>45	
Digoxin	S,P(H,E) 12?hr post dose		ng/mL	
		Therapeutic		
		CHF	0.8–1.5	×1.281
		Arrhythmias	1.5–2.0	
		Toxic		
		Child	>2.5	
		Adult	>3.0	
Diphenylhydantoin, see *Phenytoin*				
Doxepin (includes desmethyldoxepine)	S,P	Therapeutic	110–250?ng/mL	×1
Ethanol	W(O),S	Toxic	50–100?mg/dL	×0.2171
		Depression of CNS >100		

Ethosuximide	S,P(H,E) at trough	Therapeutic	40–100?µg/mL		×7.084
		Toxic	>150		
Imipramine (includes desipramine)	S	Therapeutic	150–250?ng/mL		×1
Lithium	S,P (not LiH)	12?hr after dose			
		Therapeutic	0.6–1.2?mmol/L		×1
		Toxic	>2?mmol/L		
Lysergic acid diethylamide	P(E)	After hallucinogenic dose			
	U	0.005–0.009?µg/mL			×3089
		0.001–0.050?µg/mL			
Methotrexate	S,P	After high-dose therapy			
		Toxic >5?µmol/L at 24?hr			×1
		Toxic >1?µmol/L at 48?hr			
Paraldehyde	S,P(H,E)	Sedative	10–100?µg/mL		×7.567
		Anticonvulsant	100–200		
		Toxic	>200		
		Lethal	>500		
Phenacetin	P(E)	Therapeutic 1–20?µg/mL			×5.580
		Toxic	50–250		
Phenobarbital	S,P(H,E) at trough		µg/mL		
		Therapeutic	15–40		×4.306
		Toxic			
		Slowness, ataxia, nystagmus		35–80	
		Coma with reflexes		65–117	
		Coma without reflexes		>100	

Phensuximide (both parent and *N*-desmethyl metabolite)	S,P(H,E)	Therapeutic	40–60?µg/mL	×5.71
Phenytoin	S,P(H,E)	Therapeutic	10–20?µg/mL	×3.964
Primidone	S,P(H,E) at trough	Therapeutic	5–12?µg/mL	×4.582
		Toxic	>15	
		Toxic (neonatal)	>20	
Procainamide	S,P(H,E)	Therapeutic	4–10?µg/mL	×4.25
		Toxic	>10–12?µg/mL	

Analyte or Procedure	**Specimen**	**Reference Values (USA)**	
		(Also consider concentration of metabolite *N*-acetylprocainamide [NAPA].)	
Propranolol	S,P(H,E) at trough	Therapeutic 50–100?ng/mL	
Quinidine	S,P(H,E)	Therapeutic	2–5?µg/mL
		Toxic	>6
Salicylate	S,P(H,E) at trough	Therapeutic	15–30?mg/dL
		Toxic	>30
Theophylline	S,P(H,E)		µg/mL
		Therapeutic	
		Bronchodilator	10–20
		Neonatal apnea	5–10
		Toxic	>20
Valproic acid	S,P(H,E) at trough	Therapeutic	50–100?µg/mL
		Toxic	>100
II. Analyses of Urine			
A. Formed Elements			
Sediment casts	U	Hyaline occasional (0–1) casts/hpf	
		RBC not seen	
		WBC not seen	
		Tubular epithelial not seen	

		Transitional and squamous epithelial not seen	
Cells		RBC 0–2/hpf	
		WBC	
		Males 0–3/hpf	
		Females and children 0–5/hpf	
		Epithelial few; more frequent in newborn	
		Bacterial: unspun: no organism per oil immersion field	
		Spun: <20 organisms/hpf	
Specific gravity	U	Adult 1.002–1.030	
		After 12?hr fluid restriction >1.025	
	U, 24?hr	1.015–1.025	
Urine volume	U, 24?hr		mL/24?hr
		Newborn	50–300
		Infant	350–550
		Child	500–1000
		Adolescent	700–1400
		Thereafter, M	800–1800
		F	600–1600
		(varies with intake and other factors)

			0–10 polymorphonuclear		0–10
			0–1000 RBC		0–1000
		Newborn	0–20 mononuclear		0–20
			0–10 polymorphonuclear		0–10
			0–800 RBC		0–800
		Neonate	0–5 mononuclear		0–5
			0–10 polymorphonuclear		0–10
			0–50 RBC		0–50
		Thereafter	0–5 mononuclear		0–5

		(Numbers of cells in very young infants are greater than those in olde CSF, without substantial implication for growth and development in m			
Leukocyte differential count	CSF		%		Fraction
		Lymphocytes	62 ± 34	× 0.01	0.62 ± 0.34
		Monocytes	36 ± 20		0.36 ± 0.20
		Neutrophils	2 ± – 5		0.02 ± 0.05
		Histiocytes	0-rare		0-rare
		Ependymal cells*	0-rare		0-rare
		Eosinophils	0-rare		0-rare
		*Includes pia-arachnoid mesothelial cells.			
Cerebrospinal fluid pressure	CSF		70–180?mm water		70–180?mm wa
Cerebrospinal fluid volume	CSF	Child	60–100?mL	× 0.001	0.06–0.10?L
		Adult	100–160		0.1–0.16
B. Chemical Elements					
Amino acids in CSF	CSF				
Taurine		6.3 ± 1.8?µmol/L		× 1	6.3 ± 1.8?µmol/l
Aspartic acid		0.9 ± 0.5			0.9 ± 0.5
Threonine		25 ± 10			25 ± 10
Serine + asparagine		38 ± 23			38 ± 23
Glutamine		509 ± 144			509 ± 144
Proline		0.6			0.6
Glutamic acid		7.0 ± 4.9			7.0 ± 4.9
Glycine		6.6 ± 1.8			6.6 ± 1.8
Alanine		23 ± 9.4			23 ± 9.4
Valine		14 ± 5.5			14 ± 5.5
Half cystine		0.2			0.2
Methionine		2.6 ± 1.6			2.6 ± 1.6
Isoleucine		4.4 ± 1.3			4.4 ± 1.3

Leucine		11 ± 3.6			11 ± 3.6
Tyrosine		9.1 ± 5.0			9.1 ± 5.0
Phenylalanine		9.2 ± 5.8			9.2 ± 5.8
Ornithine		5.7 ± 1.8			5.7 ± 1.8
Lysine		19 ± 6.6			19 ± 6.6
Histidine		13 ± 4.4			13 ± 4.4
Arginine		20 ± 5.8			20 ± 5.8
Calcium, total	CSF	2.1–2.7?mEq/L or		× 0.50	1.05–1.35?mmc
		4.2–5.4?mg/dL		× 0.25	1.05–1.35
Chloride	CSF	118–132?mmol/L		× 1	118–132?mmol/
Glucose	CSF	Adult	40–70?mg/dL	× 0.0555	2.2–3.9?mmol/L
Hypoxanthine	CSF	0–1 mo	1.8–5.5?µmol/L	× 1	1.8–5.5?µmol/L
Total protein column	CSF, lumbar	8–32?mg/dL		× 10	80–320?mg/L
Turbidimetry	CSF, lumbar		mg/dL		mg/L
		Premature	40–300		400–3,000
		Newborn	45–120		450–1,200
		Child	10–20		100–200
		Adolescent	15–20		150–200
		Thereafter	15–45		150–450
Electrophoresis	CSF		% of Total		Fraction of Tota
		Prealbumin	2–7	× 0.01	0.02–0.07
		Albumin	56–76		0.56–0.76
		a1-Globulin	2–7		0.02–0.07
		a2-Globulin	4–12		0.04–0.12
		ß-Globulin	8–18		0.08–0.18
		?-Globulin	3–12		0.03–0.12

Analyte or Procedure	Specimen	Reference Values (USA)		Conversion Factor	Reference Values (SI)
V. Analyses of Other Body Fluids					
A. Chemical Analyses					
1. AMNIONIC FLUID					
Amniotic fluid analysis	AF	28 wk 0–0.048 A		× 1	0–0.048 A
Ab450nm		40 wk 0–0.02 A			0–0.02 A
Bilirubin	AF	28 wk <0.075?mg/dL (or Ab450 <0.048)		× 17.10	<1.3?µmol/L (or Ab450 <0.048)
		40 wk <0.025?mg/dL (or Ab450 <0.02)			<0.43?µmol/L (or Ab450 <0.02)
Creatinine	AF	After 37 wk gestation >2.0?mg/dL		× 88.4	After 37 wk gestation >180?µmol/L
Estriol (E3), free	AF		ng/mL		nmol/L
		Wk	(95% range)		(95% range)
		16–20	1.0–3.2	×3.47	3.5–11.1
		20–24	2.1–7.8		7.3–27.1
		24–28	2.1–7.8		7.3–27.1
		28–32	4.0–13.6		13.9–47.2
		32–36	3.6–15.5		12.5–53.8
		36–38	4.6–18.0		16.0–62.5
		38–40	5.4–19.8		18.7–68.7
a-Fetoprotein (AFP)	AF	Wk	Amniotic Fluid		
			(Mean ISD) µg/mL		
		15	13.5 ± 3.42		
		16	11.7 ± 3.38		
		17	10.3 ± 3.03		
		18	9.5 ± 3.22		
		19	7.1 ± 2.86		
		20	5.7 ± 2.45		
Lecithin/sphingomyelin (L/S) ratio	AF	2.0–5.0 indicates probable fetal lung maturity (>3.0 in infants or diabetic mothers)			2.0–5.0 indicates probable fetal lung maturity (>3.0 in infants of diabetic mothers)

Lecithin phosphorus	AF	>0.10?mg/dL indicates probable adequate fetal lung maturity		×0.3229	>0.032?mmol/L indicates probable adequate fetal lung maturity
2. SWEAT					
Chloride	Sweat	Normal	<40?mmol/L	×1	<40?mmol/L
		Indeterminate	45–60		40–60
		Cystic fibrosis	>60		>60
Sodium	Sweat	Normal	<40?mmol/L	×1	<40?mmol/L
		Indeterminate	40–60		40–60
		Cystic fibrosis	>60		>60

Chapter 711 - Principles of Drug Therapy

Michael D. Reed
Peter Gal

Clinical pharmacology is concerned with the integration of the pharmacokinetic and pharmacodynamic profile of a drug to optimize drug therapy. **Pharmacokinetics** is the quantitative evaluation of each component of disposition of a compound, that is, the processes of absorption, distribution, metabolism, and excretion. The ability to estimate the pharmacokinetic parameters of a drug accurately permits the determination of the dose and dose interval to achieve a defined target concentration, desired pharmacologic effect, or both. A drug concentration in a specific body fluid is, in theory, a reflection of the drug concentration in tissue, reflecting its concentration at its site of action, the receptor. The concentration of a drug in blood (or other body fluid), however, is not necessarily equal to the concentration of the drug in tissue or at its receptor site. It is important to appreciate the challenges involved in determining drug concentrations in body fluids, including physical access of that body fluid, available volume that can be safely removed, and the sensitivity and specificity of available laboratory methodology.

Pharmacodynamics involves the correlation of pharmacologic response to a measured drug concentration in blood (or other body fluid). The pharmacologic or toxicologic effects of most drugs are a result of their interaction with micromolecular and macromolecular components of cells. Rational prescribing of drugs depends on a fundamental understanding of the pharmacokinetic and pharmacodynamic profile of the drug, and studies show that drugs dosed using pharmacokinetic/pharmacodynamic dosing approaches have better response rates and less toxicity. Understanding the effect of age is essential to understanding pediatric drug therapy, because age is one of the most important variables that influences the processes responsible for disposition of a drug and action in children.

Influence of Age on Drug Therapy.

Drugs administered orally must cross many physiologic membranes before entering the systemic circulation and being distributed to their site of action.

GASTROINTESTINAL ABSORPTION.

Although certain xenobiotics and nutrients are absorbed by active transport or facilitated diffusion, most drugs are absorbed from the gastrointestinal tract by passive diffusion. A number of important patient variables can affect the rate and extent of gastrointestinal absorption of a drug, including pH-dependent diffusion; the presence, absence, and type of gastric contents; gastric emptying time; and gastrointestinal motility. These physiologic processes reflect a clear but highly variable dependence on a patient's age (Table 711–1). Despite the clear maturational changes observed in the functional capacity of these processes and their importance to intestinal drug absorption, the overall bioavailability of most orally administered medications in neonates and young infants is adequate. Whenever possible, the oral route for drug administration is preferred.

ALTERNATIVE ROUTES OF DRUG ABSORPTION.

Another common means of extravascular drug administration in infants and children, other than the oral route, is the intramuscular route. Drugs administered intramuscularly should be water soluble at physiologic pH to prevent precipitation and the resultant decreased, delayed, or erratic absorption from the injection site. Lipid solubility of a drug favors diffusion into the capillaries. Blood flow to and from the injection site should be adequate to ensure absorption into the systemic circulation. This physiologic requirement may be compromised in seriously ill infants and children with poor peripheral perfusion resulting from low cardiac output and respiratory disease.

The skin is another important but often overlooked organ for the absorption of various therapeutic agents and environmental chemicals. This is exemplified by the toxic effects noted in newborn infants exposed to hexachlorophene, aniline-containing disinfectant solutions, and hydrocortisone. The percutaneous absorption of a compound is directly related to the degree of skin hydration and inversely related to the thickness of the stratum corneum. The full-term newborn's integument is a more effective functional barrier than the skin of a premature infant. More importantly, however, the ratio of the newborn's skin surface area to body weight is approximately three times greater than that of an adult. Therefore, the amount of drug absorbed into the systemic circulation (bioavailability) for an identical percutaneous dose of a drug is approximately three times greater in an infant than in an adult. These characteristics of skin make topical creams and patch formulation of drugs important means of drug delivery in infants with adequate perfusion.

The effects of maturational changes on the bioavailability of a drug are unpredictable. A prolonged gastric emptying time and irregular intestinal peristaltic activity can lead to erratic rates of drug absorption, reducing the amount of drug absorbed, blunting or delaying the peak serum concentration, or both. Reducing the rate or amount of total drug absorbed into the body (or both) can be therapeutically important, leading to inadequate dosing, whereas blunting or delaying a drug's peak serum concentration may be of only minor clinical significance. The extent to which maturational changes influence gastrointestinal drug absorption also depends on the specific drug formulation administered. Solid dosage forms (tablets, capsules) must dissolve into solution before the drug can cross cell membranes. Most drugs administered to infants and young children are available in a liquid formulation, including some as a suspension. In general, the rate of absorption is faster after administration of a liquid dosing formulation (liquid > suspension) as compared with

solid formulations (capsule = tablet > sustained/delayed-release tablet).

TABLE 711-1 -- **Physiologic Factors That Influence the Oral Absorption of Medications**

Parameter	Neonate	Infant	Child
Gastric acid secretion	Reduced	Normal	Normal
Gastric emptying time	Decreased	Increased	Increased
Intestinal motility	Reduced	Normal	Normal
Biliary function	Reduced	Normal	Normal
Microbial flora	Acquiring	Adult pattern	Adult pattern

DRUG DISTRIBUTION.

Understanding the distribution characteristics of the drug in the body is important when selecting the dose. Although the distribution volume, the **V_d or the apparent volume of distribution,** of a drug does not denote any real physiologic volume, an estimate of this pharmacokinetic parameter provides insight into the total amount of drug present in the body relative to its concentration in blood and thus the tissue distribution. Knowledge of the V_d of a drug is important when selecting an initial loading dose or designing an optimal drug dosage regimen to attain a pre-selected target concentration. The value of the V_d for a number of drugs differs markedly among newborns (premature vs. full-term), infants, and children as compared with adults. These differences are a result of many important age-dependent variables, including the composition and size of body water compartments, protein binding characteristics, and hemodynamic factors, including cardiac output, regional blood flow, and membrane permeability. The absolute amounts and distribution of body water and fat depend on a child's age and are well characterized. Changes in body water compartment sizes and water distribution account for the differences observed in the V_d in infants and children.

The extent to which a drug is bound to circulating plasma proteins directly influences the distribution characteristics of the drug. Only the free, unbound drug can be distributed from the vascular space into other body fluids and tissues, where it binds to its receptor and stimulates a response. Drug binding to plasma proteins depends on a number of age-related variables, including the absolute amount of proteins available, their respective number of available binding sites, the affinity constant of the drug for the protein, the influence of pathophysiologic conditions, and the presence of endogenous substances, which may compete for protein binding (protein displacement interactions). These and other clinically important variables can affect drug protein binding relative to age. The extent to which a drug is bound to protein markedly influences its V_d and body clearance (Cl) as well as intensity of pharmacologic effects.

Albumin, a_1 -acid glycoprotein, and lipoproteins are the most important circulating proteins responsible for drug binding in plasma. The absolute concentration of these proteins is influenced by age, nutrition, and disease. Basic drugs bind mainly to albumin, a_1 -acid glycoprotein, and lipoprotein, whereas acidic and neutral compounds bind primarily to albumin. Serum albumin and total protein concentrations are decreased during infancy, approaching adult values by the age of 10–12 mo. A similar pattern of maturation is observed with a_1 -acid glycoprotein; concentrations appear to be approximately three times lower in neonatal plasma compared with those in maternal plasma, achieving values comparable to those of adults by 12 mo of age.

In addition to drugs, several endogenous substances presenting in human plasma may bind to plasma proteins and compete for available drug-binding sites. During the neonatal period, free fatty acids, bilirubin, and 2-hydroxybenzoylglycine compete for albumin binding sites and influence the resultant balance between free and bound drug concentrations. Clinically significant protein binding displacement reactions occur only when a drug is more than 80–90% protein bound, the Cl of a drug is limited, and its apparent V_d is small, usually less than 0.15?L/kg. It is prudent to assess a drug's potential for displacement of bilirubin from protein-binding sites before its administration to premature and newborn infants.

DRUG METABOLISM.

The moment a drug molecule is present within the body, the process of its removal begins. The overall rate of drug removal is described by the pharmacokinetic parameter clearance (Cl), or body Cl. A drug's body Cl is the summation of all clearance mechanisms involved in removing that compound from the body (see later under " Clearance "). The primary organ for drug metabolism is the liver, although the kidney, intestine, lung, adrenals, blood (phosphatases, esterases), and skin can also biotransform certain compounds. For most drugs (lipophilic weak acids or weak bases), biotransformation to more polar, water-soluble compounds facilitates their elimination from the body through the bile, kidney, or lung. Although the biotransformation of most drugs results in pharmacologically weaker or inactive compounds, parent compounds may be transformed into active metabolites or intermediates (e.g., theophylline to caffeine, carbamazepine to 10,11-carbamazepine epoxide). Conversely, pharmacologically inactive parent compounds or prodrugs may be converted to an active moiety (e.g., chloramphenicol succinate to active chloramphenicol base, cefuroxime axetil to active cefuroxime) before subsequent biotransformation and body elimination.

Drug metabolism within the hepatocyte involves two primary enzymatic processes: phase I, or nonsynthetic, and phase II, or synthetic, reactions. **Phase I reactions** include oxidation, reduction, hydrolysis, and hydroxylation reactions, whereas **phase**

II reactions primarily involve conjugation with glycine, glucuronide, or sulfate. Most drug-metabolizing enzymes are located in the smooth endoplasmic reticulum of cells. Of these mixed-function oxidase systems, the cytochrome (CYP) P450 system has been studied in greatest detail. The **CYP450 enzyme system** is a supergene family with more than 13 primary enzymes and a number of isozymes of specific gene families. The specific subfamilies, or isozymes, most responsible for human drug metabolism involve CYP450 1A2, 2D6, 2C19, and 3A4. At birth, the concentration of drug-oxidizing enzymes in fetal liver (corrected for liver weight) is similar to that in adult liver. The activity of these oxidizing enzyme systems is reduced, however, which is reflected by a prolonged body elimination for drugs that depend on oxidation pathways in newborns (e.g., phenytoin, diazepam). Postnatally, the hepatic cytochrome P450 mono-oxygenase system appears to mature rapidly; metabolic activity similar to or in excess of the adult value is achieved by approximately 6 mo of age. An understanding of the substrates for specific isozymes and the effects certain drugs may have on isozyme activity (e.g., induction, inhibition) allows the clinician to predict the possibility of clinically important metabolic-based drug-drug interactions. Substrates, inducers, and inhibitors of specific isozymes important in human drug metabolism are summarized in Table 711–2 .

The activity of certain hydrolytic enzymes, including blood esterases, is also reduced during the neonatal period. Blood esterases are important for the metabolic clearance of cocaine, and the reduced activity of these plasma esterases in the newborn may account for the delayed metabolism of cocaine in neonates.

Because elimination of metabolites is reduced in preterm and full-term infants, accumulation of active metabolites not considered clinically relevant in older infants, children, and adults may occur in infants. Such is the case with the *N*-methylation of theophylline to caffeine. This pathway becomes more important in neonates because theophylline is less readily metabolized, making it more available for *N*-methylation. Caffeine itself is normally metabolized before elimination, but in preterm infants with immature liver enzymes the compound is mainly eliminated by the kidneys. This renal elimination is slow because of the immaturity of renal function in young infants, resulting in the potential for marked caffeine accumulation and toxicity if caffeine concentrations collected before steady-state are not appropriately interpreted.

Understanding the sequence of maturation of processes of drug metabolism is important when developing dosage recommendations for drugs that undergo extensive hepatic metabolism. An example of the consequences of failing to appreciate these processes is the tragedy that occurred after the administration of usual doses of chloramphenicol (75–100?mg/kg/24?hr) to premature and newborn infants (fatal gray-baby syndrome) and the resultant beneficial use of this compound in the same

TABLE 711-2 -- **Important Cytochrome P450 Isozymes in Human Drug Metabolism: Isozyme Substrates, Inhibitors, and Inducers**

Isoenzyme	Polymorphism	Substrates	Inhibitors	Inducers
1A2	Possible	Acetaminophen, caffeine, clomipramine, clozapine, imipramine, phenacetin, propranolol, tacrine, theophylline	Fluvoxamine, quinolones (e.g., ciprofloxacin)	Cruciferous vegetables, omeprazole, aromatic hydrocarbons, smoking
2C9	Yes	Diclofenac, ibuprofen, phenytoin, tolbutamide, S-warfarin	Fluconazole, isoniazid, itraconazole(?), ketoconazole(?), sulfaphenazole	Rifampin
2C19	Yes	Amitriptyline, citalopram, diazepam, imipramine, mephobarbital, olmeprazole, propranolol	Fluconazole, fluvoxamine, fluoxetine, omeprazole	Rifampin
2D6	Yes	Amitriptyline, citalopram, clomipramine, codeine, desipramine, dextromethorphan, doxepin, encainide, flecainide, fluoxetine, haloperidol, imipramine, loratadine, metoprolol, nortriptyline, paroxetine, perphenazine, propafenone, propranolol, risperidone, thioridazine, timolol, tramadol	Cimetidine, fluoxetine, norfluoxetine, nefazodone (plus metabolites), paroxetine, perphenazine, propoxyphene, quinidine, sertraline, thioridazine	
2E1	No	Acetaminophen, alcohol, chlorzoxazone, dapsone	Disulfiram, isoniazid	Ethanol, isoniazid

3A4	Possible	Alfentanil, alprazolam, amiodarone, amitriptyline, astemizole, carbamazepine, cisapride, cyclosporine, dapsone, diazepam, diltiazem, disopyramide, erythromycin, ethinylestradiol, imipramine, indinavir, lidocaine, loratadine, lovastatin, midazolam, nifedipine, nefazodone, progesterone, quinidine, ritonavir, saquinovir, tacrolimus (FK-506), terfenadine, testosterone, triazolam, verapamil	Cimetidine, citalopram, diltiazem, ethynylestradiol, fluconazole, fluvoxamine, fluoxetine, indinavir, norfluoxetine, itraconazole, ketoconazole, macrolides (clarithromycin, erythromycin), metronidazole, nefazodone, naringenin, ritonavir	Carbamazepine, dexamethasone, phenobarbital, phenytoin, rifampin

patient population when the dose was appropriately adjusted (15–50?mg/kg/24?hr) to compensate for the decreased hepatic ability for glucuronidation. Chloramphenicol glucuronide is the primary metabolite of chloramphenicol, which is then excreted through the kidneys.

The ultimate ability of children to metabolize drugs may be genetically modulated. Pharmacogenetic predisposition to slow drug metabolism along certain enzymatic pathways can provide important clues to patients at risk for drug toxicity. This is a rapidly developing area of research, and it is reasonable to anticipate future clinical applications for pharmacogenetic and pharmacogenomic knowledge about drug metabolism.

DRUG EXCRETION.

The amount of drug that is filtered by the glomerulus per unit of time depends on the functional ability of the glomerulus, on the integrity of renal blood flow, and on the extent of drug-protein binding. The amount of drug filtered is inversely related to the degree of protein binding. Only the free drug is filtered by the glomerulus and excreted. Although highly variable, renal blood flow averages 12?mL/min at birth, approaching the adult value by 5–12 mo of age. The glomerular filtration rate is 2–4?mL/min in full-term infants, increases to 8–20?mL/min by 2–3 days of life, and approaches the adult value by 3–5 mo of age. Before 34 wk of gestation, glomerular filtration is markedly reduced and increases slowly.

PHARMACOKINETICS

Basic Concepts.

Pharmacokinetics is the mathematical expression of the time course of drug movement in the body. It is clinically useful only when integrated with the pharmacodynamic characteristics of the drug. Because the pharmacologic effects of most drugs are reversible, the time of onset, intensity, and duration of effect of a drug are proportional to the amount of drug in the body at any point in time. Pharmacokinetic-based methods can be used to predict drug concentration at any time after a dose is administered and can facilitate calculation of a drug dose to achieve a desired concentration. Recognition that the pharmacologic effects, toxicologic effects, or both correlate best with its concentration in a biologic fluid (blood) rather than the absolute dose administered is the foundation of applied clinical pharmacokinetics.

The **biodisposition** of most drugs used clinically is best described using the principles of linear or first-order pharmacokinetics—that is, the serum concentration or, more appropriately, the amount of drug in the body is directly proportional to the dose administered. For example, if the dose of a drug that follows linear pharmacokinetics is doubled, its resultant concentration in blood (at steady state) also doubles. This characteristic of proportionality, combined with appropriate patient monitoring, is often used clinically to make adjustments in drug dosing (see later, " Individualization of Drug Dose "). In contrast, some drugs, such as phenytoin, salicylate, and alcohol, exhibit saturation kinetics; their elimination pathways become "saturated," and the resultant drug concentration in the blood changes disproportionately to the dose administered. Under usual clinical conditions, these drugs exhibit linear (first-order) elimination characteristics at low doses (low serum concentrations) but, as the amount of drug in the body increases with increasing dose, their elimination pathways become saturated. Such drugs are often called drugs that follow the principles of zero-order, or Michaelis-Menten, kinetics. The classic principles of elimination half-life ($t_{1/2}$) and Cl do not apply to drugs that exhibit zero-order kinetics. Describing more drug disposition profiles in pediatric patients, where sampling volumes and frequency must be limited has been made more feasible through newer pharmacokinetic research techniques, such as optimal sampling theory.

DRUG ABSORPTION AND BIOAVAILABILITY.

To be effective, a drug must be absorbed from its site of administration into the systemic circulation, from where it is distributed to its site of action and eliminated from the body. Bioavailability is a measure of the amount of drug absorbed into the systemic circulation over a finite period. With few exceptions (prodrugs), a drug administered intravenously is 100% bioavailable. The bioavailability of a drug is most often described as a fraction of the amount absorbed after extravascular drug administration relative to intravenous (IV) drug administration. Bioavailability is calculated as the ratio of the area under the drug concentration time curve (AUC)

determined after extravascular drug administration to the drug AUC obtained after intravenous administration (i.e., AUC oral/AUC IV).

The absorption profile of a drug is a composite that depends on both the bioavailability (amount) and the rate of absorption into the systemic circulation. The rate and extent of drug absorption are influenced by a number of physicochemical and patient-related factors. For example, the presence of food in the

---

stomach and duodenum can decrease the rate but generally does not affect the overall extent of absorption of many orally administered drugs. The clinical relevance of this interaction depends on whether the drug's efficacy is related to its peak serum concentration (decreased rate would blunt the peak concentration) or the total amount of drug in the body. Appreciating the rate of drug absorption can be important in anticipating the onset of toxicologic symptoms in cases of drug overdose. In contrast, a disease or a drug interaction that results in a decrease in drug bioavailability would be expected to influence a patient's response to therapy. The concurrent administration of phenytoin and enteral tube feedings can markedly decrease phenytoin bioavailability. Such drug-food interactions may be easily overlooked as a cause of therapeutic failure.

VOLUME OF DISTRIBUTION.

The V_d is the hypothetical volume of fluid in which a drug is distributed; it is a proportionality constant that relates the amount of drug in the body to its serum concentration. The apparent V_d is expressed by the equation $V_d = D/C_p$, where C_p is the peak concentration of drug following administration of the dose D. The V_d may be used to calculate the initial or loading dose (LD) of a drug needed to achieve a desired serum concentration (C_p). V_d may also be used to select an appropriate bolus dose to increase from a known subtherapeutic concentration to a target therapeutic concentration. If a desired C_p is selected and an age-appropriate “average” V_d is known or obtained from the literature, a dose necessary to obtain that concentration can be easily calculated:

Furthermore, it is apparent from this relationship that drug elimination from the body, or drug clearance, does not influence the initial or loading dose of a drug. For example, although a drug may be eliminated from the body only through the kidneys, the initial dose is the same for patients with normal renal function as for those with compromised or no renal function. The first dose of drug achieves an equilibrium concentration between body fluids and tissues.

ELIMINATION HALF-LIFE.

The **elimination half-life ($t_{1/2}$)** of a drug is the time required for any given concentration in blood (or other biologic fluid) to decrease to half of the initial value, that is, the time required for half the amount of drug present in the fluid to be cleared. The $t_{1/2}$ can be determined as

where Kd is equal to the slope of the terminal portion of the natural log of the linear serum concentration versus time curve. The $t_{1/2}$ depends on both the Cl and V_d of the drug. A more useful formula for $t_{1/2}$, which reflects these important relationships, is

Thus, a change in $t_{1/2}$ does not necessarily reflect a change in body Cl of a drug. This dependence of $t_{1/2}$ on V_d is exemplified by the influence of extracorporeal membrane oxygenation (ECMO) on drug disposition. For most drugs, ECMO-induced changes are due to an increase in drug V_d rather than any change in drug Cl. Nevertheless, despite this important distinction, the $t_{1/2}$ is often used clinically to adjust dosing intervals, primarily because it can easily be calculated in the clinic or at the patient's bedside. The $t_{1/2}$ of a drug can also be used to determine the time necessary to achieve the steady-state concentration, that is, the point at which the amount of drug administered (dose) is equivalent to the amount of drug cleared from the body. After three half-lives, 87.5% of a drug's steady-state concentration is achieved; after four half-lives, it is 93.8%; and after five half-lives, it is 100%. When integrated with a target concentration strategy, the $t_{1/2}$ of a drug is often used to determine a drug's dosage interval.

CLEARANCE.

Clearance (Cl) is the pharmacokinetic parameter that estimates the theoretical volume from which a drug is removed per unit of time. The body clearance of a drug reflects the amount of drug removed or eliminated from the body per unit of time, whereas renal Cl reflects the amount of drug cleared by the kidneys per unit of time. Total body Cl is the summation of all Cl mechanisms for a given drug (Cl_{renal} , $Cl_{hepatic}$, Cl_{lung}). The body Cl can be calculated as

with the preferred mathematical method of drug dose/AUC where the dose is corrected for bioavailability. Knowledge of the Cl of a drug is fundamental when determining the need for a drug and how often its dose must be repeated to maintain a given serum concentration. It is the most important pharmacokinetic parameter for determining the steady-state drug concentration for a given dose rate. Changes in organ function responsible for the removal of a drug from the body are reflected as a change in the drug Cl. A drug's body Cl is influenced by the integrity of blood flow and by the functional ability of the organs involved in removing the drug from the body.

Individualization of Drug Dose.

The clinical response to an average or usual recommended dose of drug can vary considerably, even when the dose is administered relative to a patient's body weight, surface area, and stage of maturation. This variation is a result of interindividual differences in drug pharmacokinetics and pharmacodynamics and a number of biologic variables, including genetic differences in drug metabolism or drug receptors, and concurrent pathophysiology. Individual variability with respect to drug efficacy and possibly toxicity frequently necessitates the adjustment of dosage regimens for specific patients, especially when prescribing drugs with a low therapeutic index. For some drugs the dose may be adjusted according to the patient's immediate and readily quantifiable clinical response. For other drugs,

dosage adjustment may be guided more appropriately by combining clinical response with measuring the concentration of drug in plasma or serum. Such an approach to therapy is often called a **target concentration strategy,** where a drug's pharmacologic or toxicologic response can be directly related to a specific serum concentration range. It is important to recognize that the therapeutic ranges described for drugs reflect a continuum of concentrations along which increasing percentages of patients can be expected to have a clinical response and toxicity (pharmacodynamic curves), and it is the tradeoff between benefit and risk that each clinician must use to decide whether targeting the lower or upper region of the therapeutic range or even exceeding the therapeutic range is optimal. Close attention to the pharmacologic actions and physiologic responses is necessary for this optimal target concentration strategy.

Reported therapeutic concentration ranges for drugs are usually determined from studies of only a limited number of patients, mostly adults, and these therapeutic ranges represent an average (mean) value, and therefore only 49% of the population is encompassed within the two standard deviations that surround this mean value. Thus, the clinical monitoring of serum drug concentrations serves only as a guide to pharmacologic intervention and dose adjustment. Serum drug concentration values must be interpreted individually for each patient. For example, one patient may have a complete clinical response when the serum concentration of drug X is within the “low” portion of the therapeutic range or window. Conversely, the next patient, with the same disease of similar severity requiring the same drug X, may require a serum drug concentration above or below the reported therapeutic concentration range to achieve the same degree of positive therapeutic response. Toxicity, however, may limit how much above the therapeutic

range the serum drug concentration may safely be raised. Therefore, therapeutic ranges for serum drug concentrations serve only as guidelines for therapy. Drug efficacy must be assessed by clinical response.

Serum drug concentration-time values or profiles may also be compared with previously determined patient-specific values or literature reports to assess patient compliance with a prescribed drug regimen. More commonly, the determination of a drug concentration in biologic fluid helps to achieve an optimal therapeutic regimen while reducing the likelihood of drug toxicity. Finally, the determination of a drug concentration in a biologic fluid provides a means to assess the influences, if any, of disease process or drug interaction on a drug's disposition profile.

Therapeutic drug monitoring is not appropriate, necessary, or practical for all drugs. Drugs with well-defined and easily recognizable and monitored pharmacodynamic effects do not warrant routine monitoring (diuresis with diuretics, lowering of blood pressure by an antihypertensive). For therapeutic drug monitoring to be of clinical value, a clear concentration-response or concentration-toxicity relationship should be identifiable. Patient age and the extent or severity of disease can influence the relationships among drug concentration, efficacy, and toxicity. Unfortunately, a clear relationship between a specific serum drug concentration and effect is available for only a limited number of drugs in contrast to the large number of drugs with “recommended” therapeutic ranges.

A number of variables should be considered when designing strategies to monitor therapy using a serum drug concentration. When measuring a drug's concentration in blood, the pharmacokinetic characteristics of that drug must be recalled so that blood samples can be obtained at appropriate times in relation to administration of the drug. This permits proper interpretation of drug concentrations and therapeutic effects and helps avoid serious therapeutic errors. Peak drug concentrations in blood usually do not refer to the highest concentration achieved in blood with that drug but usually to the postdistribution peak drug concentration. Thus, a lag time often exists between the time of drug administration and the time that is recommended to obtain the “peak” blood sample. Also, most clinical determinations of drug concentrations in biologic fluids routinely measure (report) the total drug concentration in that fluid (free drug concentration plus concentration of drug bound to protein equals total drug concentration). This approach assumes a constant ratio of free to bound drug at various concentrations and under differing pathophysiologic conditions, which may not always be true; thus, caution must be exercised in its extrapolation. For example, clinically important imbalances between free and total drug concentrations have been observed with the drug phenytoin in critically ill trauma patients and in patients with severe renal disease. As a result, many laboratories are now beginning to report both free *and* total serum concentrations of drugs or have these results available on request. Despite these differences, it is generally unusual for an imbalance in this ratio to be clinically significant, except for those drugs whose protein binding, under normal circumstances, is more than 90%.

Chronopharmacology is the effect of biologic rhythms on drug disposition and response. Many drugs are influenced pharmacokinetically and pharmacodynamically by this phenomenon. It is important to be aware of these situations and to time doses and blood sample collections appropriately.

ADDITIONAL CONSIDERATIONS

Method of Drug Administration.

It is often assumed that intravenous administration of a drug is rapid and complete. Neither is always true. The length of time necessary to infuse the total dose of an intravenously administered drug depends on a number of factors, including the flow rate of the primary intravenous fluid, the dead space of the system into which the drug is injected, and the total volume in which the drug is diluted. Because most standard intravenous fluid delivery systems, including their tubing, are designed for adult use, they contain a large volume/unit of length. This introduces a relatively large dead space factor, which causes substantial infusion delays when operated at the slow flow rates necessary for infants and children. Even intravenous infusion systems designed for pediatric patients can have problems and limitations that may confound drug therapy management and require clinician awareness.

Several steps can be taken to minimize problems with intravenous drug administration to small infants and children. These include the following: standardization and documentation of the total administration time; documentation of the volume and content of the solution used to “flush” an intravenous dose; standardization of specific infusion techniques (infusion duration, volumes) for drugs

with a narrow therapeutic index; standardization of dilution and infusion volumes for drugs given by intermittent IV injection; avoidance of attaching lines for drug infusion to a central hub with other solutions infused concurrently at widely disparate rates; preferential use of large-gauge cannula; maintenance of the recommended solution at a specified height above the infusion site for use with a gravity-based controller; and the use of low-volume tubing and the most distal sites for access of the drug into an existing intravenous line.

Drug-Drug Interactions.

When two or more drugs are administered to the same patient, the pharmacokinetic and pharmacodynamic properties of each agent may be modified by their combined interaction. Drugs may interact by a number of different mechanisms; these may be classified on the basis of pharmaceutics, pharmacokinetics, pharmacodynamics, or a combination thereof. These interactions may result in unpredictable clinical effects or toxicologic responses. Pharmaceutic interactions include those resulting in drug inactivation when compounds are mixed together physically prior to patient administration as in syringes, infusion tubing, or parenteral fluid preparations.

Pharmacokinetic interactions can occur when the disposition characteristics of one compound (absorption, distribution, metabolism, excretion, or a combination thereof) are influenced by those of another. This type of interaction may involve one or more aspects of the pharmacokinetic profile of the drug. One drug may reduce the rate but not the overall extent of absorption, or a compound may displace a drug from its protein binding sites while concomitantly retarding its elimination from the body. Metabolic-based drug-drug interactions can occur whenever two compounds compete for the same metabolic site (see Table 711–2).

Drugs may interact pharmacodynamically and compete for the same receptor or physiologic system, thus altering a patient's response to drug therapy. The number of known, clinically important drug interactions, combined with the ever-increasing number of available pharmacologic agents, emphasizes the need to critically assess the possibility or presence of drug-drug interactions in any patient receiving multiple drugs.

Drugs in Human Milk.

Almost all drugs administered to lactating women are secreted to some extent into their milk and may be ingested by the nursing infant. In general, drug use should be as minimal as possible during lactation; a few drugs have been reported to affect the nursing infant adversely. Obviously, it is not possible or desirable for lactating women to stop taking needed medications. If a question exists about the amount of drug a breast-feeding infant may be receiving or about possible drug effects on the infant, a sample of the mother's milk can be analyzed. Furthermore, up-to-date and specific information regarding breast milk distribution of medications and, most importantly, the amount a nursing infant would actually receive (absorb) can be obtained by consulting a clinical pharmacy/pharmacology service.

Prescribing Medications.

Factors such as taste, smell, color, consistency, dosing frequency, and cost affect the degree to which patients comply with their therapeutic drug regimen. Prescribing generically equivalent medications can sometimes reduce the cost of a drug. Such prescribing should be done only when it is clearly known that the generic brand affords equivalent bioavailability, bioeffectiveness, and patient acceptability. Unfortunately, complete bioequivalence data are not available for all drugs and, when in doubt, the prescribing physician should consult with the pharmacist.

A prescription issued by the prescribing physician should always direct the dispensing of just enough drug to treat the patient, leaving only a small amount of drug left over after the prescribed course of therapy has been completed. This small residual allows for some drug in case of doses accidentally spilled or lost. Parents should be instructed to discard all remaining doses of a prescribed medication after the completed course of therapy to protect against accidental poisoning or improper self-medication at a later date. Patient medication instructions on the prescription should state the specific number of doses the patient should receive each day and the total duration of therapy (number of days of therapy). The number of times the prescribing physician allows the prescription to be refilled should be noted on the prescription label; if no refills are to be permitted, this should also be specified on the written prescription.

Compliance with the Prescribed Regimen.

Little is known about the many factors that determine the degree of compliance with a physician's instructions, but it is clear that many patients frequently do not take medication consistently or in the manner intended or prescribed. Moreover, patients frequently take home remedies or medications not recommended or prescribed by their physician. A child's compliance with a prescribed therapeutic regimen is usually only as good as that of the parents. Compliance can often be maximized by carefully educating the family about the nature of the child's illness, the action of the medications prescribed, and the importance of following the instructions precisely. Often, if the instructions are written down clearly and in detail for the family and if the regimen results in minimal interference with the daily living schedule (particularly parental sleeping habits), compliance with the therapeutic regimen is improved. Collaboration between prescribing physician and dispensing pharmacist can often identify compliance problems and improve compliance through patient education.

TABLE 712-1 -- **General Medications**

Drug (Trade Names, Formulations)	Indications (Mechanism of Action) and Dosing	Comments (Cautions, Adverse Eve
Abciximab ReoPro Intravenous solution, 2?mg/mL in 5-mL vials.	**Inhibit platelet aggregation through inhibiting the glycoprotein Iib/IIIa receptor pathway. Used in combination with IVIG and aspirin to accelerate regression of coronary aneurysms in Kawasaki disease. In adults, used for preventing platelet aggregation with various acute coronary syndromes and procedures.** *Children and adults:* Loading dose 0.25?mg/kg, followed by an infusion of 0.125?µg/kg/min for 12?hr.	*Adverse events:* Bleeding.

Acarbose Precose. Tablet: 25, 50, 100?mg.	**Treatment of type 2 diabetes mellitus, treatment of postprandial hypoglycemia in children after Nissen fundoplication.** *Children:* 12.5 to 50?mg with each feed. *Adults:* Initial 25?mg tid at the start of each meal; titrate to response (max: 100?mg tid).	*Adverse events:* Flatulence, abdomin
Acetaminophen Analgesic, non-narcotic; antipyretic. Tempra; Tylenol; multiple generic and brand-name products. Caplet: 160, 325, 500?mg. Capsule: 325, 500?mg. Drops: 100?mg/mL (15?mL); 120?mg/2.5?mL (35?mL). Granules, premeasured packs: 30?mg (32?s). Suppositories: 120, 325?mg. Combination products with acetaminophen include cough and cold preparations and with codeine.	**Mild to moderate pain** (inhibits prostaglandin synthesis in CNS and peripheral pain impulse generation). **Fever** (inhibits hypothalamic heat regulation center). *Infants and children* <12 yr: 10–15?mg/kg/dose q4–6h. *Children* >12 yr and adults: 325–650?mg q4–6?hr or 1,000?mg 3–4 times daily. Maximum: 5 doses/24?hr (children) or 4?g/24?hr (adults) administered PO or PR.	*Cautions:* Overdose can cause fatal h acute overdoses with acetylcysteine. use with enzyme inhibitors, especially hepatic necrosis. Avoid aspartame-containing products phenylketonuria (e.g., chewable table

Acetazolamide Diuretic, carbonic anhydrase inhibitor. Dazamide; Diamox. Capsule, sustained release: 500?mg. Injection: 500?mg/5?mL. Tablet: 125, 250?mg.	**Hydrocephalus due to communicating intraventricular hemorrhage** (carbonic anhydrase inhibition decreases CSF production). *Neonates:* 25?mg/kg/24?hr to start and increase to bid, tid, and qid over 4–7 days. **Glaucoma** (carbonic anhydrase inhibition decreases formation of aqueous humor). *Children:* 8–30?mg/kg/24?hr PO divided q6–8h or 20–40?mg/kg/24?hr IV divided q6h. **Epilepsy, as adjunct to other drugs in refractory seizures** (uncertain mechanism). *Children and adults:* 8–30?mg/kg/24?hr in 1–4 divided doses (max: 1?g/24?hr). **Edema** (diuretic). *Children:* 5?mg/kg/24?hr IV or PO. *Adults:* 250–375?mg/24?hr IV or PO.	*Caution:* Used in combination with fur hydrocephalus. Reduce dose and extend dosing inter compromised. Avoid if patient has sulfa allergy. IM very painful because of alkaline ph *Adverse events:* Metabolic acidosis, h hypokalemia, nausea, anorexia, drow muscle weakness, renal calculi.

Acetylcysteine Antidote, acetaminophen; mucolytic agent. Mucomyst; Mucosil; Mucosol. Solution, as sodium: 10% [100?mg/mL] (4, 10, 30?mL); 20% [200?mg/mL] (4, 10, 30, 100?mL).	**Mucolytic** (free sulfhydryl group opens up disulfide bonds in mucoproteins, lowering viscosity). Dose is based on 10% solution or diluted 20% solution (1:1) for inhalation. *Infants:* 2–4?mL tid–qid. *Children:* 6–10?mL tid–qid. *Adolescents:* 10?mL tid–qid. Acute acetaminophen overdose (provides alternative metabolic pathway for conjugation of toxic metabolites, restoring normal glutathione levels). *Children and adults:* 140?mg/kg loading dose, followed by 70?mg/kg q4h for 17 doses. Repeat dose if emesis occurs within 1?hr of administration.	*Cautions:* Give a bronchodilator 10–1 nebulized Mucomyst to avoid broncho treatment with chest percussion and s increased secretions. Dilute nebulized doses with saline or solutions with soft drinks or orange ju as 1:1 and PO as 1:3 solutions. *Adverse events:* Stomatitis nausea, v *Monitoring:* Check acetaminophen co than 4?hr post overdose. Give compl course regardless of acetaminophen
Adenosine Antiarrhythmic agent, miscellaneous. Adenocard. Injection, preservative free: 3?mg/mL (2?mL).	**Paroxysmal supraventricular tachycardia (PSVT)** treatment (slows conduction time through the AV node). *Neonates and children:* 0.05?mg/kg IV push, then increase bolus doses by 0.05?mg/kg q 2?min until a clinical response occurs or a maximum dose of either 0.25?mg/kg or 12?mg is achieved. *Adults:* 6?mg IV push, if no response in 2?min, give 12?mg IV push. May repeat 12?mg IV bolus if needed.	*Cautions:* Use a peripheral IV site. Ma bronchoconstriction in asthmatics. Methylxanthines (e.g., theophylline or adenosine effects so higher adenosin Contraindicated in 2nd or 3rd degree syndrome. *Adverse events:* Heart block, flushing bradycardia, hypotension, dyspnea, h nausea. *Monitoring:* Continuous ECG, blood p

Albumin, human Blood product derivative; plasma volume expander. Albuminar; Albumisol; Albutein; Buminate; Plasbumin. Injection: 5% [50?mg/mL] (50, 250, 500, 1,000); 25% 250?mg/mL] (10, 20, 50, 100?mL).	**Plasma volume expansion and treatment of hypovolemia** (increase intravascular oncotic pressure and mobilize fluid from interstitium to intravascular space). *Neonates:* 0.5–1?g/kg/dose (max 1?g/kg/24?hr). *Infants and children:* 0.5–1?g/kg/dose (max 6?g/kg/24?hr). *Adults:* 25?g/dose (max 250?g/24?hr).	*Cautions:* 25% albumin may increase infants so 5% is preferred in these ca be over at least 2?hr in neonates. Infu 30–60?min for hypovolemia. *Adverse events:* Precipitation of heart edema, hypertension, tachycardia du Immune reactions (e.g., fever, chills, mortality in critically ill patients. *Monitoring:* Vital signs.
Albuterol Adrenergic agonist agent; ß$_2$ -adrenergic agonist agent; bronchodilator; sympathomimetic. Proventil; Ventolin; Volmax. Aerosol, oral: 90?µg/spary [200 inhalations] (17?g). Capsule, microfine, for inhalation, as sulfate (Rotacaps): 200?µg. Solution, inhalation, as sulfate: 0.083% [0.83?mg/mL] (3?mL); 0.5% [5?mg/mL] (20?mL). Syrup, as sulfate (strawberry flavor): 2?mg/5?mL (480?mL). Tablet, as sulfate: 2, 4?mg. Tablet, extended release: 4?mg.	**Bronchodilator** (ß$_2$ -agonist). **Inhalation dose:** *Neonates, infants, children, and adults:* **Metered dose inhaler (MDI):** 1–2 puffs prn, or 5?min before exercise or tid–qid. **Rotohaler:** 1–2 capsules prn, or q4–6h, or before exercise. **Nebulizer solution:**. *Neonates:* 0.1–0.5?mg/kg/dose prn or q2–6h. *Children:* 1.25–2.5?mg prn or q4–6h. *Adults:* 1.25–5?mg prn or q4–6h PO: *Neonates:* 0.1–0.3?mg/kg/dose q6–8h. *Children:* <6 yr: *0.1–0.2?mg/kg/dose tid.* 6–12 yr: *2?mg/dose tid–qid* >12 yr: *2–4?mg tid–qid.*	*Cautions:* Increased use or lack of eff of asthma control requiring medical a prn or before exercise. *Adverse events:* Hyperglycemia, hypo palpitations, nervousness, CNS stimu tremor. *Monitoring:* Evaluate clinical response function, e.g., peak flowmeter (patien >80% of personal best peak expirator *Comments:* May mix albuterol nebuliz cromolyn or ipratropium nebulizer sol doses with an extender device.

Alfentanil hydrochloride Analgesic, narcotic; general anesthetic. Alfenta Injection. Injection, preservative free: 500?µg/mL (2, 5, 10, 20?mL).	**Analgesia, anesthesia** (narcotic analgesic). *Neonates, infants, and children <12 yr:* 5–15?µg/kg IV injected over 3–5?min or 0.5–3?µg/kg/min continuous infusion (limited experience and doses poorly established). *Adults:* IV continuous infusion 0.5–1.5?µg/kg/min.	*Cautions:* Bolus doses of 9–15?µg/kg rigidity in 9 of 20 newborns, comprom patients. Use a skeletal muscle relaxa in patients with increased intracranial respiratory depression. *Adverse events:* Bradycardia, hypoter intracranial pressure, antidiuretic horr *Comment:* Dose based on lean weigh
Alglucerase Enzyme, glucocerebrosidase. Ceredase Injection. Injection: 10 units/mL (5?mL); 80 units/mL (5?mL).	**Enzyme replacement therapy for type I Gaucher disease** (replaces the missing enzyme ß-glucosidase needed to break down and thus avoid accumulation of glucosyl ceramide-laden macrophages in bone liver and spleen). 20–60 units/kg IV infused over 1–2?hr. Typically repeated q 2 wk but varies from q 2 days to q 4 wk depending on response.	*Adverse events:* Fever, chills, abdom nausea, vomiting, local IV site. *Monitoring:* Resolution of anemia, thr bleeding tendencies, and hepatosple mo). Improved bone mineralization (u 80–104 wk of therapy).
Allopurinol Anti-gout agent; uric acid–lowering agent. Lopurin; Zyloprim. Tablet: 100, 300?mg.	**Prevent attacks of gouty arthritis and nephropathy. Prevent cancer chemotherapy-induced hyperuricemia** (inhibits xanthine oxidase thus preventing conversion of hypoxanthine to uric acid). *Children* =10 yr: 10?mg/kg/24?hr in 2–3 divided doses. *Children >10 yr and adults:* 200–600?mg/24?hr in 2–3 divided doses. **Gout, chemotherapy-induced hyperuricemia.** 600–800?mg/24?hr in 2–3 divided doses starting 1–2 day before chemotherapy and continue for 3 days. Renal impairment: CrCl 10–50: reduce dose to 50%, CrCl <10: reduce dose to 30% of suggested.	*Cautions:* Discontinue at first sign of r *Adverse events:* Rashes including ery renal impairment, hepatitis, periphera vasculitis *Monitoring:* Uric acid levels decrease maximum effect seen in 1–3 wk.

Alprazolam Antianxiety agent. Benzodiazepine. Xanax. Tablet: 0.25, 0.5, 1, 2?mg.	**Treatment of anxiety or panic attacks** (not certain but may be mediated through ?-aminobutyric acid). *Children:* 0.005–0.02?mg/kg/dose tid. *Adults:* 0.25–0.5?mg bid–tid, max: 4?mg/24?hr (anxiety) and 10?mg/24?hr (panic).	*Cautions:* Abrupt discontinuation resu reactions including seizures. Safety n children <18 yr. Pregnancy risk factor *Adverse events:* Drowsiness, confusi
Alprostadil Prostaglandin. Prostin VR Pediatric Injection. Injection: 500?µg/mL (1?mL).	**Maintain patency of the ductus arteriosus in cyanotic heart lesions.** Direct vasodilation of ductus smooth muscle. *Neonates and infants:* 0.05–0.1?µg/kg/min as continuous IV infusion, may gradually increase to maximum of 0.4?µg/kg/min or wean as low as 0.005?µg/kg/min depending on response.	*Adverse events:* Apnea, bradycardia, tachycardia, flushing, seizure-like acti Hyperostosis (with >6 mo use), diarrh Obstruction (if =5 days use). *Monitoring:* Therapeutic response inc systemic blood pressure, improved ox PO_2 , and less acidosis on blood pH. immediately if severe apnea or brady
Aluminum acetate Topical skin product. Acid Mantle; Bluboro; Boropak; Domeboro; PediBoro. Powder, to make topical solution: 1 packet/pint of water = 1:40 solution. Solution, otic: Aluminum acetate 1:10 with acetic acid 2% (60?mL). Tablet: 1 tablet/pint = 1:40 dilution.	**Astringent wet dressing for relief of inflammatory conditions of the skin; prophylaxis of swimmer's ear.** *Children and adults:* Otic: Instill 4–6 drops q2–3h initially then q4–6h until itching or burning resolves. Topical: Soak the affected area in the solution for 15–30?min 2–4 times daily.	*Adverse events:* Local irritation.

Aminocaproic acid Hemostatic agent. Amicar. Injection: 250?mg/mL (20, 96, 100?mL). Syrup (raspberry flavor): 250?mg/mL (480?mL). Tablet: 500?mg.	**Treatment of excessive bleeding resulting from systemic hyperfibrinolysis (inhibits activation of plasminogen).** *Children:* PO, IV load 100–200?mg/kg, maintenance 100?mg/kg q6h or 33.3?mg/kg/hr continuous infusion. Traumatic hyphema: 100?mg/kg q4h (max 30?g/24?hr). *Adults:* Load 5?g over 1?hr, then 1–1.25?g/hr until bleeding stops (max: 30?g/24?hr).	*Cautions:* Avoid in disseminated intra and hematuria of the upper urinary tra alcohol, so avoid in neonates <1500? *Adverse events:* Hypotension, bradyc dizziness, headache, nasal congestic *Monitoring:* D-dimer or fibrin split prod time (target 180–200?sec), serum po renal function decreased).
Aminophylline (Theophylline equivalent listed in brackets.) Bronchodilator; respiratory stimulant; theophylline derivative. Aminophyllin; Phyllocontin; Somophyllin; Truphylline. Injection, IV (Aminophyllin): 25?mg/mL [19.7?mg/mL] (10, 20?mL). Liquid, oral: 105?mg/5?mL [90?mg/5?mL] (240?mL). Suppository, rectal (Truphylline): 250?mg [197.5?mg], 500?mg [395?mg]. Tablet (Aminophyllin): 100?mg [79?mg], 200?mg [158?mg]. Tablet, controlled release [12?hr] (Phyllocontin): 225?mg [178?mg]. Tablet, enteric coated: 100?mg [79?mg], 200?mg [158?mg]. See *Theophylline* for oral dosing.	**Apnea of prematurity, ventilator weaning in neonates, bronchodilator, weak pulmonary anti-inflammatory effects.** Increase contractility and decrease fatigability of diaphragm and respiratory muscles, weak bronchodilator, CNS stimulation, decrease airway responsiveness to stimuli. Exact mechanisms for these effects remain controversial. *Neonates* (for apnea of prematurity, ventilator weaning, or bronchospasm): Loading dose: 6?mg/kg IV or PO. Maintenance dose: 2.5–3?mg/kg/dose q12?hr IV or PO. **Asthma chronic therapy (see *Theophylline*).** Use in acute therapy is of questionable value. If used as continuous IV infusion: *Children:* *6 wk–6 mo:* 0.5?mg/kg/hr. *6 mo–1 yr:* 0.7?mg/kg/hr. *1–9 yr:* 1?mg/kg/hr. *9–12 yr:* 0.9?mg/kg/hr. *12 yr–adult:* 0.7?mg/kg/hr.	*Cautions:* May cause or worsen arrhy gastroesophageal reflux. Theophyllin modified by numerous disease states dosing adjustments guided by serum concentrations. Clearance is reduced fever >102°F for >24?hr, cor pulmona inhibit P450 enzymes (cimetidine, ver quinolones); reduce dose by 50%. *Adverse events:* Feeding intolerance gastrointestinal discomfort in children vomiting, CNS irritability, agitation, ta tachyarrhythmias. *Monitoring:* Theophylline blood levels effects and toxicity. Target levels are controversial. *Neonates:* 6–15?mg/L not have apnea eliminated until levels continuous electronic monitoring is pe above 10?mg/L are needed for ventila of 5–15?mg/L are sufficient for broncl Theophylline alone is ineffective for a chronic asthma, theophylline levels o effective, but levels should exceed 1C of exercise-induced bronchospasm.

Children:
6 wk–6 mo: 0.5?mg/kg/hr.
6 mo–1 yr: 0.7?mg/kg/hr.
1–9 yr: 1?mg/kg/hr.
9–12 yr: 0.9?mg/kg/hr.
12 yr–adult: 0.7?mg/kg/hr.

Amiodarone hydrochloride Antiarrhythmic agent, class III. Cordarone. Tablet: 200?mg. Injection: 50?mg/mL (3?mL); Cordarone contains benzyl alcohol and polysorbate (Tween) 80. Injection, benzyl alcohol-free and polysorbate-free: 15?mg/mL (10?mL); Amio-Aqueous contains an aqueous acetate buffer; available via orphan drug status or compassionate use from the manufacturer Academic Pharmaceuticals, Inc. (847) 735-1170.	**Management of resistant, life-threatening ventricular arrhythmias or PSVT unresponsive to less toxic agents** (class III antiarrhythmic agent, prolongs action potential and refractory period in myocardial tissue). **Oral dose:** *Infants and children:* *<1 yr:* 600–800?mg/1.73?m^2 /24?hr in two divided doses. *>1 yr:* 10–20?mg/kg/24?hr in two divided doses for 10 days, then 5–10?mg/kg/24?hr. *Adults:* 800?mg/24?hr in two divided doses. Cut all doses in half, i.e., one dose per day after 1–4 wk of treatment or arrhythmias are controlled. **IV dose:** *Infants and children:* load 5?mg/kg over 1?hr, then continuous infusion of 5–15?µg/kg/min. *Adults:* 150?mg over 10?min, then 0.5?mg/min.	*Cautions:* Use benzyl alcohol–free pr Minimize risk of torsades de pointes b potassium and magnesium. Inhibits c enzymes, so many drugs that are me markedly increased levels and effects theophylline, phenytoin, warfarin, othe methotrexate, and cyclosporine. *Adverse events:* Proarrhythmia (may or tachyarrhythmias or heart block); fa nightmares, behavioral changes; hyp hyperglycemia, elevated triglycerides (slate blue), photosensitivity, rash, liv fatal or just increased liver enzymes), (potentially fatal) includes pulmonary pneumonitis, hypersensitivity pneumo cough, fever, dyspnea, chest radiogra photophobia, thrombocytopenia. *Monitoring:* Pulmonary, liver, and thyr chest radiograph, ECG, eye examina and symptoms of toxicity. Amiodaron 2–4?µmol/L.

Amitriptyline hydrochloride Antidepressant, tricyclic; antimigraine agent. Elavil; Emitrip; Endep. Injection: 10?mg/mL (10?mL) Tablet: 10, 25, 50, 75, 100, 150?mg.	**Depression (increases CNS concentrations of serotonin and norepinephrine by inhibiting reuptake).** *Children:* 1–1.5?mg/kg/24?hr divided tid. *Adolescent:* 30–100?mg at bedtime or divided bid (max 200?mg/24?hr). *Adults:* 30–100?mg q 24?hr (max 300?mg/24?hr). **Analgesic for neuropathic or chronic pain or migraine prophylaxis.** *Children:* 0.1?mg/kg at bedtime and advance over 2–3 wk to effect. Maximum: 2?mg/kg at bedtime. *Adolescents:* 25?mg divided bid and increase dose to effect or max: dose: 200?mg/24?hr. *Adults:* start 25?mg at bedtime and increase to effect or max: dose: 300?mg/24?hr.	*Cautions:* Cardiac conduction abnorm monitor ECG. Do not discontinue abr withdrawal syndrome may occur. *Adverse events:* Dry mouth, constipat postural hypotension, drowsiness, co visual disturbance. *Monitoring:* Amitriptyline concentratio 100–250?ng/mL; nortriptyline concen 50–150?ng/mL.
Ammonium chloride Metabolic alkalosis, treatment agent: urinary acidifying agent. Generic. Injection: 26.75% [5?mEq/mL] (20?mL). Tablet: 500?mg. Tablet enteric coated: 500?mg.	**Systemic or urinary acidification (dissociation of ammonium and chloride then replacement of bicarbonate ions by chloride ions).** *Children:* 75?mg/kg/24?hr IV divided q6h (max: daily dose: 6?g). *Adults:* 1.5?g/dose IV q6h.	*Adverse events:* Hyperchloremia, hyp hyperkalemia.

Amrinone lactate Adrenergic agonist agent. Inocor. Injection: 5?mg/mL (20?mL).	**Treatment of low cardiac output states (increase cellular levels of cyclic AMP).** *Neonates:* 0.75?mg/kg IV bolus over 2–3?min then 3–5?µg/kg/min continuous infusion IV. *Infants and children:* 0.75?mg/kg IV bolus over 2–3?min then 5–10?µg/kg/min continuous infusion. *Adults:* 0.75?mg/kg IV bolus over 2–3?min then 5–10?µg/kg/min.	*Cautions:* Increased cardiac output m diuresis if diuretic doses are not adjus doses if clinical response is inadequa *Adverse events:* Hypotension, arrhyth thrombocytopenia.
Antihemophilic factor, human Antihemophilic agent; blood product derivative. Alphanate; Hemofil M; Humate-P; Koate-HP; Koate-HS; Monoclate-P; Profilate OSD. Injection (approximate factor VIII activity per vial): 200, 250, 500, 750, 1,000, 1,250, 1,500 units; exact potency labeled on each vial.	**Factor VIII deficiency in hemophilia (provides factor VIII).** *All patients:* Units required = weight (kg) × 0.5 × desired increase factor VIII (% of normal). *Adverse events:* Tachycardia, allergy, blood-borne viral infections.	*Monitoring:* Plasma antihemophilic fac
Antipyrine and benzocaine Otic agent, analgesic; otic agent, ceruminolytic. Allergan Ear Drops; Aurafair; Auralgan; Aurodex; Auroto; Oto; Otocalm Ear Solution, otic: antipyrine 5.4% and benzocaine 1.4% (10, 15?mL).	**Temporary relief of ear pain and inflammation (topical anesthetic and anti-inflammatory).** *All patients:* Fill ear canal, and then moisten cotton pledget and place into meatus. May repeat q1–2h until pain relief. Limit use to about 3 days.	*Adverse events:* Stinging, methemogl
Antithrombin III **Thrombate III**	**Antithrombin III deficiency due to disseminated intravascular coagulation or shock and surgery complications. Treatment of thrombosis in ATIII deficiency.** *All patients:* Dose (IU) = (120 – patient ATIII) × wt (kg).	*Monitoring:* Check ATIII levels: mainta 120%.

Antivenin (Crotalidae) polyvalent Antivenom. Generic. Injection: Lyophilized serum, diluent (10?mL); one vacuum vial to yield 10?mL of antivenom.	**Antivenom for snake bite from North and South American crotalids, i.e., rattlesnake, copperhead, cottonmouth, tropical moccasins, fer-de-lance, bushmaster.** Dosing based on severity of bite—mild: 5 vials, moderate: 10 vials, severe: > 15 vials.	*Cautions:* Sensitivity reactions, includ with epinephrine and antihistamine ar dose).
Arginine hydrochloride Diagnostic agent, growth hormone function; metabolic alkalosis, treatment agent. R-Gene. Injection: 10% [0.475?mEq chloride/mL] (500?mL).	**Pituitary function test (stimulates pituitary release of growth hormone and prolactin).** *Children:* 500?mg/kg over 30?min. *Adults:* 300?mL over 30?min.	*Adverse events:* Flushing, headache, hyperkalemia, metabolic acidosis. *Monitoring:* Plasma growth hormone (
Ascorbic acid Nutritional supplement; urinary acidifying agent; vitamin, water soluble. Ascorbicap; C-Crystals; Cecon; Cetane; Cevalin; Ce-Vi-Sol; Dull-C; Flavorcee; Vita-C. Capsule, timed-release: 500?mg. Crystals: 4?g/teaspoonful (1,000?g). Injection: 250?mg/mL (2?mL, 30?mL), 500?mg/mL (1, 2, 50?mL). Lozenge: 60?mg. Powder: 4?g/teaspoonful (1,000?g). Solution, oral: 35?mg/0.6?mL (50?mL), 100?mg/mL (50?mL). Syrup: 500?mg/5?mL (5, 10, 120, 480?mL). Tablet: 25, 50, 100, 250, 500, 1,000?mg. Tablet, chewable: 100, 250, 500, 1,000?mg. Tablet, timed release: 500, 1,000, 1,500?mg.	**Scurvy.** *Children:* 100–300?mg/24?hr. *Adults:* 100–250?mg bid. **Urinary acidification.** *Children:* 500?mg q6h. *Adults:* 4–12?g/24?hr in 3–4 divided doses.	*Adverse events:* Gastrointestinal ups

Asparaginase Antineoplastic agent, miscellaneous. Elspar. Injection: 10,000 units/vial.	**Cancer chemotherapy (inhibits protein synthesis to deprive cancer cells of asparagine).** *Children and adults:* Doses may vary depending on specific protocol being used; 6,000 units/m^2 IM, 3 times/wk for 3 wk as part of combination therapy. High-dose IM therapy: 25,000 units/m^2 /dose q wk × 9 doses. IV therapy: 1,000 units/kg/24?hr for 10 days; or 200 units/kg/24?hr × 28 days.	*Cautions:* Stop drug if any signs of re pancreatitis occur. Be prepared to tre dose. *Adverse events:* Myelosuppression (V mild and rare) onset, 7 days; nadir, 1 days. Hepatotoxicity, pancreatitis, gastroint azotemia, hyperglycemia, coagulopat
Aspirin Analgesic, non-narcotic; anti-inflammatory agent; antiplatelet agent; antipyretic; nonsteroidal anti-inflammatory agent (NSAID), oral; salicylate. Anacin; A.S.A.; Ascriptin; Aspergum; Bayer Aspirin; Bufferin; Easprin; Ecotrin; Empirin; Gensan; Halfrin; Measurin, ZORprin. Suppository, rectal: 60, 120, 125, 130, 195, 200, 300, 325, 600, 650, 1,200?mg. Tablet: 325, 500, 650?mg. Tablet, buffered: 325?mg with aluminum hydroxide 75?mg and magnesium hydroxide 75?mg; 325?mg with aluminum hydroxide 150?mg and magnesium hydroxide 150?mg; 500?mg with aluminum hydroxide 33?mg and magnesium hydroxide 150?mg. Chewable: 75, 81?mg. Chewing gum: 227?mg. Controlled release: 800?mg. Enteric coated (delayed release): 80, 165, 325, 500, 650, 975?mg. Timed release: 650?mg. Tablet, with caffeine: 400?mg and caffeine 32?mg; 500?mg and caffeine 32?mg.	**Pain, inflammation, fever (prostaglandin synthesis inhibition).** *Children:* 10–15?mg/kg/dose q4–6h. *Adults:* 650–1,000?mg/dose q4–6?hr (max: 4?g/24?hr). **Kawasaki disease (acute phase).** *Children:* 80–100?mg/kg/24?hr divided q6h. **Rheumatic fever.** 60–100?mg/kg/24?hr divided q6h.	*Cautions:* Contraindicated in children chickenpox or flu-like symptoms due syndrome. Discontinue if hearing loss *Adverse events:* Bleeding from gums tract, gastric ulcers, bronchospasm in loss, and tinnitus. *Monitoring:* Check serum concentratio for Kawasaki disease (target 150–30 fever (target: 250–400?µg/mL).

release): 80, 165, 325, 500, 650, 975?mg. Timed release: 650?mg. Tablet, with caffeine: 400?mg and caffeine 32?mg; 500?mg and caffeine 32?mg.		
Astemizole Antihistamine. Hismanal. Tablet: 10?mg.	**Allergy and rhinitis (competitive H_1 -receptor blocker).** *Children:* *<6 yr:* 0.2?mg/kg once daily. *6–12 yr:* 5?mg once daily. *>12 yr and adults:* 10–30?mg/24?hr.	*Cautions:* Syncopal episodes may be arrhythmias including QT interval pro fatal arrhythmias. Discontinue if ECG prolongation, syncopal episode, or dr metabolism (e.g., erythromycin, ketoc
Atenolol Antianginal agent; antihypertensive; ß-adrenergic blocker. Tenormin. Injection: 0.5?mg/mL (10?mL). Tablet: 25, 50, 100?mg.	**Hypertension, arrhythmias (competitive ß$_1$ -blocker).** *Children:* 0.8–1.5?mg/kg/24?hr (max: 2?mg/kg/24?hr). *Adults:* 25–200?mg/24?hr PO, 5?mg IV over 5?min.	*Cautions:* Avoid abrupt discontinuatio *Adverse events:* Bradycardia, letharg constipation, wheezing, dyspnea.
Atorvastatin calcium Lipitor. Tablet: 10, 20, 40?mg.	**Hypercholesterolemia, including homozygous familial hypercholesterolemia (inhibit HMG-CoA reductase).** *Children >6 yr:* 10–80?mg/24?hr. *Adults:* 10–80?mg/24?hr.	*Adverse events:* Dyspepsia, flatulenc hepatitis, myalgia, arthralgia. *Monitoring:* Plasma lipid profile.
Atracurium besylate Neuromuscular blocker agent, nondepolarizing; skeletal muscle relaxant, paralytic. Tracrium. Injection: 10?mg/mL (5, 10?mL).	**Neuromuscular blocker for muscle paralysis (binds to cholinergic receptor sites to block neural transmission).** *Children:* *<2 yr:* 0.3–0.4?mg/kg as needed. *>2 yr to adults:* 0.4–0.5?mg/kg then 1?mg/kg 20 to 45?min after each initial block to maintain effect. Continuous IV infusion: 0.4–0.8?mg/kg/hr.	*Cautions:* Make sure airway and resp secure before use. Contains benzyl a should be limited. Does not have sed properties, so adjunct sedative/analg *Monitoring:* Muscle twitch response tc stimulator.
Atropine sulfate Anticholinergic agent; anticholinergic agent, ophthalmic;antidote, organophosphate poisoning; antispasmodicagent, gastrointestinal; bronchodilator; ophthalmicagent, mydriatic. Atropair Ophthalmic; Atropine-Care Ophthalmic; Atropisol Ophthalmic; Isopto Atropine Ophthalmic; I-Tropine Ophthalmic; Ocu-Tropin. Ophthalmic injection: 0.05?mg/mL (5?mL); 0.1?mg/mL(5, 10?mL); 0.3?mg/mL (1, 30?mL); 0.4?mg/mL (1, 20, 30?mL); 0.5?mg/mL (1, 5, 30?mL); 0.8?mg/mL (0.5, 1?mL); 1?mg/mL (1, 10?mL). Ointment, ophthalmic: 0.5% (3.5?g); 1% (3.5?g). Solution, ophthalmic: 0.5% (1, 5?mL); 1% (1, 2, 5, 15?mL); 2% (1, 2?mL). Tablet: 0.4?mg. Tablet, soluble: 0.4, 0.6?mg.	**Preoperative medication to inhibit secretions and salivation (blocks action of acetylcholine and antagonizes histamine and serotonin).** *Neonates and children:* *<5?kg:* 0.2?mg/kg 30?min preop then q4–6h. *>5?kg:* 0.1–0.2?mg/kg/dose (max: 0.4?mg/dose). *Adults:* 0.4–0.6?mg IV or SC 30?min preoperatively. **Treatment of sinus bradycardia.** *Neonates and children:* 0.02?mg/kg (minimumdose: 0.1?mg); IV or intratracheal (max: 0.5?mg); may repeat 5?min later, one time. *Adults:* 0.5–1?mg every 5?min (maximum total dose: 2?mg). **Antidote to organophosphate poisoning.** 0.02–0.05?mg/kg q 10–20?min until atropine effect (tachycardia, mydriasis, fever), then q1–4h for at least 24?hr.	*Cautions:* Avoid in narrow angle glau obstruction, thyrotoxicosis, and tachy *Adverse events:* Tachycardia, palpita dry hot skin, tremor, impaired vision.
Attapulgite Antidiarrheal. Children's Kaopectate; Diasorb; Donnagel; Kaopectate Advanced Formula; Kaopectate Maximum Strength Caplets; K-Pec; Parepectolin; Rheaban. Caplet: 750?mg. Liquid: 600?mg activated attapulgite/15?mL (180, 240, 360, 480?mL); 750?mg activated attapulgite/15?mL (120?mL). Suspension: 600?mg/15?mL. Tablet, chewable: 300, 600, 750?mg.	**Uncomplicated diarrhea (absorbent action).** *Children:* *3–6 yr:* 300–750?mg/dose (max: 7 doses). *6–12 yr:* 600–1,500?mg/dose (max: 7 doses). *>12 yr and adults:* 1,200–3,000?mg/dose (max: 7 doses).	*Caution:* Do not use for diarrhea due enterocolitis, or toxigenic bacteria.

Auranofin Gold compound. Ridaura. Capsule: 3?mg [gold 29%].	**Treatment of active stage of rheumatoid or psoriatic arthritis (immunomodulating effect).** *Children:* Initial dose: 0.1?mg/kg/24?hr; usual maintenance dose: 0.15?mg/kg/24?hr in 1–2 doses (max: 0.2?mg/kg/24?hr). *Adults:* 6?mg/24?hr in 1–2 doses (max: 9?mg/24?hr in 1–3 doses).	*Adverse events:* Itching, skin rash, st proteinuria, alopecia, glossitis, leukop thrombocytopenia, hematuria, anemia eosinophilia, peripheral neuropathy, i angioedema, hepatotoxicity. *Monitoring:* Discontinue if WBC <4,00 granulocytes <1,500/mm^3 or platelets
Aurothioglucose Gold compound. Solganal. Suspension, sterile: 50?mg/mL [gold 50%] (10?mL).	**Treatment of active rheumatoid or psoriatic arthritis (immunomodulator).** *Children:* 0.25?mg/kg/dose wk 1, increase 0.25?mg/kg/dose every wk to maintenance dose 0.75–1.0?mg/kg/dose weekly (max: 25?mg/dose, total 20 doses). *Adults:* 10?mg wk 1, then 25?mg wk 2 and 3, then 50?mg/wk until cumulative dose 1?g given.	*Cautions:* Administer by deep IM inje *Adverse events:* Same as for auranof
Azatadine maleate Antihistamine. Optimine. Tablet: 1?mg.	**Treatment of allergy, allergic rhinitis, and urticaria (antihistamine, anticholinergic).** *Children <12 yr:* Not recommended. *Children >12 yr and adults:* 1–2?mg twice daily.	*Adverse events:* Sedation, dry mouth secretions

Azathioprine Immunosuppressant agent. Imuran. Injection, as sodium: 100?mg (10?mL). Tablet: 50?mg.	**Prevent transplant rejection.** *Children and adults:* initial 2–5?mg/kg/24?hr IV or PO, maintenance 1–3?mg/kg/24?hr. **Treatment of autoimmune diseases, e.g., lupus, arthritis, nephrotic syndrome.** (Inhibit synthesis of DNA, RNA, and proteins. Antagonize purine metabolism.) *Adults:* 1?mg/kg/24?hr × 6–8 wk.	*Cautions:* Chronic use causes increas and skin cancer. May cause irreversib suppression. Reduce dose to 25% of allopurinol used. *Adverse events:* Fever, chills, nausea thrombocytopenia, leukopenia, hepat
Baclofen Skeletal muscle relaxant, nonparalytic. Lioresal. Injection, intrathecal: 0.5?mg/mL (20?mL); 2?mg/mL (5?mL). Tablet: 10, 20?mg.	**Spasticity associated with MS or spinal cord lesions. Trigeminal neuralgia (inhibits transmission of monosynaptic and polysynaptic reflexes at the spinal cord level).** *Children: 2–7 yr:* 10–15?mg/24?hr divided q8h and titrate up q 3 days (max: 40?mg/24?hr PO). *Adults:* 5?mg q8h and gradually increase by 5?mg q 3 days (max: 80?mg/24?hr PO). Intrathecal (adults only).	*Caution:* Avoid abrupt discontinuation discontinue. *Adverse events:* Drowsiness, vertigo, ataxia, hypotonia.

Beclomethasone Adrenal corticosteroid; anti-inflammatory agent; corticosteroid, inhalant (oral); corticosteroid, nasal; glucocorticoid. Beclovent Oral Inhaler, Beconase AQ Nasal Inhaler, Beconase Nasal Inhaler, Vancenase AQ Inhaler, Vanceril Oral Inhaler. Inhalation: Nasal (Beconase, Vancenase): 42?µg/inhalation [200 metered doses] (16.8?g). Oral (Beclovent, Vanceril): 42?µg/inhalation [200 metered doses] (16.8?g). Spray, aqueous, nasal (Beconase AQ, Vancenase AQ): 42?µg/inhalation [200 metered doses] (25?g).	**Asthma (oral inhalation), rhinitis (nasal aerosol) (anti-inflammatory, immune modulator).** *Adults and children (inhaler):* 1–2 inhalations 2–4 times daily (maximum dose children: 10 puffs, adults: 20 puffs daily). *Adults and children (nasal spray):* 1 spray in each nostril 2–4 times daily	*Adverse events: Candida* in mouth, b nasal mucosa, cough, hoarseness, h *Monitoring:* Inhaled corticosteroids sh via an extender device for better lung local toxicity.
Benzocaine Local anesthetic, oral; local anesthetic, topical. Americaine; Anbesol Maximum Strength; Babee Teething Lotion: BiCOZENE; chigger tox; Dermaplast; Foille Plus; Hurricaine; Orabase-B; Orabase Gel; Orabase-O, Ora Jel Brace-Aid Oral Anesthetic; Ora Jel Maximum Strength; Ora Jel Mouth-Aid; Rhulicaine; Solar Caine; Unguentine. Topical: Aerosol: 5% (97.5?mL, 105?mL) 20% (20, 60, 120?g). Cream: 5% (30, 454?g); 6% (28.4?g). Gel 15% (7?g). Liquid: with benzyl benzoate and soft soap (30?mL). Lotion: 8% (90?mL). Ointment: 5% (3.5, 30?g).	**Temporary relief of pain associated with minor skin injuries (local anesthetic).** *Children and adults:* Apply to affected area as needed.	*Adverse events:* Local irritation or ser

Benzonatate Topical anesthetic. Tessalon Perles.	**Relief of nonproductive cough (topical anesthetic action).** *Children <10 yr:* Not indicated. *Children >10 yr and adults:* 100?mg tid or q4h to maximum of 600?mg/24?hr.	*Adverse events:* Sedation, numbness
Benzoyl peroxide Acne products, topical skin product. Benzoxyl; Benzac W; Clear by Design; Clearasil; Dermo Xyl; Desquam-X; Loroxide; Oxy-5; Panoxyl; Panoxyl-AQ; Persa-Gel; Phiso AC-BP; Vanoxide. Cleansing bar: 5% (120?g); 10% (120?g). Cleansing lotion: 5% (120?mL, 150?mL, 240?mL); 10% (120?mL, 150?mL). Cream: 5% (30?g); 10% (30?g, 45?g). Facial mask: 5%. Gel: 2.5% (45?g, 60?g, 90?g); 5% (45?g, 60?g, 90?g, 120?g); 10% (45?g, 60?g, 90?g, 120?g). Lotion: 5% (30?mL, 42.5?mL, 60?mL); 5.5% (25?mL); 10% (30?mL, 42.5?mL, 60?mL). Stick: 10%.	**Acne treatment (keratolytic and comedolytic effects and kill anaerobic bacteria).** *Children and adults:* Apply sparingly 1–3 times daily for 15?min. May increase strength and duration of exposure as tolerated.	*Adverse events:* Contact dermatitis, l or erythema.
Benztropine mesylate Anticholinergic agent: antidote, drug-induced dystonic reactions; anti-Parkinson agent. Cogentin. Injection: 1?mg/mL (2?mL). Tablet: 0.5?mg, 1?mg, 2?mg.	**Parkinsonism, drug-induced extrapyramidal reaction (block striatal cholinergic receptors).** *Children >3 yr:* 0.02–0.05?mg/kg/dose 1–2 times daily. *Adults:* 1–4?mg/24?hr 1–2 times daily.	*Adverse events:* Tachycardia, drowsi hallucinations, dry mouth, blurred visi

Benzylpenicilloyl-polylysine Diagnostic agent, penicillin allergy skin test. Pre-Pen. Injection: 0.25?mL.	**Adjunct to assessing the risk of penicillin hypersensitivity (elicits type 1 urticarial reactions by IgE-mediated reaction).** *Children and adults:* Scratch technique uses a 20-gauge needle to make a 3–5?mm scratch on dermis; apply a small drop of solution to scratch and rub it in gently with applicator. Intradermal injection of 0.1–0.2?mL of Pre-Pen and 0.9% saline in 2 sites at least 1 inch apart.	*Monitoring:* Scratch test is positive if a 5–15?mm or more occurs within 10?r positive in 5–15?min. Discontinue ant performing tests (hydroxyzine and dip least 4 days, astemizole for 6–8 wk).
Beractant Lung surfactant. Survanta. Suspension: 200?mg (8?mL).	**Prophylaxis and treatment of respiratory distress syndrome in premature infants (replace deficiency of endogenous surfactant).** *Neonates:* 4?mL/kg via endotracheal tube. May repeat q6h to a total of 4 doses. Rotate infant to right, then left and administer ½ dose on each side over 2–3?sec.	*Adverse events:* Bradycardia, hypote desaturation, pulmonary air leaks, air pulmonary hemorrhage, hypocarbia. *Monitoring:* Heart rate, oxygen satura arterial blood gases. Adjust ventilator of hyperoxia and hypocarbia.

Betamethasone Adrenal corticosteroid; anti-inflammatory agent; corticosteroid, systematic; corticosteroid, topical; glucocorticoid. Alphatrex Topical; Betalene Topical; Betatrex Topical; Beta Val Topical; Celestone Oral, Celestone Phosphate Injection; Celestone Soluspan; Cel-U-Jec Injection; Diprolene AF Topical; Diprolene Topical; Diprosone Topical; Maxivate Topical; Psorion Topical; Selestoject Injection; Teledar Topical; Uticort Topical; Valisone Topical. Base (Celestone): Syrup: 0.6?mg/5?mL. Tablet: 0.6?mg. Benzoate (Uticort): Cream, emollient base: 0.025% (60?g). Gel, topical: 0.025% (15?g, 60?g). Lotion: 0.025% (60?mL). Dipropionate (Alphatrex, Diprosone, Maxivate, Tela Dar): Aerosol, topical: 0.1% (85?g). Cream: 0.05% (15, 45?g). Lotion: 0.05% (20, 30, 60?mL). Ointment, topical: 0.05% (15, 45?g). Diproprionate (Psorion): Cream: 0.05% (15, 45?g). Dipropionate, augmented (Diprolene, Diprolene AF): Cream, emollient base: 0.05% (15?g, 45?g). Gel, topical: 0.05% (15, 45?g). Lotion: 0.05% (30, 60?mL). Ointment, topical: 0.05% (15, 45?g). Valerate (Betatrex, Beta-Val, Valisone): Cream: 0.01% (15, 60?g); 0.1% (15, 45, 110, 430?g). Lotion: 0.1% (20?mL, 60?mL).	**Systemic use to stimulate fetal lung maturation in preterm labor. Topical use to treat inflammatory dermatoses.** *Children and adults:* Topical application of thin film to affected area 2–4 times daily. *Pregnant female:* 12?mg IM q24h for 2 doses.	*Adverse events:* Maternal pulmonary hypertension, headache.

Valerate (Betatrex, Beta-Val, Valisone): Cream: 0.01% (15, 60?g); 0.1% (15, 45, 110, 430?g). Lotion: 0.1% (20?mL, 60?mL). Ointment, topical: 0.1% (15?g, 45?g). Powder for compounding: 5, 10?g. Sodium phosphate (Celestone Phosphate, Selestoject): Injection: Equivalent to 3?g/mL (5?mL). Sodium phosphate and acetate (Celestone Soluspan): Injection, suspension: 6?mg/mL [3?mg betamethasone and betamethasone sodium phosphate and 3?mg betamethasone acetate per mL] (5?mL).		
Bethanechol Cholinergic agent. Duvoid; Myotonachol, Urecholine. Injection: 5?mg/mL (1?mL). Tablet: 5, 10, 25, 50?mg.	**Treatment of nonobstructive urinary retention or gastroesophageal reflux (stimulate cholinergic receptors in smooth muscle in urinary and gastrointestinal tracts).** *Children:* 0.3–0.6?mg/kg/24?hr divided into 3–4 doses. *Adults:* 10–50?mg 2–4 times/24?hr.	*Adverse events:* Hypotension, abdom vomiting, salivation, urinary frequency constriction, sweating.
Biotin Biotinidase deficiency; treatment agent; vitamin, water soluble. Biotin Forte; Biotin Forte Extra Strength; Bio-Tn; d-Biotin. Tablet: 300, 400, 600, 800?µg; 2.5, 3, 5, 10?mg.	**Treatment of primary biotinidase deficiency or nutritional biotin deficiency, component of vitamin B complex (required for various metabolic functions).** *Children and adults:* Biotin deficiency: 5–20?mg once/24?hr. Biotinidase deficiency: 5–10?mg once daily.	

Bisacodyl Laxative, stimulant. Bisacodyl Uniserts; Bisco-Lax; Carter's Little Pills; Clysodrast V; Dulcagen; Dulcolax; Fleet laxative. Enema: 10?mg/30?mL. Powder: 1.5?mg with tannic acid 2.5?g per packet (25?s, 50?s). Suppository, rectal: 5, 10?mg. Tablet, enteric coated: 5?mg.	**Treatment of constipation (direct smooth muscle irritation to stimulate gastrointestinal peristalsis).** *Children:* <2 yr: 5?mg rectal suppository. *>2 yr:* 10?mg rectal suppository. *>6 yr:* 5–10?mg PO at bedtime or before breakfast. *Adults:* 5–30?mg PO dose, 10?mg rectal suppository.	*Adverse events:* Fluid and electrolyte cramps.
Bismuth subsalicylate Antidiarrheal, gastrointestinal agent, gastric or duodenal ulcer treatment. Bismatrol; Pepto-Bismol. Liquid: 262?mg/15?mL (120?mL, 240?mL, 360?mL, 480?mL); 524?mg/15?mL (120, 240, 360?mL). Tablet, chewable: 262?mg.	**Treatment of diarrhea or gastrointestinal ulcer (adsorbs extra water and toxins in large intestine and kills bacterial pathogens).** *Children or adults:* Up to 8 doses/24?hr. *3–6 yr:* ? tablet or 5?mL. *6–9 yr:* ? tablet or 10?mL. *9–12 yr:* 1 tablet or 15?mL. *Adults:* 2 tablets or 30?mL.	*Cautions:* Avoid in patients with influe because of salicylate content. *Adverse events:* Discoloration of tong stools.
Bleomycin Antineoplastic agent, antibiotic type. Blenoxane. Powder for injection: 15 units.	**Palliative treatment for several cancers and sclerosing agent for malignant effusions (inhibit synthesis of DNA).** *Children and adults:* 10–20 units/m^2 /dose IV, IM, SC (0.25–0.5 unit/kg) 1–2 times per wk in combination regimens.	*Cautions:* Reduce dose in renal dysfu *Adverse events:* Interstitial pneumoni nonproductive cough, phlebitis, leuko thrombocytopenia, stomatitis, vomitin hyperkeratosis of hand and nails, des phenomenon; avoid oxygen use.

Bretylium Antiarrhythmic agent, class III. Bretylol. Injection: 50?mg/mL (10?mL, 20?mL); 100?mg/mL. Injection, premixed in D_5 W: 1?mg/mL (500?mL); 2?mg/mL (250?mL); 4?mg/mL (250, 500?mL).	**Treatment of serious or life-threatening arrhythmias (inhibits release of norepinephrine at postganglionic nerve endings).** *Children:* 2–5?mg/kg IV or IM, may repeat q 10–20?min to maximum 30?mg/kg. *Adults:* Initial dose 5?mg/kg, then 10?mg/kg q 15–30?min to maximum 35?mg/kg. Note: Cardioversion/defibrillation must be attempted before and after each dose of bretylium.	*Adverse events:* Hypotension, increas ventricular contractions, bradycardia, sweating, hiccups. *Monitoring:* ECG, blood pressure.
Brompheniramine Antihistamine. Bromarest, Bromphen Elixir, Chlorphed, Cophene-B Injection, Dehist Injection, Dimetane Oral, Nasahist B Injection, ND-Stat Injection, Oraminic II Injection, Sinusol-B Injection, Veltane Tablet. Elixir: 2?mg/5?mL with alcohol 3% (120, 480, 4,000?mL). Injection: 10?mg/mL (10?mL). Tablet: 4, 8, 12?mg. Tablet, sustained release: 8, 12?mg.	**Treatment of allergic symptoms, e.g., rhinitis and urticaria (competes with histamine for H_1 -receptor sites).** *Children: <6 yr:* 0.125?mg/kg/dose q6h (max: 8?mg/24?hr) PO. *6–12 yr:* 2–4?mg/dose q6–8h (max: 16?mg/24?hr) PO. *Adults:* 4–8?mg/dose q4–6h (max: 24?mg/24?hr) PO. IV, IM, SC route: *<12 yr:* 0.5?mg/kg/24?hr divided q6h. *>12 yr:* 10?mg/dose (max: 40?mg/24?hr).	*Adverse events:* Sedation, dry mouth
Budesonide Adrenal corticosteroid; anti-inflammatory agent; corticosteroid, nasal, glucocorticoid. Rhinocort. Aerosol: 50?µg released per actuation to deliver ~32?µg to patient via nasal adapter [200 metered doses] (7?g). Pulmicort Turbohaler (dry powder inhaler). Inhalation powder 200?µg/inhalation.	**Treatment of chronic rhinitis or asthma (suppress inflammation).** *Children >6 and adults:* Rhinocort nasal spray 2 puffs in each nostril twice daily or 4 puffs in each nostril once daily. *Children >6 yr:* Pulmicort Turbohaler 1–2 Inhalations bid. *Adults:* 1–4 inhalations bid.	*Adverse events:* Oral thrush, dysphor rinsing mouth after dose).
Bumetanide Antihypertensive; diuretic, loop. Bumex Injection: 0.25?mg/mL (2, 4, 10?mL). Tablet: 0.5, 1, 2?mg.	**Management of edema or fluid overload states (prevent sodium and chloride reabsorption at the ascending loop of Henle and proximal tubule).** PO, IV, IM: *Neonates:* 0.01–0.05?mg/kg/dose q 24–48h. *Infants and children:* 0.015–0.1?mg/kg/dose q6–24h (max: 10?mg/24?hr). *Adults:* 0.5–2?mg/dose (max: 10?mg/24?hr).	*Adverse events:* Electrolyte depletion
Bupivacaine Local anesthetic, injectable. Marcaine, Sensorcaine, Sensorcaine-MPF Bupivacaine. Injection: Preservative free: 0.25% [2.5?mg/mL]; 0.5% [5?mg/mL]; 0.75% [7.5?mg/mL]. With preservative: 0.25% [2.5?mg/mL]; 0.5% [5?mg/mL]. Bupivacaine and epinephrine [2:2 million] injection: Preservative free: 0.25% [2.5?mg/mL]; 0.5% [5?mg/mL]; 0.75% [7.5?mg/mL]. With preservative: 0.25% [2.5?mg/mL]; 0.5% [5?mg/mL]. Bupivacaine in dextrose [8.25% injection (spinal): Preservative free: 0.75% [7.5?mg/mL].	**Local anesthetic (block initiation and conduction of nerve impulses by decreasing permeability of neuron to sodium ions).** Caudal Block *Children:* 1–3.7?mg/kg. *Adults:* 15–30?mL of 0.25% or 0.5%. Epidural Block *Children:* 1.25?mg/kg/dose. *Adults:* 10–20?mL of 0.25% or 0.5%. Peripheral nerve block: 5?mL dose of 0.25% (12.5?mg) or 0.5% (25?mg); max: 400?mg/24?hr. Sympathetic nerve block: 20–50?mL of 0.25% (no epinephrine).	*Cautions:* Excess doses may result ir bradyarrhythmias, metabolic acidosis methemoglobinemia. Avoid epinephri near end artery since risk of necrosis.

Bupropion Antidepressant. Wellbutrin. Tablet: 75, 100?mg.	**Depression, attention deficit disorder, smoking cessation (block serotonin activity and norepinephrine reuptake).** *Children:* Anecdotal experience had benefits at 75–100?mg 2–3 times/24?hr. *Adults:* Begin 100?mg twice daily and may gradually increase to maximum of 450?mg/24?hr.	*Adverse events:* Agitation, insomnia, confusion, anxiety, seizures, akathisia mouth, constipation, nausea, vomiting
Busulfan Antineoplastic agent, alkylating agent. Myleran. Tablet: 2?mg.	**Treatment of chronic myelogenous leukemia (CML) or as part of marrow ablation conditioning before bone marrow transplant (interferes with DNA alkylation).** *Children:* (for CML remission) 0.06–0.12?mg/kg/24?hr; titrate dose to keep leukocyte count >40,000/mm^3 ; (for BMT conditioning) 1?mg/kg/dose q6h for 16 doses. *Adults:* (for CML remission) 0.06?mg/kg/24?hr.	*Adverse events:* Severe pancytopenia thrombocytopenia, and bone marrow 7–10 days; nadir, 14–21 days; recove *Monitoring:* CBC with differential and (discontinue if WBC <20,000/mm^3). I function tests.
Caffeine, citrated Central nervous system stimulant, nonamphetamine; respiratory stimulant. Tablet: 65?mg [anhydrous caffeine 32.5?mg], caffeine citrate, caffeine benzoate.	**Treatment of apnea of prematurity (stimulate central inspiratory drive and sensitivity to carbon dioxide).** *Neonates:* PO or IV (citrate or benzoate). Dose as caffeine base: loading dose 10?mg/kg. Maintenance dose: 5–10?mg/ kg/24?hr as 1 or 2 doses/24?hr.	*Cautions:* Sodium benzoate displaces and should be avoided in neonates w bilirubin. *Adverse events:* Tachycardia, agitatic irritation. *Monitoring:* Caffeine concentrations: t >10?µg/mL; toxic >50?µg/mL.

Calcifediol 25-hydroxycholecalciferol; 25-hydroxyvitamin D_3 ; vitamin D analog. Calderol. Capsule: 20, 50?µg.	**Treatment of metabolic bone disease associated with chronic renal failure (regulates serum calcium homeostasis as a vitamin D analog).** *Infants:* 5–7?µg/kg/24?hr. *Children and adults:* 20–100?µg/kg daily or every other day titrated to obtain normal serum calcium and phosphate levels.	*Cautions:* Avoid in hypercalcemia, hy malabsorption states. Ensure adequa during use. *Adverse events:* Hypercalcemia, gast intolerance.
Calcitriol Vitamin D analog; 1,25 dihydroxycholecalciferol, vitamin, fat soluble. Calcijex, Rocaltrol. Capsule: 0.25, 0.5?µg. Injection: 1?µg/mL (1?mL); 2?µg/mL (1?mL).	**Treatment of hypocalcemia and metabolic bone disease, reduce elevated parathyroid hormone levels, decrease severity of psoriatic lesions in psoriatic vulgaris (regulate serum calcium homeostasis and increase calcium absorption).** *Premature infants* (hypocalcemia): 0.05?µg/kg/24?hr IV or 1?µg/24?hr PO. *Children:* 0.01–0.08?µg/kg/24?hr. *Adults:* 0.25–1?µg/24?hr.	*Adverse events:* Hypercalcemia, vitar

Drug	Indication and dosage	Cautions / Adverse events / Monitoring
Calcium salts (PO and IV) Calcium carbonate Elemental calcium listed in brackets. Antacid; calcium salt; electrolyte supplement, oral Alka-Mints, Cal-Plus, Mylanta, Os-Cal, Tums. Capsule: 1,500?mg [600?mg]. Liquid: 1,000?mg/5?mL (360?mL). Cardiac Arrest Lozenge: 600?mg [240?mg]. Powder: 6.5?g/packet [2.6]. Suspension, oral: 1,250?mg/5?mL [500?mg]. Tablet: 650?mg [260?mg], 1,500?mg [600?mg] Tablet, chewable.	**Hypocalcemic tetany, cardiac disturbances of hyperkalemia (moderate nerve and muscle performance).** Hypocalcemic Tetany *Neonates:* 2.4?mEq/kg/24?hr in divided doses (if due to citrated blood transfusion give 0.45?mEq/dL transfused blood). *Infants and children:* 10?mg/kg over 5–10?min (may repeat in 6–8?hr) followed by infusion with maximum of 200?mg/kg/24?hr. *Adults:* 4.5–16?mEq repeated until response. *Infants and children:* 20?mg/kg IV and may repeat in 10?min. *Adults:* 2–4?mg/kg repeated every 10?min as needed.	*Caution:* Make sure of IV access site burns; bradycardia. *Adverse events:* Constipation, hyperc syndrome. *Monitoring:* Continuous ECG; serum and magnesium levels. **Calcium Content of Salts** Salt — Mg of Calcium of Salt (Elemental) Ca carbonate — 4 Ca chloride — 2 Ca glubionate Ca gluceptate Ca gluconate Ca lactate Ca phosphate — 3
Calcium chloride Calcium salt, electrolyte supplement, parenteral. Cal Plus. Elemental calcium listed in brackets. Injection: 10% = 100?mg/mL [27.2?mg/mL] (10?mL) (1.4?mEq calcium/mL).	**Prevention of calcium depletion, relief of acid indigestion (source of calcium and neutralizes acid).** *Children:* *<6 mo:* 400?mg/24?hr. *6–12 mo:* 600?mg/24?hr. *1–5 yr:* 800?mg/24?hr. *6–10 yr:* 800–1,200?mg/24?hr. *>10 yr and adult:* 1,000–1,500?mg/24?hr.	
Calcium glubionate Calcium Salt; Electrolyte Supplement, Oral. Neo-Calglucon. Syrup: 1.8?g/5?mL [115?mg/5?mL] (480?mL) (1.2?mEq calcium/mL).		

Drug	Indication and dosage	Cautions / Adverse events
Capsaicin Analgesic, topical; topical skin product. R-Gel, Zostrix-HP Topical, Zostrix Topical. Cream: 0.025% (45, 90?g); 0.075% (30, 60?g). Gel: 0.025% (15, 30?mL).	**Topical treatment of pain associated with postherpetic neuralgia, rheumatoid arthritis, osteoarthritis, diabetic neuropathy, and postsurgical pain (induces release of substance P depleting peripheral nerves and preventing reaccumulation).** *Children >2 yr and adults:* Apply to affected area at least 3–4 times daily.	*Adverse events:* Local itching, stingin erythema.
Calfactant Infasurf Intratracheal suspension of calf lung surfactant (35?mg phospholipids, 0.65?mg proteins, 0.26?mg SP-B/mL)	**Prophylaxis or treatment of respiratory distress syndrome, treatment of persistent pulmonary hypertension.** *Neonates:* 3?mL/kg/dose 1–4 times q12h *Children and adults:* Not indicated	*Caution:* Monitor ventilator status clos weaning within minutes of the dose. *Adverse events:* Bradycardia, airway cyanosis.
Captopril Angiotensin-converting enzyme (ACE) inhibitors; antihypertensive. Capoten. Tablet: 12.5, 25, 50, 100?mg.	**Management of hypertension and treatment of heart failure (ACE inhibitor).** *Premature newborns:* 0.01?mg/kg q8–12h. *Neonates:* Initial 0.05–0.1?mg/kg/dose q8–24h and titrate upward to response (max: 0.5?mg/kg/dose q6–24h). *Infants:* Initial 0.15–0.3?mg/kg/dose; and titrate upward (max: 6?mg/kg/24?hr in 1–4 divided doses). *Children:* Initial 0.3–0.5?mg/kg/dose and titrate upward (max: 6?mg/kg/24?hr divided into 2–4 doses). *Older children:* Initial 6.25–12.5?mg/kg/dose q12–24h then titrate (max: 6?mg/kg/24?hr in 2–4 doses). *Adolescents and adults:*	*Cautions:* Use with caution in renal ar patients with volume depletion. *Adverse events:* Cough, angioedema hyperkalemia.

	Older children: Initial 6.25–12.5?mg/kg/dose q12–24h then titrate (max: 6?mg/kg/24?hr in 2–4 doses). *Adolescents and adults:* Initial 12.5–25?mg/ dose and titrate (max: 450?mg/24?hr).	
Carbamazepine Anticonvulsant, miscellaneous. Epitol, Tegretol. Suspension, oral (citrus-vanilla flavor): 100?mg/5?mL (450?mL). Tablet: 200?mg. Tablet, chewable: 100?mg. Tegretol XR: 100, 200, 400?mg (sustained-release product).	**Treatment of generalized tonic-clonic and partial seizures, pain relief in trigeminal neuralgia and diabetic neuropathy, bipolar disorders (limit influx of sodium ions across cell membranes or other unknown mechanisms).** *Children:* *<6 yr:* initial 5?mg/kg/24?hr in 2–4 divided doses; may increase q 5–7 days by 5?mg/kg based on effect or toxicity and serum concentration. *6–12 yr:* initial 10?mg/kg/24?hr in 2–4 divided doses; increase by 100?mg or 5?mg/kg/24?hr at weekly intervals until therapeutic levels are achieved (usual dose: 800–1,200?mg/24?hr). *Adults:* Initial 200?mg twice daily; increase by 200?mg at weekly intervals until therapeutic levels are achieved (usual dose 1.6 to 2.4?g/24?hr in 3–4 divided doses).	*Caution:* Avoid in patients with bone r may cross-react in patients with tricyc hypersensitivity. *Adverse events:* Sedation, dizziness, confusion, nausea, vomiting, blurred bone marrow depression, leukopenia thrombocytopenia, pancytopenia, apl hepatitis, hypersensitivity reactions. *Monitoring:* Serum concentrations co response (6–12?µg/mL), and neurolo (>8?µg/mL but particularly >12?µg/m requirements will increase over first 4 hepatic enzyme induction by carbam serum concentrations to increase dos

Carbamide peroxide Otic agent, ceruminolytic. Auro Ear Drops, Gly-Oxide Oral, Proxigel Oral, Murine Ear Drops. Gel, oral: 11% (36?g). Solution, oral: 10% in glycerin (15, 22.5, 30, 60?mL). Otic: 6.5% in glycerin (15, 30?mL).	**Relief of minor inflammation of oral mucosa including gums and lips, and removal of ear wax (release of hydrogen peroxide, which inhibits bacteria and softens ear wax).** *Children and adults:* *Gel:* Gently massage on affected area 4 times daily. Oral solution: Apply several drops to affected area 4 times daily for up to 7 days. (expectorate 2–3?min after each use). Otic solution: Tilt head sideways and instill 5–10 drops bid for up to 4 days. Keep drops in ear canal for several minutes by tilting head and placing cotton in ear.	*Adverse events:* Local irritation.
Carbinoxamine and pseudoephedrine Antihistamine/decongestant combination. Carbiset Tablet; Carbodec Syrup; Rondec Drops. Drops: carbinoxamine maleate 2?mg and pseudo-ephedrine hydrochloride 25?mg/mL (30?mL with dropper). Syrup: carbinoxamine maleate 4?mg and pseudo-ephedrine hydrochloride 60?mg/5?mL (120, 480?mL). Tablet: Film-coated: carbinoxamine maleate 4?mg and pseudoephedrine hydrochloride 60?mg. Sustained release: carbinoxamine maleate 8?mg and pseudoephedrine hydrochloride 120?mg.	**Temporary relief of nasal congestion, runny nose, sneezing, and allergy symptoms (antihistamine as H_1 -blocker, and decongestant as a- and ß-receptor stimulant).** *Children:* Dose 4 times daily: *1–3 mo:* ¼ dropper (0.25?mL). *3–6 mo:* ½ dropper (0.5?mL). *6–9 mo:* ¾ dropper (0.75?mL). *9–18 mo:* 1 dropper (1.0?mL). *18 mo–6 yr:* 2.5?mL syrup. *6–12 yr:* 5?mL syrup or 1 tablet. *Children >12 yr and adults:* 1 tablet 4 times daily, or 1 sustained-release tablet twice/24?hr.	*Cautions:* Avoid in narrow angle glau disease, gastrointestinal or genitourin monoamine oxidase inhibitor therapy. *Adverse events:* Hypertension, tachy sedation, thickening of bronchial secr

Carboplatin Antineoplastic agent, alkylating agent. Paraplatin powder for injection, lyophilized: 50, 150, 450?mg.	**Treatment of multiple tumors including pediatric brain tumor and neuroblastoma (platination of DNA interferes with DNA function).** *Children:* Solid tumor: 300–600?mg/m^2 IV once q 4 wk. Brain tumor: 175?mg/m^2 IV once wk for 4 wk (2 wk recovery period between courses). *Adults:* 360?mg/m^2 IV once q 4 wk.	*Adverse events:* Neutropenia, leukop thrombocytopenia, peripheral neurop abnormal liver and renal function, alo vomiting. *Monitoring:* Neutrophil and platelet co selection as follows: platelets <50,00 <500/mm^3 : give 75% of recommende days post dose).
Carmustine Antineoplastic agent, alkylating agent (nitrosourea). BiCNU powder for injection: 100?mg/vial packaged with 3?mL of absolute alcohol for use as a sterile diluent.	**Treatment of cancers including brain tumor, Hodgkin disease and non-Hodgkin lymphoma, and multiple myeloma (inhibits key enzymatic reactions involved in DNA synthesis).** *Children:* 200–250?mg/m^2 IV q 4–6 wk as a single dose. *Adults:* 150–200?mg/m^2 IV q 6 wk as a single dose.	*Adverse events:* Nausea, vomiting, m (nadir 4–6 wk post dose), alopecia, st diarrhea, dizziness, ataxia, pulmonar renal dysfunction, retinitis, optic neuri

Carnitine Dietary supplement. Carnitor, Vitacarn. Capsule: 250?mg. Injection: 1?g/5?mL (5?mL). Liquid (cherry flavor): 100?mg/mL (10?mL). Tablet: 330?mg.	**Treatment of carnitine deficiency and improve utilization of IV fat emulsions by premature infants (facilitates long-chain fatty acid entry into the mitochondria and required in energy metabolism).** *Premature infants:* 8–16?mg/kg/24?hr IV infusion. *Children:* 50–100?mg/kg/24?hr in 2–3 divided doses PO, 50?mg/kg/dose q4–6h IV (max: 300?mg/kg/24?hr). *Adults:* 0.33–1?g/dose 2–3 times daily PO, 50?mg/kg/dose q4–6h (max: 300?mg/kg/24?hr).	*Adverse events:* Nausea, vomiting, al body odor.
Carvedilol Coreg. Tablet: 3.125, 6.25, 12.5, 25?mg.	**ß-Receptor blocker with vasodilator activity, used to treat congestive heart failure or hypertension.** *Children:* Initial dose 0.08?mg/kg and gradual increase dose over 2–3 mo based on response to maximum 0.5?mg/kg/24?hr divided q12h.	*Caution:* May cause AV block, arrhyth worsen asthma or heart failure. *Drug interactions:* May cause excessi used with other antihypertensives.
Cascara sagrada Laxative, stimulant. Liquid, aromatic fluid extract: 5, 120?mL. Tablet: 325?mg.	**Temporary relief of constipation (direct chemical irritation of gastrointestinal mucosa).** *Infants:* 1.25?mL once daily. *Children 2–11 yr:* 2.5?mL once daily. *>12 yr and adults:* 5?mL once daily.	*Cautions:* Fecal impaction, gastrointe gastrointestinal bleeding. Onset of eff at bedtime. *Adverse events:* Gastrointestinal cram red or brown.
Castor oil Laxative, Stimulant. Alphamul, Emulsoil, Fleet, Purge. Emulsion, oral; Liquid, oral: 100% (60, 120, 480?mL).	**Bowel or rectal evacuation for surgery (stimulates peristalsis).** *Infants <2 yr:* 1–5?mL single dose. *Children 2–11 yr:* 5–15?mL. *>12 yr and adults:* 15–60?mL	*Adverse events:* Electrolyte disturban cramps.

Charcoal Adsorbent, antidote. Actidose-Aqua, Actidose with Sorbitol, Charcocaps.	**Emergency treatment of poisoning by certain drugs and chemicals; gastrointestinal dialysis to promote elimination of certain drugs and toxins; treat diarrhea (adsorb toxic substance; interfere with enterohepatic recycling of certain drugs).** *Children and adults:* 1–2?g/kg or 5–10 times the weight of the ingested poison (limit sorbitol to 1–2 times daily); may repeat doses q2–6h.	*Adverse events:* Constipation, black s
Chloral hydrate Hypnotic; sedative. Noctec; capsules: 250, 500?mg. Syrup: 250, 500?mg/5?mL. Suppository: 324, 500, 648?mg.	**Short-term sedative/hypnotic (mechanism unknown).** *Neonates:* 25?mg/kg/dose. *Infants and children:* 25–100?mg/kg/dose. *Adults:* 250–1,000?mg/dose. Doses may be repeated q6–8h. Lower-end doses cause sedation; higher-end doses cause hypnosis.	*Cautions:* Repeat doses in neonates accumulation of active metabolite tric which can cause hepatic toxicity and
Chlorambucil Antineoplastic alkylating agent. Leukeran, 2-mg tablet.	**Management of various cancers including Hodgkin and non-Hodgkin lymphoma, and chronic lymphocytic leukemia; and nephrotic syndrome (alkylation interferes with DNA replication and RNA transcription).** *Children and adults:* 0.1–0.2?mg/kg/24?hr for 3–6 wk. Longer treatment doses are adjusted based on blood counts.	*Adverse events:* Bone marrow suppre nadir, 10–14 days; recovery, 28 days hyperuricemia, nausea, vomiting, diar pulmonary fibrosis, hepatic necrosis,
Chlorothiazide Diuretic. Generic tablets: 250, mg 500?mg; suspension: 250?mg/5?mL; powder for injection: 500?mg.	**Treatment of fluid overload states and hypertension (inhibits sodium reabsorption in distal tubule).** *Neonates and infants <6 mo:* PO: 20–40?mg/kg/24?hr divided q12h; IV: 2–8?mg/kg/24?hr divided q12h. *Infants >6 mo and children:* PO: 20?mg/kg/24?hr in 2 divided doses; IV: 4?mg/kg/24?hr. *Adults:* PO: 500?mg–2?g/24?hr in 1–2 doses; IV: 500–1,000?mg/24?hr.	*Adverse events:* Hypokalemia, hypoc hyperglycemia, hyperlipidemia, hyper hyperuricemia, leukopenia, prerenal a
Chlorpheniramine maleate Antihistamine, generic. Capsule: 12?mg; timed-release capsule: 6, 8, 12?mg; syrup: 2?mg/5?mL; tablet: 4, 8, 12?mg; chewable tablet: 2?mg; timed-release tablet: 8, 12?mg.	**Treat allergic symptoms (compete with histamine for H_1 -receptor sites).** *Children: 2–6 yr:* 1?mg q4–6h. *6–12 yr:* 2?mg q4–6h or sustained-release 8?mg at bedtime. *>12 yr and adults:* 4?mg q4–6h or sustained-release 12?mg at bedtime.	*Adverse events:* Drowsiness, excitati children), dry mouth, blurred vision.

Chlorpromazine Phenothiazine. Thorazine. Capsule: 30, 75, 150, 200, 300?mg. Oral concentrate: 30?mg/mL, 100?mg/mL. Suppository: 25, 100?mg. Syrup: 10?mg/5?mL. Tablet: 10, 25, 50, 100, 200?mg. Injection: 25?mg/mL.	**Treatment of psychosis, mania, Tourette syndrome, behavioral problems, nausea, and vomiting (blocks postsynaptic mesolimbic dopaminergic receptors in the brain, strong a-adrenergic blocking effect).** *Children >6 mo:* PO: 0.5–1?mg/kg/dose q4–6h; rectal: 1?mg/kg/dose q6–8?h; IM or IV: 0.5–1?mg/kg/dose q6–8h. *Adults:* Psychosis: PO: 30–800?mg/24?hr in 1–4 divided doses (start low and titrate up to effect); IV or IM: 25?mg initial dose and titrate up to effect (maximum: 400?mg/dose q4–6h). Nausea or vomiting: PO: 10–25?mg q4–6h. IM or IV: 25–50?mg q4–6?h. Rectal: 50–100?mg q6–8h.	*Adverse events:* Hypotension, tachyc pseudoparkinsonism, tardive dyskine dystonias, constipation, nasal conges malignant hyperpyrexia. *Monitoring:* Chlorpromazine concentr 50–300?ng/mL; toxic >750?ng/mL.
Chlorpropamide Sulfonylurea. Diabinese. Tablet: 100, 250?mg.	**Control blood sugar in non–insulin-dependent diabetes mellitus (type II)** (stimulate insulin release from pancreatic islet cells). *Adults:* Initial 250?mg once daily, may increase to response by 125?mg q 3–5 days to response (max: 750?mg/24?hr).	*Adverse events:* Gastrointestinal prob hepatotoxicity, hyponatremia, SIADH

Chlorthalidone Thiazide diuretic. Hygroton. Tablet: 20, 25, 100?mg.	**Treatment of fluid overload and mild hypertension (inhibits sodium and chloride reabsorption in the cortical-diluting segment of the ascending loop of Henle).** *Children:* 1–2?mg/kg once daily. *Adults:* 25–100?mg once daily.	*Adverse events:* Photosensitivity, fluic imbalance, hypokalemia.
Chlorzoxazone Skeletal muscle relaxant. Parafon Forte, Paraflex. Tablet: 250, 500?mg.	**Symptomatic relief of muscle spasm and pain (depress polysynaptic reflexes at spinal cord and subcortical levels).** *Children:* 20?mg/kg/24?hr in 3–4 divided doses. *Adults:* 250–500?mg 3–4 times daily.	*Adverse events:* Drowsiness.
Cholestyramine resin Antilipemic agent. Questran. Powder: 4?g resin/9?g powder.	**Management of elevated cholesterol (forms a nonabsorbable complex with bile salts and low-density lipoprotein-cholesterol).** *Children:* 240?mg/kg/24?hr in 3 divided doses. *Adults:* 4?g/dose 1–6 times daily.	*Adverse events:* Hyperchloremic acid nausea, vomiting, abdominal pain anc malabsorption of fat-soluble vitamins.
Choline magnesium trisalicylate Nonsteroidal anti-inflammatory agent (NSAID). Trilisate. Liquid: 500?mg salicylate/5?mL. Tablet: 500, 750, 1,000?mg.	**Management of arthritis disorders (inhibit prostaglandin synthesis).** *Children:* 30–60?mg/kg/24?hr in 3–4 divided doses. *Adults:* 500–1,500?mg/dose 1–3 times daily.	*Cautions:* Avoid in patients with suspe varicella infections due to risk for Rey asthmatics and others at risk for serio reactions. *Adverse events:* Gastrointestinal intol hepatotoxicity, pulmonary edema. *Monitoring:* Salicylate concentrations: 150–300?µg/mL; analgesic or antipyr 30–50?µg/mL.

Chorionic gonadotropin Gonadotropin, ovulation stimulator. Chorex, Choron, Pregnyl. Powder for injection 200, 500, 1,000, 2,000 units/mL (10?mL).	**Treatment of hypogonadotropic hypogonadism; cryptorchidism; induce ovulation (stimulate production of gonadal steroid hormones; substitute for luteinizing hormone to stimulate ovulation).** *Children:* *Prepubertal cryptorchidism:* 1,000–2,000 units/ m^2 /dose 3 times/wk for 3 wk or 500 units 3 times/wk for 4–6 wk. *Hypogonadotropic hypogonadism:* 500–1,000 units/dose 3 times/wk for 3 wk; or 4,000 units 3 times/wk for 6–9 mo then taper to 2,000 units 3 times/wk for 3 mo. *Adults (menotropin dose):* 5,000 units 3 times/ wk for 4–6 mo.	*Adverse events:* Mental depression, t puberty, premature closure of the epi
Cimetidine Histamine-2 antagonist. Cimetidine. Tablet: 200, 300, 400, 800?mg. Liquid: 300?mg/5 mL. Injection: 150?mg/mL.	**Short-term treatment and long-term prophylaxis of gastroesophageal reflux disease and gastrointestinal ulcers and hyperacidity (competitive inhibition of histamine at H2 receptors).** *Neonates:* PO, IV, IM: 5–10?mg/kg/24?hr divided q8–12h. *Infants:* PO, IV, IM: 10–20?mg/kg/24?hr divided q6–12h. *Children:* PO, IV, IM: 20–40?mg/kg/24?hr divided q6h. *Adults:* 300?mg q6h (prolong dosing interval for creatinine clearance below 40?mL/min).	*Cautions:* Potent enzyme inhibitor thu accumulation of drugs that are metab antidepressants, anticonvulsants, the cisapride). *Adverse events:* Dizziness, drowsines *Monitoring:* Target gastric pH =5.

Cisapride Prokinetic gastrointestinal agent. Propulsid. Tablet: 10?mg.	**Treatment of gastroesophageal reflux, gastroparesis, and refractory constipation (enhances release of acetylcholine at myenteric plexus).** *Neonates–Children:* 0.15–0.3?mg/kg/dose 3–4 times daily. *Adults:* 10–20?mg 4 times daily. Give doses 15–30?min before meals.	*Cautions:* High doses or combination inhibitors (e.g., erythromycin, cimetidi QT-interval prolongation predisposing pointes. *Adverse events:* Tachycardia, prolong headache, anxiety, insomnia, gastroir flatulence, diarrhea. *Monitoring:* ECG baseline and early tı
Cisplatin Antineoplastic agent, alkylating agent. Platinol. Injection, aqueous: 1?mg/mL. Powder for injection: 10?mg, 50?mg.	**Treatment of multiple tumor types (inhibit DNA synthesis).** *Children and adults:* 37–75?mg/m^2 once q 2–3 wk or 50–120?mg/m^2 once q 21–28 days (administer over 4–6?hr). Adjust dose in renal impairment: CrCl 10–50?mL/min = 75% of dose; CrCl <10?mL/min = 50% of dose.	*Adverse events:* Nausea vomiting (las dose), myelosuppression (onset, 10 c days; recovery, 21–39 days), acute re nephropathy (sodium, magnesium, ar hyperuricemia), peripheral neuropath ototoxicity (high-frequency hearing lo: injury, elevated liver enzymes, alopec arrhythmias.
Citrate solutions Alkalinizing agent. Bicitra (sodium citrate 500?mg and citric acid 334?mg/5?mL = 1?mEq sodium + 1?mEq bicarbonate equivalent per mL). Polycitra (sodium citrate 500?mg and citric acid 334?mg and potassium citrate 550?mg/5?mL = 1?mEq sodium + 1?mEq potassium + 2?mEq bicarbonate equivalent per mL).	**Treatment of chronic metabolic acidosis (citrate salts are oxidized in the body to form bicarbonate).** *Neonates, infants, and children:* 2–3?mEq/kg/24?hr in 3–4 divided doses with water after meals. *Adults:* 15–30?mL with water after meals and at bedtime.	*Adverse events:* Hypernatremia, hype alkalosis.

Clomipramine Antidepressant. Anafranil. Capsule: 25, 50, 75?mg.	**Treatment of obsessive-compulsive disorder and panic attacks (affects serotonin and norepinephrine uptake).** *Children:* Start 25?mg/24?hr and gradually increase to response (max: 200?mg/24?hr). *Adults:* Start 25?mg/24?hr and dose to response (max: 250?mg/24?hr).	*Adverse events:* Dizziness, drowsines constipation, nausea, weight gain, ne seizures, hypotension, arrhythmias, p syndrome, insomnia.
Clonazepam Benzodiazepine. Klonopin. Tablets: 0.5, 1, 2?mg.	**Prophylaxis of seizure types: absence, Lennox-Gastaut, akinetic, myoclonic (depress nerve transmission in the motor cortex).** *Children:* 0.01–0.3?mg/kg/24?hr in 2–3 divided doses, then increase by 0.5?mg/24?hr q 3–5 days to response (max: 0.3?mg/kg/24?hr). *Adults:* Initial dose 0.1?mg bid; then 0.2–2.4?mg/24?hr in 2–4 divided doses.	*Adverse events:* Tachycardia, chest p fatigue, impaired memory and coordi blurred vision, nausea, vomiting, dry r hypersalivation, anorexia, bronchial h respiratory depression, physical and p dependence. *Monitoring:* Clonazepam concentratio 20–80?ng/mL; toxic >80?ng/mL; loss prolonged use (tachyphylaxis).

Clonidine a-Adrenergic agonist. Catapres. Tablet 0.1, 0.2, 0.3?mg. Transdermal patch 0.1, 0.2, 0.3?mg/24?hr.	**Treatment of hypertension; attention deficit disorder (ADD); narcotic withdrawal; aid in diagnosis of pheochromocytoma and growth hormone deficiency (stimulates a_2 -adrenoreceptors in the brainstem).** *Neonates:* Narcotic withdrawal: 1?µg/kg q6–8h to start And may titrate to targeted abstinence score (max: 2?µg/kg/dose q4h). *Children:* ADD: initial 0.05?mg/24?hr, increase q 3–7 days by 0.05?mg/24?hr given in 3–4 divided doses to response (max: 0.4?mg/24?hr). Hypertension: 5–10?µg/kg/24?hr in 2–4 divided doses (max: 0.9?mg/24?hr). Clonidine tolerance test for growth hormone release: 4?µg/kg 1 × dose. *Adults:* hypertension oral: 0.2–2.4?mg/24?hr in 2–4 doses titrated to response; transdermal: 0.1–0.3?mg/24?hr titrated to effect.	*Cautions:* Taper doses gradually to a overactivity symptoms. *Adverse events:* Drowsiness, dizzines constipation, hypotension.
Clorazepate Benzodiazepine. Tranxene. Tablet 3.75, 7.5, 15?mg.	**Anxiety and panic disorders; adjunct in management of partial seizures (facilitate transmission of inhibitory neurotransmitter, ?-aminobutyric acid [GABA]).** *Children: 9–12 yr:* 3.75–7.5?mg/dose bid (max: 60?mg/24?hr). *>12 yr and adults:* 7.5?mg/dose bid–tid (max: 90?mg/24?hr). *Adults:* 7.5–15?mg/dose bid–qid.	*Adverse events:* Drowsiness, confusi blurred vision.

Clozapine Clozaril, generic. Tablets: 25, 100?mg.	**Atypical antipsychotic, dibenzepin chemical group.** *Children:* Start at 6.25?mg bid, increase by 6.25?mg/24?hr weekly as needed. Typical dose: 50–300?mg/24?hr. *Adults:* Start 25?mg q 24?hr and titrate up by 25–50?mg/24?hr to 450–500?mg/24?hr divided tid at 2 wk. Further dose increases should not exceed 100?mg/wk (max: 900?mg/24?hr).	*Caution:* Agranulocytosis, sometimes reported in 1.3% of patients. Thus wh counts must be done at baseline and mo of treatment, then every other wk. checked every other week thereafter. discontinued, check WBC weekly for *Adverse events:* Seizures, orthostatic extrapyramidal symptoms (less often antipsychotics), hyperglycemia, dizzir headache, tremor, excessive salivatic sleep) *Drug interactions:* Clozapine levels m concurrent use of enzyme inhibitors. protein bound and may displace othe drugs (e.g., warfarin).
Codeine Narcotic analgesic. Generic, combination products. Injection. Tablet.	**Treatment of mild to moderate pain and cough (inhibition of ascending pain pathways; central action in medulla to suppress cough).** *Children:* Pain: 0.5–1?mg/kg/dose q4–6h (max: 60?mg/dose). Cough: 1–1.5?mg/kg/24?hr divided q4–6h. *Adults:* Pain: 15–60?mg/dose q4–6h as needed. Cough: 10–20?mg/dose q4–6h (max: 120?mg/24?hr).	*Adverse events:* Drowsiness, constipa anorexia, vomiting, sedation, dizzines

Colchicine Anti-inflammatory/anti-gout agent. Generic. Injection: 0.5?mg/mL.. Tablet: 0.5, 0.6?mg.	**Management of familial Mediterranean fever, acute and chronic gouty arthritis (decrease leukocyte motility and phagocytosis in joints).** *Children:* Prophylaxis of familial Mediterranean fever: *<5 yr:* 0.5?mg/24?hr. *>5 yr:* 1–1.5?mg/24?hr in 2–3 divided doses. *Adults:* gouty arthritis: PO: 0.5–0.6?mg q2h to symptom relief or gastrointestinal toxicity (max: 8?mg/24?hr). IV: 1–3?mg load then 0.5?mg/dose q6h until response (max: 4?mg/24?hr).	*Caution:* Reduce dose by 50% if CrCl *Adverse events:* Nausea, vomiting, di pain.
Colfosceril palmitate Lung surfactant. Exosurf. Intratracheal suspension, 108?mg/10?mL.	**Neonatal respiratory distress syndrome (RDS) (replaces deficient surfactant, lowers surface tension at air-fluid interface in alveoli).** *Neonates:* 5?mL/kg/dose as prophylaxis or rescue therapy for RDS (max: 4 doses, although no proven benefit for >2 doses).	*Caution:* Administer via sideport using tube adaptor with ½ dose with head a and ½ dose head and torso tilted to ri over 1–2?min. *Adverse events:* Pulmonary hemorrha (causing hyperoxia and hypocarbia),

Corticotropin, ACTH Adrenal corticosteroid. Acthar. Injection, repository: 40, 80 units/mL. Tablet: 5, 10, 25?mg.	**Infantile spasms; diagnostic agent in adrenocortical insufficiency; acute exacerbations of multiple sclerosis; severe muscle weakness in myasthenia gravis (stimulates adrenal cortex to release adrenal steroids, androgenic substances, and a small amount of aldosterone).** *Children:* Inflammation or immunosuppression: IV, IM, SC (aqueous): 1.6 units/kg/24?hr or 50 units/m^2 divided q6–8h; IM (gel): 0.8 unit/kg/24?hr or 25 units/m^2 /day divided q12–24h. Infantile spasms: 5–160 units/kg/24?hr has been used for 1 wk–12 mo as IM gel (prednisone 2?mg/kg/24?hr has equal efficacy). *Adults:* Acute exacerbations of MS: 80–120 units/24?hr for 2–3 wk.	*Caution:* May mask signs of infection vaccines; may exacerbate heart failur *Adverse events:* Insomnia, nervousne appetite, indigestion, diabetes mellitu mood swings, pancreatitis, esophagit bone growth suppression, opportunis
Cortisone acetate Adrenal corticosteroid. Cortone. Injection: 50?mg/mL. Tablet: 5, 10, 25?mg.	**Management of adrenocortical insufficiency (replacement).** *Children:* PO: 0.5–0.75?mg/kg/24?hr divided q8h; IM: 0.25–0.35?mg/kg/24?hr. *Adults:* PO, IM: 20–300?mg/24?hr in 1–2 doses.	*Cautions:* Avoid in active fungal infec serious infections except shock or me *Adverse events:* Insomnia, nervousne cerebri, headache, increased appetite diabetes mellitus, edema, hypertensic glaucoma, and hypokalemia. *Comment:* See comparison of cortico *Hydrocortisone.*

Cosyntropin Adrenal corticosteroid. Cortrosyn. Powder for injection: 0.25?mg.	**Diagnosis of primary versus secondary adrenocortical deficiency (stimulates adrenal cortex to release adrenal steroids).** *Neonates:* 0.015?mg/kg/dose. *Children <2 yr:* 0.125?mg. *Children >2 yr and adults:* 0.25?mg. Give dose in early morning	*Adverse events:* Flushing, mild fever, *Monitoring:* Measure plasma cortisol l 30?min after dose. Normal response increase >7?µg/dL (>193?nmol/L), or increase >18?µg/dL (497?nmol/L).
Cromolyn sodium Mast cell stabilizer. Intal, Gastrocrom, NasalCrom, Crolom, ophthalmic solution. Capsule (oral): 100?mg. Inhalation: 20?mg. Metered dose inhaler: 800?µg/spray Nebulizer solution: 10?mg/mL (2?mL). Nasal solution: 40?mg/mL. Ophthalmic solution: 4%	**Prevention of chronic symptoms of asthma, rhinitis, conjunctivitis, systemic mastocytosis, food allergy, and inflammatory bowel disease (prevents mast cell release of histamine and leukotrienes).** *Children and adults:* Asthma: 1–2 puffs (MDI) or 2?mL (nebulizer solution) 3–4 times daily. Rhinitis: 1 spray each nostril 3–4 times daily. Conjunctivitis: 1–2 drops 4–6 times daily. Mastocytosis, food allergy: *Children:* 100?mg/dose qid (max: 40?mg/kg/24?hr). *Adults:* 200?mg/dose qid (max: 400?mg/dose qid).	*Adverse events:* Hoarseness and cou powder for inhalation), burning and st administration site.
Crotamiton Scabicidal Eurax. Cream: 10%. Lotion: 10%.	**Treatment of scabies (mechanism unknown).** *Infants, children, and adults:* Wash area thoroughly, towel dry, apply a thin layer, and massage drug into skin. Repeat application in 24?hr. Take a cleansing bath 48?hr after final application. May repeat in 7 days if needed.	*Adverse events:* Local irritation.

Cyanocobalamin, vitamin B_{12} Nutritional supplement. Generic. Injection: 100, 1,000?µg/mL. Tablet: 25, 50, 100, 250, 500, 1,000?µg	**Pernicious anemia, vitamin B_{12} deficiency (coenzyme for various metabolic functions).** Pernicious anemia: *Children:* 30–50?µg/24?hr to total dose 1,000–5,000?µg and then follow with 100?µg mo. *Adults:* 100?µg/24?hr for 6–7 days, then 100?µg/mo. Vitamin B_{12} deficiency: *Children:* 100?µg/24?hr for 10–15 days then once or twice/wk for several mo. *Adults:* 30?µg/24?hr for 5–10 days then 100–200?µg/mo.	*Monitoring:* Serum B_{12} levels (normal Some reports of neuropsychiatric pro reported with levels <300 pg/mL.
Cyclizine Antinauseant. Marezine. Injection: 50?mg/mL. Tablet: 50?mg.	**Prevent and treat motion-related nausea, vomiting, and vertigo; control postoperative nausea and vomiting (mechanism unknown).** *Children 6–12 yr:* PO: 25?mg/dose up to 3 times / 24?hr as needed. *Adults:* PO: 50?mg up to q4–6h (30?min before travel); max: 200?mg/24?hr; IM 50?mg q4–6h as needed.	*Adverse events:* Drowsiness, dry mou diplopia, urinary retention.
Cyclopentolate Mydriatic. Cyclogyl, AK-Pentolate. Ophthalmic solution: 0.5%, 1%, 2%.	**Diagnostic procedures requiring mydriasis and cycloplegia (prevents the muscles of the ciliary body and iris from responding to cholinergic stimulation).** *Infants:* 1 drop 0.5% into each eye 5–10?min before examination. *Children and adults:* 1 drop 0.5% or 1% in eye 40–50?min before procedure (may repeat 1 drop in 5?min if necessary); may use 2% if heavily pigmented iris.	*Caution:* Avoid in narrow angle glauc *Adverse events:* Tachycardia, CNS s agitation, local burning. *Monitoring:* Cycloplegia and mydriasi and last up to 24?hr (reduce to 3–6?h
Cyclophosphamide Antineoplastic alkylating agent. Cytoxan; Neosar. Powder for injection: 0.1, 0.2, 0.5, 1.0, 2.0?g. Tablet: 25, 50?mg.	**Management of various cancers including Hodgkin disease, malignant lymphomas, leukemias, etc.; nephrotic syndrome; systemic lupus erythematosus (SLE); rheumatoid arthritis (RA); and rheumatoid vasculitis (interferes with normal function of DNA by alkylation).** *Children and adults with no hematologic problems:* Induction: IV: 40–50?mg/kg (1.5–1.8?g/m^2) in divided doses over 2–5 days. PO: 1–5?mg/kg/24?hr. Maintenance: IV: 10–15?mg/kg (350–550?mg/m^2) q 7–10 days or 3–5?mg/kg twice/wk. PO: *Children:* 2–5?mg/kg twice/wk. *Adults:* 1–5?mg/kg/24?hr. *Children:* SLE: 500–750?mg/m^2 /mo. Juvenile RA/vasculitis: IV 10?mg/kg q 2 wk. Bone marrow transplant conditioning: IV 50?mg/kg/24?hr for 3–4 days. Nephrotic syndrome: PO: 2–3?mg/kg/24?hr (when steroids fail, use for up to 12 wk). Adjust doses for: Renal function: CrCl 25–50?mL/min: decrease 50% CrCl <25?mL/min: avoid use. For decreased bone marrow function: reduce dose 33–50%.	*Cautions:* Maintain high fluid intake to cystitis and consider administration o *Adverse events:* Cardiotoxicity with hi effusion, congestive heart failure, alo vomiting, taste distortion, stomatitis, a cystitis, leukopenia (onset: 7 days; na recovery: 21 days), thrombocytopeni jaundice, renal toxicity, secondary ma

Cyproheptadine hydrochloride Antihistamine. Generic, Periactin. Syrup: 2?mg/5?mL. Tablet: 4?mg.	**Treatment of allergic symptoms (H_1 -receptor and serotonin antagonist).** *Children 2–6 yr:* 2?mg/dose q8–12h. *>7 yr and adults:* 4?mg/dose q8–12h (max: 0.5?mg/kg/24?hr).	*Adverse events:* Drowsiness, sedatio secretions, bronchospasm, appetite s photosensitivity.
Cysteine Nutritional supplement. Generic. Injection: 50?mg/mL.	**Supplement to crystalline amino acid solutions to meet amino acid nutritional requirements during parenteral nutrition (replace deficiency, also enhances solubility of calcium and phosphate in TPN solutions).** *Neonates and infants:* Add 40?mg cysteine to 1?g of amino acids (typically results in 20–100?mg/kg/24?hr of cysteine).	*Adverse events:* Metabolic acidosis, a blood urea nitrogen, nausea.
Cytarabine HCl, Ara-C Antineoplastic, antimetabolite. Cytosar-U (powder for injection: 0.1, 0.5, 1, 2?g). Tarabine PFS. Injection: 20?mg/mL.	**Used in combination therapy to treat leukemias and lymphomas (inhibits DNA polymerase to inhibit DNA synthesis, works in S-phase of cell division).** *Children and adults:* (doses depend on individual protocols). *Typical dose:* Induction: IV 100–200?mg/m^2 /24?hr for 5–10 days or until remission. Maintenance: IV 70–200?mg/m^2 /24?hr for 2–5 days at monthly intervals; IM, SC: 1–1.5?mg/kg single dose at 1–4 wk intervals. IT: 5–75?mg/m^2 q 2–7 days until CNS findings normalize (concentration should not exceed 100?mg/mL).	*Adverse events:* Fever, rash, oral/ana vomiting, diarrhea, mucositis, liver dy myelosuppression (onset 4–7 days, n recovery 21–28 days), alopecia, conju corticosteroid eye drops around-the-c and after high dose Ara-C), dizziness (prevent CNS toxicities with pyridoxin days of high-dose Ara-C administratic
Dacarbazine Antineoplastic agent. DTIC-Dome, generic. Injection: 100, 200, 500?mg.	**Treatment of various tumors (alkylating agent and possibly some antimetabolite activity).** *Children:* Solid tumors: 200–470?mg/m^2 /24?hr over 5 days q 21–28 days; neuroblastoma: 800–900?mg/m^2 on day 1 of combination therapy q 3–4 wk. Hodgkin disease: 375?mg/m^2 on days 1 and 15 of combination treatment; repeat q 28 days. *Adults:* Hodgkin disease: 150?mg/m^2 /24?hr for 5 days; repeat q 4 wk.	*Adverse events:* Pain and burning at and vomiting, leukopenia (onset: 7 da recovery: 21–28 days), weakness, po paresthesias, elevated liver enzymes alopecia, metallic taste.

Dactinomycin Antineoplastic agent. Actinomycin D, Cosmegen. Powder for injection: 0.5?mg.	**Treatment of various tumor types (binds to guanine portion of DNA blocking replication and transcription of the DNA template).** *Children >6 mo and adults:* 15?μg/m^2 /24?hr or 400–600?μg/m^2 /24?hr for 5 days; may repeat every 3–6 wk.	*Adverse events:* Myelosuppression (c 14–21 days; recovery: 21–28 days), f alopecia, skin eruptions, acne, severe vomiting, diarrhea, mucositis, stomati hyperuricemia.
Danaparoid Orgaran Injection: 750 anti-Xa units in 0.6?mL.	**Antithrombotic agent, acts by inhibiting anti- Xa and anti-IIa effects (anti Xa/anti-IIa activity >22). Low molecular weight heparinoid consisting mainly of heparan sulfate. Use for heparin-induced thrombocytopenia (cross-reactivity with heparin antibodies is <10%, compared with >90% for low molecular weight heparin).** *Children:* Loading dose: 30?U/kg, maintenance dose: 1.2–2.0?U/kg/hr. *Adults:* Treatment: Loading dose *<50?kg:* 1,500?U; *50–90?kg:* 2,250?U; *>90?kg:* 3,000?U. Follow loading dose with 400?U/hr for 4?hr, then 300?U/h for 4?hr, then maintenance dose 150–200?U/hr. Prophylaxis: *<50?kg:* 750?U q12?hr; *50–90?kg:* 1500?U q8h; *>90?kg:* 1,500?U q12?h.	*Monitoring:* Check plasma anti-Xa lev 0.5–0.8?U/mL for treatment, target 0. prophylaxis. Monitoring traditional clo APTT, ACT) is not beneficial as no ef *Adverse events:* Bleeding (risk is low unfractionated heparin).
Dantrolene sodium Skeletal muscle relaxant. Dantrium. Capsule: 25, 50, 100?mg. Powder for injection: 20?mg.	**Treatment of spasticity associated with upper motor neuron disorders such as spinal cord injury, stroke, cerebral palsy or multiple sclerosis; also used to treat malignant hyperthermia (interferes with release of calcium ion from the sarcoplasmic reticulum).** Spasticity: *Children:* 0.5?mg/kg/dose twice daily; increase frequency q 4–7 days to 3–4 times daily; then increase dose by 0.5?mg/kg to maximum of 3?mg/kg/dose 2–4 times daily. *Adults:* Start 25?mg/24?hr and increase dose by 25?mg or frequency q 4–7 days to maximum of 100?mg 2–4 times daily. Hyperthermia: *Children and adults:* Oral: 4–8?mg/kg/24?hr in 4 divided doses given 1–2 days before surgery (prophylaxis), or for 1–3 days post surgery (post-crisis follow-up). IV: 2.5?mg/kg starting 1.5?hr before surgery and run over 1?hr (prophylaxis) or 1?mg/kg/dose and repeated as needed (crisis); max: 10?mg/kg.	*Cautions:* Should not be used where maintain posture or balance; avoid in liver disease. *Adverse events:* Drowsiness, fatigue, blurred vision, seizures, diarrhea, sto nausea, vomiting, pleural effusion wit hepatitis.

Daunorubicin hydrochloride Antineoplastic. Cerubidine. Powder for injection: 20?mg.	**Treatment of acute nonlymphocytic leukemia (ANLL) and myeloblastic leukemia (inhibition of DNA and RNA synthesis).** *Children:* Remission induction for acute lymphocytic leukemia (combination therapy): 25–45?mg/m^2 on day 1 every wk for 4 cycles (max: total 300?mg/m^2). *Adults:* 30–60?mg/m^2 /24?hr for 3–5 days; repeat dose in 3–4 wk; total cumulative dose should not exceed 400–600?mg/m^2 (lower end if prior cardiotoxic drugs or chest irradiation).	*Caution:* Avoid in patients with heart f Irreversible cardiotoxicity may occur i exceeds: 550?mg/m^2 in adults, 400?r irradiation, 300?mg/m^2 in children >2 children <2 yr. *Adverse events:* Alopecia, red discolo nausea, vomiting, diarrhea, gastrointe stomatitis, myelosuppression (onset, days; recovery, 21–28 days), extrava ulceration and necrosis, congestive h hyperuricemia, hepatotoxicity. *Monitoring:* Serum bilirubin and aspar (AST) (to adjust doses for hepatic im 1.2–3?mg/dL or AST 60–180 IU: redu bilirubin 3.1–5?mg/dL or AST >180 IU 50%; bilirubin >5?mg/dL: omit use.
Deferoxamine mesylate Chelating agent. Desferal. Powder for injection: 500?mg.	**Treatment of acute iron intoxication or secondary chronic iron overload (forms complex with iron to form ferrioxamine, which is removed by kidneys).** *Children:* Acute iron intoxication: IM: 90?mg/kg/dose q8h. IV: 15?mg/kg/hr (max: 6?g/24?hr). Chronic iron overload: IV: 15?mg/kg/hr (max: 12?g/24?hr). SC: 20–40?mg/kg/24?hr over 8–12?hr via portable infusion device. *Adults:* Acute iron intoxication: IM: 1?g STAT, then 0.5?g q4h (max: 6?g/24?hr). IV: 15?mg/kg/hr (max: 6?g/24?hr). Chronic iron overload: IM: 0.5–1?g/24?hr. SC: infuse 1–2?g/24?hr over 8–24?hr.	*Caution:* Contraindicated in patients w hemochromatosis. *Adverse events:* Local pain and indur hypotension, tachycardia, fever, hear vision, cataracts. *Monitoring:* Serum ferritin, iron, total i Audiometry and eye examination with

Desipramine hydrochloride Antidepressant, tricyclic. Norpramin, Pertofrane. Tablet: 10, 25, 50, 75, 100, 150?mg. Capsule: 25, 50?mg.	**Treatment of depression, attention deficit disorder, neuropathic pain (increases synaptic concentrations or serotonin and norepinephrine by inhibiting reuptake).** *Children 6–12 yr:* 1–3?mg/kg/24?hr (max: 5?mg/kg/24?hr). *Adolescents:* Initial 25–50?mg/24?hr, gradually increase (max: 150?mg/24?hr). *Adults:* Initial 75?mg/24?hr, gradually increase (max: 300?mg/24?hr).	*Cautions:* Abrupt discontinuation can symptoms; tablets contain tartrazine (asthmatics), contraindicated in narrow *Adverse events:* Dizziness, drowsines vision, dry mouth, constipation, increa arrhythmias, and hypotension. *Monitoring:* Desipramine concentratio 100–300?ng/mL, toxic >300?ng/mL; c
Desmopressin acetate Vasopressin analog. DDAVP, Stimate. Injection: 4?µ/mL. Nasal solution: 0.1?mg/mL.	**Treatment of diabetes insipidus, control of bleeding in certain types of hemophilia, primary nocturnal enuresis (enhances reabsorption of water in the kidneys, dose-dependent increase in factor VIII and plasminogen activator).** *Children:* Diabetes insipidus: *3 mo–12 yr:* PO: 0.05?mg initially then titrate to response. IV: 5?µg/24hr in 1–2 doses. Hemophilia: *>3 mo:* IV: 0.3?µ/kg, may repeat dose if needed, use 30?min before procedure. Nocturnal enuresis: *>6 yr:* 20?µg at bedtime. *Children >12 yr and adults:* Diabetes insipidus: PO: 0.05?mg twice daily then titrate to response. IV, SC: 2–4?µg/24hr. Intranasal: 5–40?µg/24hr in 1–3 doses. Hemophilia: IV: 0.3?µg/kg. Intranasal: <50?kg = 150?µg>50?kg = 300?µg. Enuresis: PO: 0.2–0.4?mg at bedtime.	*Cautions:* Avoid using in patients with platelet-type von Willebrand disease, factor VII levels <5% or hemophilia B *Adverse events:* Facial flushing, head increased blood pressure, hyponatren *Monitoring:* Serum electrolytes, plasm osmolality, urine output, factor VIII an partial thromboplastin time, factor VII

Drug	Indications and dosage	Remarks
	1–3 doses. Hemophilia: IV: 0.3?µg/kg. Intranasal: <50?kg = 150?µg>50?kg = 300?µg. Enuresis: PO: 0.2–0.4?mg at bedtime.	
Dexamethasone Adrenal corticosteroid. Decadron. Aerosol: Oral 84?µg/nasal 84?µg/spray. Cream: 0.1%, 0.04%. Injection: 4, 8, 10, 16, 20, 24?mg/mL. Ophthalmic ointment: 0.05%. Ophthalmic suspension: 0.1, 0.5%. Oral solution: 0.5?mg/5?mL. Tablet: 0.25, 0.5, 0.75, 1, 1.5, 2, 4, 6?mg. Elixir: 0.5?mg/5?mL.	**Systemically and locally for acute and chronic inflammation; allergic, neoplastic and autoimmune diseases; cerebral edema, septic shock, *Haemophilus influenzae* meningitis, diagnostic agent (decreases inflammation and suppresse normal immune response).** *Neonates:* Airway edema or extubation: IV: 0.25?mg/kg every 12?hr for 3–4 doses (start >4?hr before scheduled extubation). Bronchopulmonary dysplasia: IV, PO: 0.25?mg/kg/dose q12h for 6 doses then taper over 1 to 6 wk (regimens may begin as early as day 1). *Children:* Airway edema or extubation: PO, IM, IV: 0.5–2?mg/kg/24?hr divided q6h (begin 24?hr before extubation and continue for 4–6 doses post extubation). Antiemetic (chemotherapy-induced): IV: 10?mg/m^2 first dose then 5?mg/m^2 /dose q6h as needed (start before chemotherapy). Anti-inflammatory: PO, IM, IV: 0.08–0.3?mg/kg/ 24?hr divided q6–12h. Bacterial meningitis: IV: 0.6?mg/kg/24?hr divided q6h for days 1–4 of antibiotics. Cerebral edema: PO, IM, IV: loading dose 1–2?mg/kg, then 1–1.5?mg/kg/24?hr divided q4–6h. taper over 1 to 6 wk Inhalation: 2 puffs 3–4 times daily. Nasal spray: 1–2 sprays in each nostril twice daily. Physiologic replacement: PO, IM, IV: 0.03–0.15?mg/kg/24?hr divided q6–12h. *Adults:* Anti-inflammatory: PO, IM, IV: 0.5–9?mg/24?hr divided q6–12h. Antiemetic: Same as for children. Cerebral edema: IV: 10?mg STAT, then 4?mg q6h. Diagnosis of Cushing syndrome: 1?mg at 11 P.M., draw plasma cortisol at 8 A.M. the following day. Shock: IV: 1–6?mg/kg (max: 40?mg) and may repeat q2–6h. *Children and adults:* Ophthalmic: Ointment: apply q3–4h to conjunctival sac as thin coating; suspension: instill 2 drops into conjunctival sac every?hr during day and every other?hr at night. Gradually taper doses when inflammation resolves. Topical: Apply 1–4 times daily.	*Caution:* Dexamethasone use for nec bronchopulmonary dysplasia has bee increased incidence of cerebral palsy be weighed against potential benefits *Adverse events:* Insomnia, nervousne appetite, hypertension, hyperglycemi hyperacidity (stress ulcer risk), catara suppression, poor growth. Comment: See comparison of cortico *Hydrocortisone*.
Dextran Plasma volume expander. Dextran 40 (low molecular weight): Gentran; LMD. Dextran 70 (high molecular weight): Gentran; Macro Dex.	**Blood volume expander in shock or impending shock (similar to albumin).** *Children:* Max: 20?mL/kg on day 1, then 10?mL/ kg/24?hr for not more than 5 days. *Adults:* 500–1,000?mL at a rate of 20–40?mL/min (max: 10?mL/kg/24?hr for 5 days).	*Adverse events:* (Primarily associated doses)—pulmonary edema, bleeding platelet function.

Dextroamphetamine CNS stimulant. Generic, Dexedrine, Adderall. Tablet: 5, 10?mg. Sustained-release capsule: 5, 10, 15?mg.	**Treatment of attention deficit disorder, narcolepsy, and exogenous obesity (blocks reuptake of dopamine and norepinephrine from the synapse).** *Children 6–12 yr:* Narcolepsy and attention deficit disorder: Initial 5?mg/24?hr, may increase by 5?mg/24?hr at weekly intervals to response (max: 60?mg/24?hr). *>12 yr and adults:* Initial 20?mg/24?hr, may increase at 10-mg increments weekly (max: 60?mg/24?hr).	*Caution:* Avoid concurrent use of mor inhibitors. *Adverse events:* Hypertension, tachy arrhythmias, insomnia, agitation, irrita headache, depression, tremor, exace movement disorders, mydriasis, phys dependence, anorexia, nausea, diarrl cramps, growth suppression. *Monitoring:* Blood pressure, growth, (
Dextromethorphan Antitussive. Robitussin, generics. Liquid: 7.5?mg/5?mL. Lozenge: 5?mg.	**Symptomatic relief of coughs, best when cough is nonproductive (depresses the medullary cough center).** *Children 2–6 yr:* 2.5–7.5?mg q4–8h or extendedrelease 15?mg q12h (max: 30?mg/24?hr). *6–12 yr:* 10–15?mg q4–8h or extended-release 30?mg twice daily (max: 60?mg/24?hr). *>12 yr and adults:* 10–30?mg q4–8h or extendedrelease 60?mg twice daily (max: 120?mg/24?hr).	*Adverse events:* (Mainly with overdos dizziness, respiratory depression, blu gastrointestinal upset, constipation.

Diazepam Benzodiazepine. Generic, Valium. Tablet: 2, 5, 10?mg. Oral solution: 5?mg/mL. Injection: 5?mg/mL.	**Treatment of anxiety, panic disorders, status epilepticus, alcohol withdrawal; provide sedation; skeletal muscle relaxant (thought to increase neuroinhibitory action of ?-aminobutyric acid).** *Infants and children:* Status epilepticus: IV: 0.05–0.3?mg/kg/dose given over 2–3?min; may repeat q 30?min to maximal total dose of 5–10?mg. Rectal:0.5mg/kg,then 0.25mg//kg in 10?min if needed. Sedation: PO: 0.2–0.3?mg/kg (max: 10?mg); IM, IV: 0.04–0.3?mg/kg (max: 0.6?mg/kg/8?hr). *Adults:* Status epilepticus: IV: 5–10?mg q 30?min (max: 30?mg/8?hr). Anxiety, sedation, muscle relaxant: PO, IM, IV: 2–10?mg 2–4 times daily.	*Adverse events:* Hypotension, bradyc (with IV dose), drowsiness, ataxia, fat impaired coordination, paradoxical ex blurred vision, diplopia, sweating, dry or diarrhea, increased or decreased a physical and psychological dependen *Monitoring:* Desired clinical endpoints endpointsshould be monitored; doses varyconsiderably between patients.

Diazoxide Antihypertensive. Hyperstat, injection: 15?mg/mL. Proglycem, oral suspension: 50?mg/mL. Capsule: 50?mg.	**Emergency lowering of blood pressure, treatment of hyperinsulinemic hypoglycemia related to islet cell tumors or nesidioblastosis (smooth muscle relaxation, inhibit insulin release from the pancreas).** Hypertension: *Children and adults:* 1–3?mg/kg; may repeat in 5–15?min, dose every 4–24?hr. Hyperinsulinemic hypoglycemia: *Newborns and infants:* PO: 8–15?mg/kg/24?hr divided q8–12h (start on low end). *Children and adults:* PO: 3–8?mg/kg/24?hr divided q8–12h (start on low end).	*Adverse events:* Hypotension, dizzine nausea, vomiting.
Dibucaine Local anesthetic. Nupercainal. Cream: 0.5%. Ointment: 1%.	**Temporary relief of pain and itching due to hemorrhoids and minor skin irritation or damage (block initiation and conduction of nerve impulses).** *Children and adults:* Topical: Apply gently to affected area (children 7.5?g/24?hr, adults 30?g/24?hr). Rectal: Insert with rectal applicator morning, evening, and after each bowel movement.	*Adverse events:* Local irritation, conta

Diclofenac sodium Nonsteroidal anti-inflammatory agent. Cataflam, tablets: 50?mg. Voltaren, tablets: 25, 50, 75?mg. Ophthalmic solution: 0.1%.	**Treatment of mild to moderate acute or chronic pain; postoperative inflammation after cataract extraction (inhibit prostaglandin synthesis).** PO: *Children:* 2–3?mg/kg/24?hr in 2–4 divided doses. *Adults:* 100–200?mg/24?hr in 2–4 divided doses. Ophthalmic: 1 drop in affected eye qid for 2 wk, to begin 24?hr after cataract surgery.	*Adverse events:* Dizziness, headache indigestion, abdominal pain, peptic ul bleeding, renal impairment.
Dicyclomine Anticholinergic agent. Antispas, Bentyl, generic. Capsule: 10, 20?mg. Tablet: 20?mg. Syrup: 10?mg/5?mL. Injection: 10?mg/mL.	**Treatment of functional disturbances of gastrointestinal motility, e.g., irritable bowel syndrome (block the actions of acetylcholine).** *Infants >6 mo:* PO: 5?mg/dose tid–qid. *Children:* 10?mg tid–qid. *Adults:* 40?mg qid (start at 12 dose and gradually increase; IM: Use 20?mg qid). *Cautions:* Avoid in narrow angle glaucoma, gastrointestinal obstruction, urinary tract obstruction, and myasthenia gravis.	*Adverse events:* Tachycardia, palpita irritability, confusion, muscle hypotoni photophobia, urinary retention, nause constipation, dry mouth, urticaria, pru

Digoxin Cardiac glycoside. Lanoxin, generic. Capsule: 50, 100, 200?µg. Elixir: 50?µg/mL. Tablet: 125, 250, 500?µg. Injection: 100, 250?µg/mL.	**Treatment of systolic heart failure and supraventricular tachyarrhythmias (increase intracellular calcium through inhibition of sodium/potassium ATPase pump; suppression of AV node conduction).** *Neonate:* 10–30?µg/kg IV load, then 5–10?µg/kg/24?hr maintenance dose. *1 mo–2 yr:* 30?µg/g;kg load, then 10–15?µg/kg/24hr maintenance dose. *2–10 yr:* 30?µg/kg load, then 5–10?µg/kg/24hr maintenance dose. *Child >10 yr:* 10?µg/kg load, then 2–5?µg/kg/24hr maintenance dose. *Adult:* 10–15?µg/kg load, then 0.1 to 0.5?mg/24?hr maintenance dose. Adjust doses for reduced renal function: CrCl 10–50?mL/min: reduce dose to 25–75% CrCl <10?mL/min: reduce dose to 10–25% of normal.	*Cautions:* Contraindicated in AV block hypertrophic subaortic stenosis, or co *Adverse events:* Anorexia, nausea, vo feeding intolerance, bradycardia, arrh depression, vertigo, blurred vision, dip yellow or green vision. *Monitoring:* Efficacy and toxicity are c serum concentrations and dosing sho measuring serum digoxin concentrati 0.8–2?ng/mL; toxic: >2–2.5?ng/mL. D substances (DLIS) may falsely elevat neonates and children, so pretreatme be obtained and subtracted from trea samples can be run through a free-le DLIS before assay. Check post-distrib least 6–8?hr post dose) at steady-sta or clinical signs of toxicity. Check EC calcium, and magnesium. Check hea

Digoxin Immune Fab Digoxin antidote. Digibind. Powder for injection: 38?mg.	**Treatment of digitalis intoxication from digoxin or digitoxin (binds with molecules of unbound digoxin or digitoxin and is renally cleared).** *Infants, children, and adults:* Dose is based on amount of digoxin or digitoxin ingested or estimated total body load (TBL) based on post-distributive serum concentration: TBL Digoxin = concentration (ng/mL) × 5.6 ×weight (kg)/1,000. TBL Digoxin = mg ingested × 0.8. TBL Digitoxin = concentration (ng/mL) × 0.56 ×wt (kg)/1,000. TBL Digitoxin = mg ingested. Dose Digoxin Immune Fab (mg) = TBL Digoxin × 76. Dose Digoxin Immune Fab (# vials) = TBL/0.5.	*Adverse events:* Worsening of heart f fibrillation, hypokalemia, facial swellin *Monitoring:* ECG, digoxin serum conc increase with digoxin immune Fab an stores or correlate with clinical toxicity
Dihydrotachysterol Vitamin D analog. Hytakerol, generic. Capsule: 0.125?mg. Tablet: 0.125?mg. Solution: 0.2?mg/mL, 0.2?mg/5?mL.	**Treatment of hypocalcemia associated with hypoparathyroidism and renal osteodystrophy (stimulates calcium and phosphate intestinal absorption).** *Neonates:* 0.05–0.1?mg/24?hr. *Infants and young children:* 1–5?mg/24?hr for 4 days then 0.5–1.5?mg/24?hr. *Older children and adults:* 0.75–2.5?mg/24?hr for 4 days, then 0.2–1?mg/24?hr (max: 1.5?mg/24?hr). Renal osteodystrophy: 0.1–0.6?mg/24?hr.	*Adverse events:* Hypercalcemia, hype serum creatinine.

Diltiazem Calcium channel blocker. Cardizem, Dilacor. Tablet: 30, 60, 90, 120?mg. Capsule (sustained-release): 60, 90, 120, 180, 240, 300?mg. Injection: 5?mg/mL.	**Treatment of hypertension and atrial tachyarrhythmias (inhibit calcium ions from entering the "slow channels" during depolarization).** *Children:* PO: 1.5–2?mg/kg/24?hr in 3–4 divided doses. *Adolescents and adults:* PO: 90–480?mg/24?hr in 3–4 divided doses as tablets or 1–2 doses as sustained-release capsules. IV: 0.25?mg/kg load, then 5–15?mg/hr continuous infusion.	*Cautions:* Diltiazem is a hepatic enzy cause accumulation and toxicity for c drugs which are metabolized. *Adverse events:* Hypotension, bradyc block, dizziness, nausea, vomiting.
Dimenhydrinate Antihistamine. Dramamine, generic. Capsule: 50?mg Injection: 50?mg/mL. Tablet: 50?mg. Liquid: 12.5?mg/4?mL.	**Treatment of nausea, vomiting, and vertigo associated with motion sickness (competes with histamine for H_1 -receptor).** *Children:* *2–5 yr:* 12.5–25?mg q6–8h (max: 75?mg/24?hr). *6–12 yr:* 25–50?mg q6–8h (max: 150?mg/24?hr). *Adults:* 50–100?mg q4–6h (max: 400?mg/24?hr).	*Adverse events:* Drowsiness, dizzines tachycardia.

Dimercaprol BAL. Injection: 100?mg/mL.	**Antidote to gold, arsenic, and mercury poisoning and adjunct to edetate calcium disodium in lead poisoning (chelates with heavy metals to form nontoxic stable compounds).** *Children and adults:* Mild arsenic and gold poisoning: 2.5?mg/kg/ dose IM q6h for 2 days, then q12h on day 3, then q24h for 10 days. Severe arsenic or gold poisoning: 3?mg/kg/dose q4h for 2 days, then q6h on day 3, then q12h for 10 days. Mercury poisoning: 5?mg/kg load, then 2.5?mg/kg/dose 1–2 times/day for 10 days. Lead poisoning: Mild: 4?mg/kg load, then 3?mg/kg/dose q4h for 2–7 days. Severe: 4?mg/kg/dose q4h for 2–7 days.	*Adverse events:* Hypertension, tachy nausea, vomiting, fever, headache, n blepharospasm, nephrotoxicity. *Monitoring:* Specific heavy metal leve kept alkaline
Diphenhydramine Benadryl, generic. Capsule or tablet: 25, 50?mg. Injection: 10?mg/mL, 50?mg/mL. Syrup or elixir: 12.5?mg/5?mL. Cream or lotion: 1%.	**Antihistamine (competitive inhibitor of H_1 -receptor).** *Children:* 5?mg/kg/24?hr divided q6h as needed IM, IV, PO (max: 300?mg/24?hr). *Adults:* 10–50?mg/dose q4h as needed (max: 400?mg/24?hr). *Topical:* Apply 3–4 times daily.	*Adverse events:* Hypotension, tachyc paradoxical excitement, thickened bro mouth.

Diphenoxylate and Atropine Lomotil. Tablet, oral solution.	**Antidiarrheal (diphenoxylate inhibits excessive gastrointestinal motility, atropine is to prevent abuse).** *Children:* *2–5 yr:* 4?mL (2?mg diphenoxylate) tid. *5–8 yr:* 4?mL qid. *8–12 yr:* 4?mL 5 times daily. *Adults:* 15–20?mg/24?hr in 3–4 divided doses.	*Adverse events:* Nervousness, dizzin headache, dry mouth, urinary retentic paralytic ileus.
Disopyramide Norpace. Capsule: 100, 150?mg.	**Treatment of ventricular arrhythmias and atrial tachyarrhythmias (antiarrhythmic class 1a, decreases myocardial excitability and conduction velocity).** *Children:* *<1 yr:* 10–30?mg/kg/24?hr divided q6h. *1–4 yr:* 10–20?mg/kg/24?hr divided q6h. *4–12 yr:* 10–15?mg/kg/24?hr divided q6h. *12–18 yr:* 6–15?mg/kg/24?hr divided q6h. *Adults:* 100–200?mg q6h.	*Cautions:* Avoid in 2nd- or 3rd-degree heart failure, urinary retention, glauco arrhythmias. *Adverse events:* Urinary retention/hes fatigue, malaise, constipation, choles enzymes. *Monitoring:* Creatinine clearance (decrease dose 30–40?mL/min, q12h if 15–30?mL/mi <15?mL/min). ECG, blood pressure, : Blood levels (therapeutic range: atrial 2.8–3.2?µg/mL. ventricular arrhythmi:
Dobutamine Dobutrex. Injection.	**Treatment of hypotension (stimulates β_1 -adrenergic receptors).** *Neonates:* 2–20?µg/kg/min *Children and adults:* 2.5–40?µg/kg/min constant infusion.	*Cautions:* Avoid in patients with IHSS flutter, or sulfite sensitivity. *Adverse events:* Tachycardia, ectopic palpitations, tachyarrhythmias, tinglin paresthesias, and leg cramps.

Docusate Colace, Surfak, generic. Capsule, liquid, syrup (may be combined with casanthrol).	**Stool softener, laxative (reduces surface tension of oil-water interface of stool).** *<3 yr:* 10–40?mg/24?hr in 1–4 doses. *3–6 yr:* 20–60?mg/24?hr in 1–4 doses. *6–12 yr:* 40–150?mg/24?hr. *> 12 yr and adults:* 50–400?mg/24?hr.	*Adverse events:* Diarrhea, abdominal
Dolasetron mesylate Anzemet. Tablet: 50, 100?mg. Injection.	**Prevention and treatment of chemotherapy and postoperative nausea and vomiting (5-HT_3 receptor antagonist).** *Children >2 yr and adults:* IV, PO: 1.8?mg/kg (max: 100?mg) as single dose 30?min before chemotherapy; 0.35?mg/kg (max: 12.5?mg) given 15?min before stopping anesthesia for postoperative nausea.	*Adverse events:* Hypotension, heada dizziness.
Dopamine Intropin. Injection.	**Treatment of hypotension and shock (stimulates dopaminergic receptors and adrenergic receptors).** *Neonates, children, and adults:* 1–20?µg/kg/min IV infusion rate (mL/hr) = 6 × weight (kg) × desired dose (µg/kg/min)/mg drug per 100?mL IV fluid.	*Cautions:* Contains sulfites. *Adverse events:* Tachycardia, ectopic arrhythmias, tissue necrosis with extr vasoconstriction, gangrene of extrem output (doses <5?µg/kg/min), oliguria >10?µg/kg/min).
Dornase alpha Pulmozyme. Inhalation solution: 1?mg/mL.	**Management of cystic fibrosis to improve pulmonary function (DNA enzyme which reduces viscosity of mucus).** *Neonates, children, and adults:* 2.5?mL 1–2 times daily, nebulized with Pulmo-Aide or Pari-Proneb compressor.	*Adverse events:* Pharyngitis, voice alt rhinitis, hemoptysis.

Doxacurium Nuromax. Injection: 1?mg/mL.	**Skeletal muscle paralysis (neuromuscular blockade by competing with acetylcholine for neuromuscular receptor).** *Children 2–12 yr:* Initial 30–50?µg/kg, then 5–10?µg/kg/hr every 1–2?hr. *Adults:* Initial 50?µg/kg, then 5–10?µg/kg/ does every 1–2?hr.	*Adverse events:* Skeletal muscle wea *Monitoring:* Peripheral nerve stimulat
Doxapram Dopram. Injection: 20?mg/mL.	**Treatment of apnea of prematurity refractory to methylxanthines (respiratory and CNS stimulant).** *Neonates:* Initial 2.5–3?mg/kg followed by infusion of 1?mg/kg/hr (max: 2.5?mg/kg/hr). *Caution:* Contains benzyl alcohol (recommended doses deliver 5.4–27?mg/kg/24?hr).	*Adverse events:* Hypertension, tachy CNS stimulation, irritability, seizures, vomiting, increased gastric residuals,
Doxepin Adapin, Sinequan. Tricyclic antidepressant. Capsule: 10, 25, 50, 75, 100, 150?mg. Oral concentrate: 10?mg/mL. Cream: 5%.	**Treatment of depression, analgesic for neuropathic pain (increase synaptic concentrations of serotonin and norepinephrine).** *Children:* 1–3?mg/kg/24?hr. *Adolescent:* 25–50?mg/24?hr to start, max: 100?mg/24?hr. *Adults:* 30–150?mg/24?hr to start, max: 300?mg/24?hr (single dose max: 150?mg).	*Caution:* Contraindicated for narrow-a *Adverse events:* Sedation, drowsines headache, dry mouth, constipation, ir weight gain, urinary retention, difficult vision, hypotension, arrhythmias. *Monitoring:* ECG, doxepin concentrat 30–150?ng/mL, toxic >500?ng/mL.

Doxorubicin hydrochloride Adriamycin, Rubex. Injection: 2?mg/mL. Powder for injection.	**Antineoplastic used for various tumor types (inhibit DNA and RNA synthesis).** *Children:* 35–75?mg/m^2 /dose repeat every 21 days; or 20–30?mg/m^2 repeat every wk; or 60–90?mg/m^2 given as continuous infusion over 96?hr q 3–4 wk. *Adults:* 60–75?mg/m^2 /dose every 21 days. *Liver disease:* reduce dose: bilirubin 1.2–3 (reduce by 50%), bilirubin >3 (reduce by 75%).	*Caution:* Contraindicated if patient ha failure, cardiomyopathy, received a to 550?mg/m^2 (400?mg/m^2 if prior or co idarubicin, mitoxantrone, cyclophosph cardiac area). *Adverse events:* Cardiotoxicity, alope hyperpigmentation of nail bed, hyper esophagitis, mucositis, nausea, vomi (onset, 7 days; nadir, 10–14 days; re lacrimation, extravasation tissue necr
Dronabinol, tetrahydrocannabinol Marinol. Capsule: 2.5, 5, 10?mg.	**Antiemetic for cancer chemotherapy (inhibits the vomiting center).** *Children and adults:* 5?mg/m^2 /dose q2–4h starting 1–3?hr before chemotherapy (max: 15?mg/m^2 /dose).	*Adverse events:* Drowsiness, difficult change, hallucinations. *Monitoring:* Monitor for abuse.
Droperidol Inapsine. Injection: 2.5?mg/mL.	**Antiemetic, antipsychotic (alters the action of dopamine in the CNS and has a-adrenergic blockade).** *Children 2–12 yr:* IV, IM: 0.05–0.06?mg/kg/dose q4–6h as needed for nausea. *Adults:* IV, IM: 2.5–5?mg/dose q3–4h as needed.	*Adverse events:* Hypotension, tachyc reactions, confusion, memory loss.
D-Xylose Xylo-pfan. Powder for oral solution. .	**Diagnostic agent used to evaluate intestinal disorders due to disease or injury (mechanism not understood).** *Children:* 500?mg/kg as 5–10% solution; max: 25?g. *Adults:* 5–25?g as 10% solution followed by 200–400?mL of water.	*Adverse events:* Nausea, vomiting, cr bloating. *Monitoring:* Blood and urinary D-Xylos

Edetate calcium disodium Calcium Disodium Versenate. Injection: 200?mg/mL.	**Antidote for acute and chronic lead poisoning (chelating agent).** *Children and adults:* 500?mg/m^2 /dose once daily.	*Cautions:* Contraindicated in severe r patients with active tuberculosis or he tubercular lesions. *Adverse events:* Arrhythmias, hypoter headache, chills, skin eruptions, hypo hypokalemia, hypocalcemia, hyperuri diarrhea, abdominal cramps, back pa paresthesia, tetany, nephrotoxicity, re *Monitoring:* 24-hr urine collection afte lead excretion/mg calcium EDTA (pos blood lead level.
Edetate disodium Chealamide, Disotate, generic. Injection: 150?mg/mL.	**Emergency treatment of hypercalcemia and digitalis-induced ventricular dysrhythmias (chelating agent).** *Children:* 40–70?mg/kg/24?hr slow infusion over 3–4?hr; administer for 5 days then 5 days off drug. *Adults:* 50?mg/kg/dose for 5 days, then 2 days off, then restart for total of 15 doses. *Digitalis arrhythmias (children and adults):* 15?mg/kg/hr continuous infusion (max: 60?mg/kg/24?hr).	*Cautions:* Contraindicated in severe r tuberculosis. *Adverse events:* Arrhythmias, hypoter headache, chills, hypokalemia, hypoc hypomagnesemia, hyperuricemia, vo abdominal cramps, dysuria, back pai
Edrophonium chloride Reversol, Tensilon, Enlon. Injection: 10?mg/mL.	**Diagnosis of myasthenia gravis, differentiation of cholinergic crisis from myasthenia crisis, reversal of nondepolarizing neuromuscular blockers, treatment of paroxysmal atrial tachycardia (inhibits destruction of acetylcholine by acetylcholinesterase).** *Infants:* IM: 0.5–1?mg; IV: 0.1?mg followed by 0.4?mg (if no response). *Children:* diagnosis (initial): IM: <34?kg: 1?mg; >34?kg: 5?mg IV: 0.04?mg/kg over 1?min followed by 0.16?mg/kg given within 45?sec (if no response); max:: 10?mg total. Titration of oral anticholinesterase therapy: IV 0.04?mg/kg given 1?hr after oral intake of treatment drug; if strength improves increase dose of neostigmine or pyridostigmine. *Adults:* Diagnosis: IM: Initial 10?mg; if cholinergic reaction occurs, give 2?mg in 30?min to rule out false-negative reaction. IV: 2?mg given over 15?sec, 8?mg given 45?sec later (if no response). Titration of oral anticholinesterase therapy: IV 1–2?mg given 1?hr after an oral dose. Increase oral dose if strength improves.	*Adverse events:* Arrhythmias, hypoter vomiting, diarrhea, stomach cramps, urinary frequency, lacrimation, diplopi laryngospasm, bronchospasm, respir

Enalapril/Enalaprilat Vasotec. Oral (enalapril): 2.5, 5, 10, 20?mg. Injection (enalaprilat): 1.25?mg/mL. Extemporaneous formulations are available.	**Treatment of hypertension and congestive heart failure (angiotensin-converting enzyme inhibition).** *Neonate:* PO: 0.1?mg/kg/24?hr in 1–2 doses (may increase to 0.4?mg/kg/24?hr for congestive heart failure or adequate hypertension response). IV: 5–10?µg/kg/does every 8–24?hr. *Infants and children:* PO: 0.1–0.5?mg/kg/24?hr in 1–2 doses. IV: 5–10 ?mg/kg / does q8–24h. *Adolescent and adults:* PO: 2.5–5?mg/24?hr and titrate to max 40?mg/ 24?hr in 2 doses. IV: 0.625–1.25?mg/dose q6h (max: 20?mg/24?hr). *Caution:* Avoid or adjust dose in patients with renal impairment (CrCl 10–50?mL/min, give 75% of dose; CrCl <10?mL/min, give 50% of dose).	*Adverse events:* Hypotension, tachyc fatigue, dizziness, headache, cough, hypoglycemia. *Comments:* Lower doses if concurren renal function, concurrent indomethac response.
Enoxaparin sodium Lovenox. Injection: 30?mg/0.3?mL.	**Prophylaxis and treatment of venous thromboembolism (low molecular weight heparin with activity against factor Xa and IIa).** *Neonates and children:* SC: 1?mg/kg q8–12h. *Adults:* SC: 30?mg twice daily or 1?mg/kg twice daily (depends on indication).	*Adverse events:* Thrombocytopenia a than unfractionated heparin). *Monitoring:* Dose to heparin plasma le assay) mid-interval 0.5–1.0?U/mL, or

Epinephrine Adrenalin. Injection: 0.01?mg/mL, 0.1?mg/mL, 1?mg/mL. Suspension: 5?mg/mL. Aerosol MDI, inhalation solution, ophthalmic solution, topical solution.	**Treatment of cardiac arrest, bronchospasm, anaphylactic reactions, open-angle glaucoma (stimulates a, ß$_1$ and ß$_2$ receptors).** *Neonates:* IV, intratracheal: 0.01–0.03?mg/kg (0.1–0.3?mL/kg of 1:10,000 solution) q 3–5?min. *Infants and children:* SC: 0.01?mg/kg (0.01?mL/kg/dose of 1:1,000 solution, or 0.005?mL/kg/dose of suspension). IV: 0.01?mg/kg (0.1?mL/kg of 1:10,000 solution) (max: 1?mg). IT: 0.1?mg/kg/dose (0.1?mL/kg of 1:1,000 solution) (max: 0.2?mL/kg). Continuous infusion: 0.1–1?µg/kg/min per response. Nebulization: 0.25–0.5?mL of 2.25% racemic epinephrine diluted in 3?mL normal saline. Ophthalmic: instill 1–2 drops in eye(s) 1–2 times daily. *Adults:* IV: 1–5?mg q 3–5?min. IT: 1?mg initial; max: 12.5?mg/dose. IM, SC: 0.1–0.5?mg q 10–15?min. Continuous infusion: 1–10?µg/min. Ophthalmic: Instill 1–2 drops in eye(s) 1–2 times daily.	*Adverse events:* Tachycardia, hyperte restlessness, irritability, headache, tre nausea, vomiting, acute urinary reten

Epoetin alfa, erythropoietin, EPO Epogen, Procrit. Injection: Preservative-free vial 2,000, 3,000, 4,000, 10,000?U/mL. Preserved 10,000?U/mL.	**Anemia associated with prematurity, end-stage renal disease, zidovudine-treated HIV-infected patients, cancer patients receiving chemotherapy (induces erythropoiesis).** Administer IV, SC. *Neonates:* 100–500 units/kg/dose q 1–2 days for 10–21 days. *Children and adults:* Cancer patients: 150 units/kg/dose 3 times/wk (may increase to 300 units/kg/dose). Hemodialysis patients: 50–100 units 3 times/wk. Zidovudine-treated patients: 100 units/kg/dose 3 times/wk.	*Caution:* Uncontrolled hypertension, r newborns must have adequate iron s oral or intravenous iron supplement. *Adverse events:* Hypertension, edem rash, arthralgias, hypersensitivity. *Monitoring:* Serum iron, reticulocyte c (reduce dose or stop EPO if hematoc pressure.
Ergocalciferol Calciferol, Drisdol, generic. Tablet, capsule: 50,000 units. Liquid: 8,000 units/mL. Injection: 500,000 units/mL (1?µg = 40 units).	**Treatment of refractory rickets, hypophosphatemia, hypoparathyroidism (vitamin D analog stimulates calcium and phosphate absorption).** *Premature infants:* 10–20?µg/24hr. Renal failure: *Children:* 100–1,000?µg/24hr. *Adults:* 500?µg/24hr. Hypoparathyroidism: *Children:* 1.25–5?mg/24?hr. *Adults:* 0.625–5?mg/24?hr. Rickets: *Children:* 75–125?µ:g/24hr. *Adults:* 0.25–1.5?mg/24?hr.	*Adverse events:* Hypercalcemia, wea hypertension, arrhythmias, mild acidc hypercholesterolemia, nausea, vomiti nephrocalcinosis, photophobia. *Monitoring:* Serum calcium and phosp phosphatase, bone radiography.
Ergotamine Cafatine, Cafergot. Tablet: 1?mg/2?mg. Aerosol: 9?mg/mL. Suppository: 2?mg.	**Prevent or abort vascular headaches, e.g., migraine or cluster headache (ergot alkaloid a-adrenergic blocker).** *Older children and adolescents:* 1?mg SL or PO at onset of attack and q30?min to relief (max: 3?mg per attack). *Adults:* 1–2?mg SL or PO, may repeat q30?min to maximum of 6?mg (maximal dose/wk: 10?mg).	*Caution:* Reduce dose by 50% if patie methysergide. *Adverse events:* Tachypnea, vasospa diarrhea, leg cramps, muscle weakne
Esmolol Brevibloc. Injection: 10?mg/mL.	**Antiarrhythmic, antihypertensive (ß-blocker, class II antiarrhythmic).** *Children:* 100–500?µg/kg over 1?min then continuous infusion 200–1,000?µg/kg /min *Adults:* 500?µg/kg over 1?min then 50–200?µg/kg/min.	*Caution:* Contraindicated in sinus bra uncompensated heart failure. *Adverse events:* Hypotension, bradyc phenomenon, dizziness, confusion, le bronchoconstriction
Ethacrynic acid Edecrin. Tablet: 25, 50?mg. Injection.	**Diuretic (act at ascending loop of Henle).** *Children:* PO: 1–3?mg/kg/24?hr. IV: 0.5–1?mg/kg/ dose q8–24h. *Adults:* PO: 25–400?mg/24?hr. IV: 0.5–1?mg/kg/ dose q8–24h.	*Adverse events:* Hypotension, fluid ar depletion, hyperuricemia, ototoxicity,

Ethosuximide Zarontin. Capsule: 250?mg. Syrup: 250?mg/5?mL.	**Anticonvulsant for treatment of absence, myoclonic, and akinetic epilepsy (increased seizure threshold).** *Children:* *<6 yr:* Start 15?mg/kg/24?hr in 2 doses; increase q 4–7 days to therapeutic level, usually 15–40?mg/kg/24?hr in 2 doses. Max: 1.5?g/24?hr. *>6 yr and adults:* Start 250?mg twice daily; increase by 250?mg/24?hr q 4–7 days up to therapeutic level or 1.5?g/24?hr.	*Adverse events:* Sedation, lethargy, r anorexia, abdominal pain, leukopenia aplastic anemia. *Monitoring:* Ethosuximide concentrati 40–100?µg/mL; toxic 150?µg/mL.
Etoposide, VP-16 VePesid. Capsule: 50?mg. Injection: 20?mg/mL.	**Antineoplastic for treatment of various cancers (inhibits mitotic activity).** *Children:* IV: 150?mg/m^2 /24?hr for 3 days for 2–3 cycles for acute myelocytic leukemia remission or brain tumor; 160?mg/m^2 /24?hr for 4 days for bone marrow transplant conditioning. *Adults:* IV: 50–100?mg/m^2 /24?hr for 3–5 days per course. PO = IV dose × 2 to nearest 50?mg.	*Adverse events:* Hypotension, tachyc headache, chills, alopecia, rash, urtic diarrhea, mucositis, myelosuppressio days), thrombocytopenia (nadir, 9–16 neuropathy, bronchospasm.
Factor IX complex (human) Konyne 80, Proplex, Profilnine. Injection.	**Antihemophilic agent to control bleeding in patients with factor IX deficiency, i.e., hemophilia B or Christmas disease, or with inhibitors to factor VIII, i.e., hemophilia A (replacement of deficient factor).** *Children and adults:* 20–25 units/kg/dose up to q24h; factor VIII–inhibitor patients: 75–100 units/kg/dose up to q6h.	*Adverse events:* Flushing, fever, heac thrombosis (with high doses), tingling and neck.

Famotidine Pepcid. Tablet: 20, 40?mg. Injection.	**Treatment of gastric and duodenal ulcer and control of gastric pH in critically ill patients (blocks H_2 -receptors).** *Infants and children:* PO, IV: 1–2?mg/kg/24?hr in 1–2 doses; max: 40?mg/24?hr. *Adults:* PO: 40?mg/24?hr at bedtime; IV: 20?mg q12h.	*Cautions:* Reduce dose for renal func 30–50?mL/min give 50% of dose; Cr(25% of dose. *Adverse events:* Gastrointestinal disc thrombocytopenia, increased liver en:
Fat emulsion Intralipid, Liposyn. Injection: 10%, 20%.	**Source of essential fatty acids and calories (nutritional supplement with parenteral nutrition).** *Premature infants:* start 0.5?g/kg/24?hr and increase by 0.5?g/kg/24?hr as tolerated to 3?g/kg/24?hr. *Infants and children:* start 0.5–1?g/kg/24?hr and increase at 0.5?g/kg/24?hr increments as tolerated to maximum of 3–4?g/kg/24?hr. *Adolescents and adults:* 1?g/kg/24?hr and increase as tolerated to maximum of 2.5?g/kg/24?hr.	*Cautions:* Fat calories should not exc calories. Contraindicated in patients v soybean allergies. *Adverse events:* Hyperlipidemia, hepa and hypoxemia may occur if infused t excessive dose. *Monitoring:* Serum triglycerides.

Felbamate Felbatol. Tablet: 400, 600?mg. Oral suspension: 600?mg/5?mL.	**Adjunctive therapy primarily used for refractory generalized and partial seizures associated with Lennox-Gastaut syndrome (anticonvulsant with unknown mechanism of action).** *Children: 2–14 yr:* Start 15?mg/kg/24?hr in 3–4 doses, increase weekly by 15?mg/kg/24?hr to maximum of 45?mg/kg/24?hr or 3,600?mg (whichever is less). *> 14 yr:* Start 1,200?mg/24?hr in 3–4 doses; increase weekly by 1,200?mg/24?hr to max 3,600?mg/24?hr.	*Caution:* Over 30 cases each of hepa anemia with multiple fatalities have be *Adverse events:* Headache, insomnia behavioral changes, depression, atax vomiting, diarrhea, thrombocytopenia leukopenia, agranulocytosis, aplastic acute liver failure. *Monitoring:* Interacts with phenytoin, c valproate; monitor drug levels if felba
Fentanyl citrate Duragesic, Sublimaze. Injection, transdermal, oral lozenge.	**Relief of pain, sedation, preoperative medication, anesthesia adjunct (narcotic analgesic, binds to opium receptors).** *Neonates and infants:* IV: 1–4?µg/kg/does; may repeat every 2–4?hr or continuous infusion 0.5–5?µg/kg/hr. *Children 1–12 yr:* Pain: IM, IV: 1–3?µg/kg/does, may repeat q 30–60?min; continuous infusion 1–5?µg/kg/hr; Oralet 5–15?µg/kg. *Children >12 yr and adults:* Pain: IV, IM: 0.5–1?µg/kg/does, may repeat in 30–60?min. Transdermal: 25–100?µg/hr system as needed for relief. PO: 5?µg/kg or 400?µg (whichever is less). Anesthesia: IV, IM: 2–50?µg/kg.	*Cautions:* Rapid IV infusion may resu and chest wall rigidity with impaired v respiratory distress; physical depende days. *Adverse events:* Hypotension, bradyc depression, constipation, biliary tract vomiting, urinary tract spasm, respira
Fexofenadine Allegra. Capsule: 60?mg. Tablet: 30, 60, 180?mg.	**Antihistamine with selective peripheral H_1 -receptor activity. Treat seasonal allergic rhinitis and chronic idiopathic urticaria.** *Children<12 yr:* 30?mg bid. *Children >12 yr and adults:* 60?mg bid, or 180?mg q24h.	*Adverse events:* Very good safety pro even with overdoses (mainly dizzines mouth).
Filgrastim, G-CSF Neupogen. Injection: 300?µg/mL.	**Granulocyte colony-stimulating factor; reduces duration of neutropenia (stimulates the production, maturation, and activation of neutrophils).** *Neonates:* 5?µg/kg/does daily for 3–6 doses. *Children and adults:* 5–10?µg/kg/does daily for up to 14 days, may discontinue if absolute neutrophil count remains >1,000/mm^3 for 3 consecutive days.	*Cautions:* Malignancy with myeloid ch *Adverse events:* Hypotension, vascul exacerbation of pre-existing skin diso acid, thrombocytopenia, medullary pa mostly located in lower back, iliac cre hematuria, proteinuria.
Flecainide Tambocor. Tablet: 50, 100, 150?mg. Extemporaneous formulation.	**Treatment of supraventricular tachycardia and ventricular arrhythmias (antiarrhythmic class 1c, slows conduction in cardiac tissue).** *Children:* Initial 1–3?mg/kg/24?hr in 3 divided doses; may increase up to 12?mg/kg/24?hr. *Adults:* Initial 100?mg q12h; may increase by 100?mg/24?hr q 4 days to max 400?mg/24?hr.	*Caution:* Decrease dose by 25–50% i in 2nd- or 3rd-degree heart block. *Adverse events:* Bradycardia, heart b arrhythmias, congestive heart failure, disturbances, headache, fatigue, asth constipation, abdominal pain, elevate paresthesias, and tremor. *Monitoring:* Serum trough concentrati 0.2–1?µg/mL).

Fludarabine, FAMP Fludara. Injection powder.	**Treatment of B-cell chronic lymphocytic leukemia and acute lymphocytic leukemia unresponsive to previous therapy (antineoplastic, antimetabolite).** *Children:* 10?mg/m^2 over 15?min, followed by 30.5?mg/m^2 /24?hr by continuous infusion for 5 days. *Adults:* 20–25?mg/m^2 over 30?min for 5 days.	*Adverse events:* Neurotoxicity (prima demyelinating encephalopathy with m deterioration), somnolence, weakness acidosis, hyperuricemia, hyperphosp hyperkalemia, hypocalcemia, nausea stomatitis, metallic taste, myelosuppr days; platelet nadir, 16 days; recover pneumonitis, dyspnea, nonproductive pneumonitis, hearing loss, reversible
Fludrocortisone acetate Florinef. Tablet: 0.1?mg.	**Partial replacement therapy for adrenal insufficiency (mineralocorticoid with glucocorticoid activity).** *Infants and children:* 0.05–0.1?mg/24?hr. *Adults:* 0.05–0.2?mg/24?hr.	*Adverse events:* Hypertension, edem failure, convulsions, headache, acne, hypokalemia, HPA-axis (adrenal) sup muscle weakness.
Flumazenil Romazicon. Injection.	**Benzodiazepine antagonist to reverse sedative effects (antagonize benzodiazepine effects on ?-aminobutyric acid/benzodiazepine receptor complex).** *Children:* 0.005–0.01?mg/kg load, then as continuous infusion 0.005–0.01?mg/kg/hr (maximal cumulative dose: 1?mg).	*Caution:* Avoid if benzodiazepine is u potentially life-threatening conditions, epilepticus, increased intracranial pre *Adverse events:* Arrhythmias, hypote seizures, acute withdrawal symptoms on benzodiazepine or tricyclic antidep
Flunisolide AeroBid, Nasalide. Metered-dose inhaler: 250?µg/puff. Nasal spray: 25?µg/actuation.	**Treatment of asthma and rhinitis (inhaled steroid, anti-inflammatory).** *Children and adults:* Oral inhalation: 2–4 puffs twice daily; nasal spray: 1–2 sprays in each nostril bid–tid.	*Adverse events:* Candidal infections o dysphonia, sore throat, bitter taste, na headache, dizziness, short-term grow

Fluocinolone acetonide Fluonid, Synalar, generic. Topical cream, ointment, shampoo, solution, oil: 0.01–0.025%.	**Inflammation and corticosteroid-responsive dermatoses (topical adrenocorticosteroid, anti-inflammatory).** *Children and adults:* Apply a thin layer bid–qid.	*Adverse events:* Acne, hypopigmenta dermatitis, skin atrophy, folliculitis, se HPA-axis suppression, growth retarda
Fluocinonide Fluonex, Lidex, generic. Cream, gel, ointment, solution: 0.05%.	**Inflammation and corticosteroid-responsive dermatoses (topical adrenocorticosteroid, anti-inflammatory).** *Children and adults:* Apply a thin layer 2–4 times qid.	*Adverse events:* Acne, hypopigmenta dermatitis, skin atrophy, folliculitis, se HPA-axis suppression, growth retarda
Fluoride Generic. Oral drops, topical gel, lozenge, tablet, topical rinse, oral solution.	**Prevention of dental caries (promotes remineralization, increase resistance to acid dissolution).** Dental rinse or gel: *Children:* 5–10?mL after brushing. *Adults:* 10?mL after brushing.	*Adverse events:* Gastrointestinal ups stannous fluoride may stain teeth.
Fluorometholone Flarex, FML. Ophthalmic ointment 0.1%. Ophthalmic suspension: 0.1, 0.25%.	**Inflammatory conditions of the eye (ophthalmic glucocorticoid, anti-inflammatory).** *Children >2 yr and adults:* Ointment: Apply 3 times daily in mild to moderate cases and q4h in severe cases. Drops: instill 1–2 drops into conjunctival sac every hr while awake and q2h at night until response, then q4–8h.	*Adverse events:* Local stinging and bu intraocular pressure.

Fluorouracil Adrucil, Efudex, Fluoroplex. Injection, topical solution, cream.	**Cancer chemotherapy (antineoplastic antimetabolite that inhibits thymidylate synthase leading to thymidine depletion).** *Children and adults:* IV: 12?mg/kg/24?hr (max: 800?mg/24?hr) for 4–5 days then 6?mg/kg every other day for 4 doses. Repeat in 4 wk. Cream or solution 5%: Apply to entire affected area bid.	*Adverse events:* Arrhythmias, hypoter cerebellar ataxia, somnolence, alopec pruritic maculopapular rash, photosen erythrodysesthesias of hands and fee hyperpigmentation of nail beds, naus gastrointestinal hemorrhage, esophag hepatotoxicity, conjunctivitis, myelosu platelets: onset, 7–10 days; nadir, 9– days).
Fluoxetine hydrochloride Prozac. Capsule: 10, 20?mg. Liquid: 20?mg/5?mL.	**Treatment of depression and obsessive-compulsive disorders (antidepressant, inhibits CNS serotonin uptake).** *Children 5–18 yr:* Initial 5–10?mg/24?hr then titrate slowly to effect (max: 20?mg/24?hr). *Adults:* Initial 20?mg/24?hr then slowly increase daily dose in 20?mg increments to effect (max: 80?mg/24?hr).	*Caution:* Avoid in patients on monoar inhibitors. *Adverse events:* Headache, nervousr anxiety, mania, suicidal ideation, trem diarrhea,constipation, dry mouth, wei *Monitoring:* Serum concentrations of 100–800?ng/mL), norfluoxetine (thera 100–600?ng/mL).
Fluticasone Flonase, Flovent. Nasal solution: 50?µg/spray. Metered-dose inhaler (MDI): 44, 110, 220?µg/spray. Rotadisk: 50, 100, 250?µg/dose.	**Treatment of allergic rhinitis and chronic asthma (inhaled corticosteroid).** *Children and adults:* Nasal spray: 1–2 sprays in each nostril once daily. MDI: 88–880?µg bid (depending on asthma severity and need for systemic corticosteroids). Rotadisk: 50–1,000?µg bid (depending on asthma severity and need for systemic corticosteroids).	*Adverse events:* Dysphonia, oral thru suppression, growth suppression, cat
Fluvoxamine Luvox, generic. Tablet: 25, 50, 100?mg.	**Serotonin reuptake inhibitor; treatment of depression, obsessive-compulsive disorder (OCD).** *Children <12 yr:* Start 25?mg/hr increase by 25?mg/24?hr q 4–7 days to effect or maximum of 200?mg/24?hr. Divide into 2 daily doses if >50?mg/24?hr needed. *Children >12 yr:* Start 25?mg/24?hr; increase by 25?mg/24?hr q 4–7 days to effect or maximum of 300?mg/24?hr. Divide into 2 daily doses if >50?mg/24?hr needed. *Adults:* Start 50?mg/24?hr; increase by 50?mg/24?hr q 4–7 days to effect or maximum of 300?mg/24?hr. If more than 100?mg/24?hr is needed, divide into 2 doses/24?hr.	*Caution:* Do not abruptly discontinue syndrome may occur over several da 25–50?mg/24?hr q 5–7 days. *Adverse events:* Somnolence, heada nausea, constipation. *Drug interactions:* Inhibits cytochrome drugs such as methadone and pheno increased levels when used concurre
Folic acid Generic. Injection. Tablet: 0.4, 0, 8, 1?mg. Extemporaneous formulation.	**Treatment of folate deficiency anemias, i.e., megaloblastic, macrocytic (cofactor for normal erythropoiesis).** *Neonates to 6 mo:* PO: 25–35?µg/24hr. *6 mo–3 yr:* 50?µg/24hr. *4–6 yr:* 75?µg/24hr. *7– 10 yr:* 100?µg/24hr. *11–14 yr:* 150?µg/24hr. *>15 yr and adults:* 200?µg/24hr. Folate deficiency: 1?mg/24?hr.	*Caution:* Large folate doses may mas of vitamin B_{12} deficiency while allowin consequences to progress.

Fosphenytoin Cerebyx Injection: 10?mL vials contain 750?mg fosphenytoin (500?mg phenytoin), 2-mL vials contain 150?mg fosphenytoin.	**Treatment of acute seizures (may substitute or intravenous phenytoin).** *Children and adults:* Loading dose is 15–20?mg/kg phenytoin dosing equivalents (maximum rate: 150?mg/min). May substitute IV or IM for phenytoin maintenance doses. Each 1.5?mg fosphenytoin = 1?mg phenytoin dosing equivalent.	*Cautions:* Same as phenytoin. *Drug interactions:* Same as phenytoir
Furosemide Lasix, generic. Injection: 10?mg/mL. Oral solution: 10?mg/mL, 40?mg/mL. Tablet: 20, 40, 80?mg.	**Diuretic (inhibits sodium and chloride reabsorption at the ascending loop of Henle and distal tubule).** *Premature infants:* 0.5–2?mg/kg IV or 1–4?mg/kg PO q12–48h (dose to response). *Infants and children:* 1–2?mg/kg IV or 1–4?mg/kg PO q6–24h or continuous infusion (start at 0.05?mg/kg/hr and adjust dose to response). *Adults:* 10–600?mg/24?hr in 1–4 divided doses; or continuous infusion 0.05?mg/kg/hr (adjust dose to effect).	*Adverse events:* Dehydration, electro hyperuricemia, photosensitivity, ische hypercalciuria, renal stones, ototoxici >4?mL/min), gastrointestinal intolerar
Gabapentin Neurontin. Capsule: 100, 300, 400?mg.	**Adjunct to treatment of partial and secondarily generalized seizures; treatment of neuropathic pain (mechanism not certain).** *Children 2–12 yr:* 15–35?mg/kg/24?hr in 3 divided doses (max: 50?mg/kg/24?hr). *Children >12 yr and adults:* Start 300?mg daily, then daily increase by 300?mg to 900–3,600?mg/24?hr in 3 divided doses.	*Adverse events:* Somnolence, dizzine depression, hyperactivity, aggression constipation, nausea, weight gain, dip
Gamma globulin *See Immune globulin*		
Gentian violet Generic. Topical solution: 1%, 2%.	**Treatment of cutaneous and mucocutaneous infections (kills *Candida,* staphylococcal species, and some vegetative gram-positive bacteria).** *Infants:* Apply 3 or 4 drops of a 0.5% solution under tongue or on lesion after feedings. *Children and adults:* Apply 0.5–2% with cotton to lesion bid–tid for 3 days.	*Caution:* Do not swallow. *Adverse events:* Burning, local irritatic reactions.
Glucagon Powder for injection.	**Treatment of hypoglycemia (stimulates hepatic glycolysis and gluconeogenesis).** *Neonates:* 0.3?mg/kg/dose (max: 1?mg) IV, IM, SC. *Children:* 0.025–0.1?mg/kg/dose (max: 1?mg); may repeat in 20?min. *Adults:* 0.5–1?mg; may repeat in 20?min as needed.	*Adverse events:* Nausea, vomiting, hy reactions.
Glycopyrrolate Robinul, generic. Injection: 0.2?mg/mL. Tablet: 1?mg.	**Inhibits salivation and excessive secretions of the respiratory tract; bronchodilator, adjunct to treatment of peptic ulcer, reversal of muscarinic effects on cholinergic agents (anticholinergic).** *Children:* Control of secretions: PO: 40–100?µg/kg/dose tid–qid. IM, IV: 4–10?µg/kg/dose q3–4h. Preoperative IM: 4.4–8.8?µg/kg/dose 30–60?min before procedure.	*Adverse events:* Tachycardia, nervou insomnia, drowsiness, dry mouth, cor urinary retention, blurred vision.

Gold sodium thiomalate Myochrysine, generic. Injection: 25?mg/mL.	**Treatment of rheumatoid arthritis (mechanism unknown).** *Children:* Test dose: 10?mg IM; followed by 1?mg/kg IM q wk for 20 wk; then 1?mg/kg/dose q 2–4 wk (max: 50?mg/dose). *Adults:* Test dose: 10?mg IM; then 25–50?mg/wk; then 25–50?mg IM every 2–4 wk once response is noted.	*Cautions:* Patient should be sitting or the dose; avoid in patients with syster erythematosus or blood dyscrasias. *Adverse events:* Headache, flushing, dermatitis, erythema nodosum, hives nails, stomatitis, gingivitis, glossitis, c eosinophilia, leukopenia, thrombocyt proteinuria, nephrotic syndrome, puln interstitial pneumonitis, hepatotoxicity neuropathy. *Monitoring:* Gold serum concentratior 1–3?µg/mL
Gonadorelin Factrel, Lutrepulse. Injection.	**Evaluate gonadotropin regulation in precocious or delayed puberty, treat primary hypothalamic amenorrhea (stimulates release** of **luteinizing hormone).** *Children:* IV (HCl salt) 100?µg *Children >12 yr and adults:* IV, SC: 100?µg during days 1–7 of menstrual cycle.	*Adverse events:* Flushing, lightheade abdominal discomfort. *Monitoring:* Plasma luteinizing hormo follicle-stimulating hormone.
Granisetron Kytril. Injection: 1?mg/mL. Tablet: 1?mg.	**Antiemetic (selective 5-HT_3 antagonist).** *Children >2 yr and adults:* IV 10–20?µg/kg 15–30?min before chemotherapy; may repeat 2–3 doses in 24?hr. PO: 1?mg bid starting 1?hr before chemotherapy.	*Adverse events:* Arrhythmias, bradyc pressure changes, agitation, anxiety, elevations.
Guaifenesin, Glycerol Guaiacolate Generic. ± Codeine, dextromethorphan, phenylpropanolamine, or phenylephrine. Syrup, tablet, capsule, liquid.	**Temporary control of cough (expectorant).** *Children <2 yr:* 12?mg/kg/24?hr in 6 divided doses. *2–5 yr:* 50–100?mg q4h (max: 600?mg/24?hr). *6–11 yr:* 100–200?mg q4h (max: 1,200?mg/24?hr). *>12 yr and adults:* 200–400?mg q4h (max: 2.4?g/24?hr).	*Caution:* Monitor doses and toxicities combination products.

Guanethidine Ismelin. Tablet: 10, 25?mg.	**Treatment of moderate to severe hypertension (acts as false neurotransmitter).** *Children:* 0.2?mg/kg/24?hr; may increase by 0.2?mg/kg/24?hr every wk to maximum of 3?mg/kg/24?hr. *Adults:* Initial 10?mg/24?hr; increase weekly to maximum of 25–50?mg/24?hr.	*Adverse events:* Palpitations, chest p fatigue, headache, drowsiness, confu anorexia, urinary frequency, nocturia, disturbances, orthostatic hypotension
Guanfacine HCl Tenex. Tablet: 1?mg.	**Treatment of hypertension and attention deficit disorder (ADD) (stimulate a_2 -receptors in the brainstem)** *Children:* ADD: 1?mg/24?hr. *Adults:* 1?mg/24?hr; may increase q 4 wk to maximum of 3?mg/24?hr.	*Adverse events:* Somnolence, dizzine constipation, gastrointestinal upset.
Haloperidol Haldol, generic. Oral concentrate: 2?mg/mL. Tablet: 0.5, 1, 2, 5, 10, 20?mg. Injection.	**Treatment of severe behavioral problems including psychoses and Tourette disorder (competitive blocker of dopamine receptors).** *Children 3–12 yr:* PO: start 0.25–0.5?mg/24?hr in 2–3 divided doses, then increase weekly by 0.25–0.5?mg daily based on response to max 0.15?mg/kg/24?hr. *6–12 yr:* IM: 1–3?mg/dose q4–8h (max: 0.15?mg/kg/24?hr). *Adults:* PO: 0.5–5?mg 2–3 times daily. IM: 2–5?mg q4–8h.	*Adverse events:* Drowsiness, restless extrapyramidal symptoms, dystonia, a pseudoparkinsonism, tardive dyskine malignant syndrome, seizures, consti swelling of breasts, hypotension, tach urinary retention, blurred vision, renta cholestatic liver disease, agranulocyt *Monitoring:* Plasma concentrations (th 5–15?ng/mL, toxic >42?ng/mL).

Heparin (unfractionated) Generic Injection.	**Prophylaxis and treatment of thromboembolism (potentiates actions of antithrombin III**). *Neonates, infants, and children:* Thrombosis and ECMO: load 50 units/kg IV bolus, and 15–35 units/kg/hr continuous IV infusion maintenance dose (adjust to target activated partial thromboplastin time [APTT] or heparin level). Catheter patency: 0.5–1 unit/mL. *Adults:* load 70–100 units/kg IV push, 15–25 units/kg/hr continuous IV infusion (target APTT or heparin level); SC: 5,000 units q8–12h for prophylaxis.	*Caution:* Avoid if severe thrombocyto hemorrhage, bacterial endocarditis. *Adverse events:* Bleeding from variou gums, nose; bruising, thrombocytope *Monitoring:* APTT (therapeutic, 1.5–2 toxic >2.5 times baseline); plasma he (anti-factor X assay: therapeutic 0.3–
Histrelin Supprelin. Injection.	**Central idiopathic precocious puberty (gonadotropin-releasing hormone analog).** *Children:* SC: 10?µg/kg once daily. *Adult female:* 100?µg/24?hr for endometriosis.	*Adverse events:* Anxiety, depression, headaches.
Homatropine hydrobromide Isopto Homatropine, generic. Ophthalmic solution: 2%, 5%.	**Producing cycloplegia and mydriasis for refraction, treatment of uveitis (anticholinergic).** *Children:* For mydriasis: 1 drop of 2% solution before procedure; may repeat every 10?min as needed. Uveitis: 1 drop 2% solution bid–tid. *Adults:* Mydriasis: 1–2 drops of 2% or 5% solution before procedure; may repeat every 10?min. Uveitis: 1–2 drops of 2% or 5% solution bid–tid.	*Adverse events:* Blurred vision, photc and respiratory congestion.

Human growth hormone Humatrope, Nutropin, Protropin. Injection.	**Treatment of growth failure due to inadequate growth hormone secretion (replacement therapy).** *Children:* Humatrope: 0.06?mg/kg (0.15?IU/kg) 3 times/wk. Nutropin: 0.043?mg/kg/24?hr. Protropin: 0.1?mg/kg (0.26?IU/kg) 3 times/wk.	*Adverse events:* Local lipoatrophy, hy hip or knee.
Hyaluronidase Wydase. Injection: 150 units/mL.	**Treatment of extravasation, enhance absorption of fluids administered by hypodermoclysis (hydrolysis of hyaluronic acid to modify permeability of connective tissue).** *Neonates, infants, children:* inject using 25–26?g needle (total 1?mL, 150?U) SC or intradermal at 5 sites (0.2?mL to each) at the leading edge of the extravasation.	*Adverse events:* Tachycardia, hypote

Hydralazine Generic. Injection: 20?mg/mL. Tablet. Extemporaneous formulations.	**Treatment of hypertension, adjunct treatment of congestive heart failure with nitrates (direct vasodilation of arterioles).** *Neonates:* IV: 0.1–0.5?mg/kg/dose q6–8h. PO: 0.25–1?mg/kg/dose q6–8h. *Infants and children:* IM, IV start 0.1–0.2?mg/kg/dose q4–6h and titrate to effect (max: 3.5?mg/kg/24?hr). PO: 0.75–1?mg/kg/24?hr in 2–4 divided doses (max: 7.5?mg/kg/24?hr). *Adults:* IM, IV: 10–20?mg/dose every 4–6?hr (max 40?mg/dose). PO: 10–25?mg/dose qid and titrate to effect (max: 300?mg/24?hr).	*Adverse events:* Palpitations, flushing headache, nausea, vomiting, anorexi syndrome, arthralgias, and peripheral to pyridoxine deficiency).
Hydrochlorothiazide Generic. Oral solution: 50?mg/5?mL. Tablet: 25, 50, 100?mg. Combination products (e.g., spironolactone).	**Treatment of hypertension and fluid overload (edema) states, e.g., bronchopulmonary dysplasia, congestive heart failure; prevention of recurrent renal calcium stones (diuretic inhibits sodium reabsorption in distal tubule).** *Neonates and infants:* 2–4?mg/kg/24?hr in 2 divided doses. *Infants >6 mo and children:* 2?mg/kg/24?hr in 2 divided doses. *Adults:* 12.5–100?mg/24?hr.	*Adverse events:* Hypokalemia, hypoc hypomagnesemia, hyperglycemia, hy hyperlipidemia, pancreatitis, leukoper aplastic anemia, hepatitis, intrahepati azotemia.

Hydrocortisone Generic. Cream, ointment, gel, lotion, injection, oral suspension, rectal foam	**Treatment of adrenal insufficiency, congenital adrenal hyperplasia, shock, corticosteroid-responsive dermatoses, adjunctive treatment of ulcerative colitis (anti-inflammatory, glucocorticoid).** *Neonates, infants, young children:* Adrenal insufficiency: 1–2?mg/kg IV bolus, then 25–150?mg/24?hr divided q6h. Congenital adrenal hyperplasia: IV 0.5–0.7?mg/kg/24?hr start, then 0.3–0.4?mg/kg/24?hr maintenance therapy; give doses as ¼ in AM, ¼ at noon, and ½ at night. Shock: IV: 35–50?mg/kg, then 50–150?mg/kg/24?hr divided q6h for 48–72?hr. *Infants and older children:* Adrenal insufficiency: 1–2?mg/kg IV bolus, then 150–250?mg/24?hr divided q6–8h. Anti-inflammatory: IV, IM: 1–5?mg/kg/24?hr in 1–2 doses; PO: 2.5–10?mg/kg/24?hr divided q6–8h. Shock: IV: 50?mg/kg/dose q4h. Status asthmaticus: IV: 1–2?mg/kg/dose q6h. *Adults:* Anti-inflammatory: IV, IM, PO: 15–240?mg/dose q12h. Shock: IV: 0.5–2?g q2–6h. Rectal: 1 Application 1–2 times/24?hr for 2–3 wk. Topical: Apply 3–4 times/24?hr.	*Caution:* Abrupt withdrawal may caus insufficiency. *Adverse events:* Hypertension, hyper hypokalemia, euphoria, insomnia, hea syndrome, peptic ulcer, cataracts, imı skin and muscle atrophy, acne, edem **Relative Potency of Corticosteroid**

Drug	Anti-inflammat Effect (mg)
Hydrocortisone	
Cortisone

Desoxycorticosterone	

Hydromorphone Dilaudid, generic. Injection. Tablet: 2, 4?mg. Syrup: 1?mg/5?mL. Suppository: 3?mg.	**Analgesic, antitussive (narcotic).** *Children 6–12 yr:* Cough: PO: 0.5?mg q3–4h as needed. Pain: PO: 0.03–0.08?mg/kg/dose q4–6h as needed. IV: 0.015?mg/kg/dose q4–6h as needed. *Children >12 yr and adults:* Cough: PO: 1?mg every 3–4?hr as needed. Pain: PO, IV, IM, SC: 1–4?mg/dose q4–6h as needed.	*Caution:* Tablet and syrup contain tar exacerbate asthma; do not discontinu continuous use. *Adverse events:* Sedation, drowsines restlessness, headache, tachycardia, and psychological addiction, nausea, constipation, stomach cramps, decre ureteral spasm, respiratory depressio breath, miosis, antidiuretic hormone r reactions (due to histamine release). *Comment:* IV, IM hydromorphone 1.5 10?mg; oral hydromorphone 7.5?mg (acute) or 60?mg (chronic).
Hydroxocobalamin, vitamin B_{12} Codroxomin, Hybalamin, others. Injection.	**Treatment of pernicious anemia, vitamin B_{12} deficiency, increased vitamin B_{12} requirements (replacement therapy).** *Children:* 100?µg/24?hr IM to total 1?mg over 2 wk, then 30–50?µg/mo. *Adults:* 30?µg/24?hr for 5–10 days, then 100–200?µg/mo	*Comment:* May require co-administra

Hydroxychloroquine Plaquenil sulfate. Tablet: 200?mg. Extemporaneous formulations.	**Suppression or chemoprophylaxis of malaria; treatment of systemic lupus erythematosus and rheumatoid arthritis (interferes with digestive vacuole function within sensitive malarial parasites, impairs complement-dependent antigen-antibody reactions).** *Children:* Chemoprophylaxis of malaria: 5?mg/kg once wk (begin 1–2 wk before exposure and continue for 4 wk after leaving high-risk area). Acute malaria attack: 10?mg/kg initial dose followed by 5?mg/kg in 6–8?hr on day 1, 400?mg once on day 2 and day 3. *Adults:* Malaria prophylaxis: 400?mg once wk (timing as above). Acute malaria attack: Day 1: 800?mg, then 400?mg in 6–8?hr; day 2: 400?mg once; day 3: 400?mg once. Rheumatoid arthritis and lupus erythematosus: 400?mg once daily, may increase by 200?mg if inadequate response in 4–12 wk, reduce to 200–400?mg/24?hr once response occurs and long-term maintenance is needed.	*Caution:* Avoid in porphyria or psorias *Adverse events:* Headache, confusio nightmares, psychosis, visual field de blindness, bone marrow suppression, liver failure, anorexia, nausea, vomiti dermatitis, bleaching of hair, itching, *Monitoring*: Ophthalmologic exams fo

Hydroxyurea Mylocel tablets, Hydrea, generic. Tablet: 1,000?mg. Capsule: 500?mg.	**Cancer chemotherapy, sickle cell anemia (interfere with DNA synthesis during S-phase of cell division).** *Children:* 1,500–3,000?mg/m^2 q 4–6 wk. *Adults:* Cancer chemotherapy: 80?mg/kg every third day, or 20–30?mg/kg/24?hr sickle cell anemia: 10–20?mg/kg/24?hr.	*Adverse events:* Drowsiness, headac seizures, nausea, vomiting, mucositis myelosuppression (onset, day 7; nadi day 21), alopecia, maculopapular ras of face and hands, hepatitis, increase and creatinine, hyperuricemia.
Hydroxyzine Generic. Injection, syrup, tablet, capsule.	**Treatment of allergy, itching, anxiety, and nausea and adjunct for chronic pain management (H_1 -receptor blocker).** PO, IM: *Children:* 0.6?mg/kg/dose q6h. *Adults:* 10–100?mg/dose tid–qid.	*Caution:* May worsen narrow-angle g hypertrophy, bladder neck obstructior obstructive pulmonary disease. *Adverse events:* Hypotension, drowsi headache, dry mouth, urinary retentic site.
Hyoscyamine (with atropine, scopolamine, and phenobarbital) Donnatal, generic. Capsule, elixir, tablet.	**Treatment of irritable bowel, spastic colon, spastic bladder, and renal colic (anticholinergic).** *Children:* Donnatal 0.1?mL/kg/dose q4h (max: 5?mL). *Adults:* 1–2 tablets (or 5–10?mL) tid–qid. *Caution:* Contraindicated in narrow-angle glaucoma, myasthenia gravis, gastrointestinal and genitourinary obstruction.	*Adverse events:* Tachycardia, palpita drowsiness, nervousness, dry mouth, dysphagia, paralytic ileus, blurred visi

Ibuprofen Generic. Suspension: 100?mg/5?mL. Tablet: 200, 300, 400, 600, 800?mg.	**Treatment of pain, fever, rheumatoid arthritis (nonsteroidal anti-inflammatory, inhibit prostaglandin synthesis).** *Children:* Pain, fever: 5–10?mg/kg/dose q6–8h. Juvenile rheumatoid arthritis: 30–50?mg/kg/24?hr in 4 divided doses. *Adults:* 400–800?mg/dose tid–qid (max: 3.2?g/24?hr).	*Adverse events:* Abdominal cramps, l gastrointestinal bleeding and perforat edema, hypertension, tachycardia, ac
Idarubicin Idamycin. Injection.	**Combination chemotherapy for acute myelocytic and lymphocytic leukemia (AML and ALL) (inhibits DNA and RNA synthesis).** *Children:* ALL: 10–12?mg/m^2 IV once daily for 3 days per treatment course. *Adults:* AML: 8–12?mg/m^2 IV daily for 3 days per treatment course.	*Adverse events:* Headache, infection, mucositis, stomatitis, alopecia, rash, u vomiting, diarrhea, leukopenia (nadir, thrombocytopenia (nadir, 10–15 days (arrhythmias, cardiomyopathy, heart f *Monitoring:* Maximal lifetime dose = 1 dose by 25% if severe mucositis pres creatinine >2?mg/dL; lower dose by 5 >2.5?mg/dL; do not give dose if bilirul
Ifosfamide Ifex. Injection.	**Cancer chemotherapy (alkylating agent).** *Children:* IV: 1,200–1,800?mg/m^2 /24?hr for 5 days q 21–28 days; or 5?g/m^2 as single IV infusion. *Adults:* 700–2,000?mg/m^2 /24?hr for 5 days q 21–28 days; or 5?g/m^2 as single IV infusion.	*Adverse events:* Alopecia, nausea, vo hemorrhagic cystitis (administer MES hematuria, renal damage, somnolenc hallucinations, coma, polyneuropathy psychosis, elevated liver enzymes, m (onset, day 7; nadir, 10–14 days), pul stuffiness, cardiotoxicity.

Imipramine Tofranil, generic. Injection, capsule, tablet.	**Treatment of depression, enuresis, pain (tricyclic antidepressant, increase synaptic concentrations of norepinephrine and serotonin).** *Children:* Depression: start 1.5?mg/kg/24?hr; may increase by 1?mg/kg/24?hr q 3–4 days (max: 5?mg/kg/24?hr). Enuresis: >6 yr, 10–25?mg at bedtime. Cancer pain: 0.2–0.4?mg/kg at bedtime; may increase dose 50% q 3–4 days (max: 3?mg/kg). *Adolescents:* PO: start 25–50?mg/24?hr; may gradually increase to maximum of 200?mg/24?hr. *Adults:* PO: 25?mg tid–qid; may increase dose gradually to maximum of 300?mg/24?hr; IM: Initial up to 100?mg in divided doses.	*Adverse events:* Arrhythmias, postura drowsiness, sedation, confusion, hea constipation, urinary retention, increa seizures, urinary retention. *Monitoring:* Imipramine concentration imipramine and desipramine 150–25(>1,000?ng/mL).

Immune globulin, intravenous (IVIG) Gamimune, Sandoglobulin, generic. Injection.	**Immunodeficiency syndrome, idiopathic thrombocytopenic purpura, acute bacterial or viral infections in immunocompromised or neutropenic patients, Kawasaki disease, Guillain-Barré syndrome, demyelinating polyneuropathy (replacement therapy or interference with Fc receptors in the reticulo-endothelial system for autoimmune diseases).** *Neonates:* 500–750?mg/kg once. *Children and adults:* Immunodeficiency syndrome: 100–400?mg/kg/dose q 2–4 wk. Chronic lymphocytic leukemia: 400?mg/kg/dose q 3 wk. Idiopathic thrombocytopenic purpura: 1,000?mg/kg/dose for 2–5 consecutive days then q 3–6 wk. Kawasaki disease: 2?g/kg single dose. Cytomegalovirus infection: 500?mg/kg/dose every other day for 7 doses. Severe systemic infection: 500–1,000?mg/kg/wk. Polyneuropathy: 1?g/kg/24?hr for 2 consecutive days each mo.	*Caution:* Doses should be based on i total body weight). *Adverse events:* Flushing, tachycardi dyspnea, fever, hypersensitivity react aseptic meningitis.

Indomethacin Indocin, generic (oral forms). Capsule: 25, 50?mg. Suspension: 25?mg/5?mL. Injection.	**Closure of the patent ductus arteriosus (PDA) in neonates, treatment of rheumatoid disorders, acute gouty arthritis, pain (NSAID, prostaglandin inhibition), hereditary hypokalemic salt-losing renal tubulopathies.** *Neonates:* IV: 0.10–0.25?mg/kg/dose q12h for 3–6 doses. Inflammatory rheumatoid disorders: *Children:* 1–2?mg/kg/24?hr in 2–4 doses (max: 4?mg/kg/24?hr). *Adults:* 25–50?mg/dose 2–3 times/24?hr (max: 200?mg/24?hr).	*Caution:* Avoid in premature neonate enterocolitis, poor renal function, or a patients with active gastrointestinal bl *Adverse events:* Confusion, dizziness vomiting, abdominal pain, gastrointes gastrointestinal perforation, bone mar impaired platelet aggregation, oliguria hypertension, edema, hyperkalemia. *Monitoring:* Indomethacin (concentrat therapeutic 1–3?µg/mL.
Insulin ***Rapid-acting:*** Lispro, Regular, Semilente; ***Intermediate-acting:*** NPH, Lente; ***Long-acting:*** Ultralente; ***Combination products*** (e.g., Novolin 70/30, contains Lente 70 units, Regular 30 units). Humulin, Novolin (human insulin, preferred form); beef insulin, pork insulin. Injection.	**Treatment of insulin-dependent diabetes mellitus and non–insulin-dependent diabetes not adequately controlled with oral hypoglycemic agents (replacement therapy).** *Neonates:* Regular insulin 0.01–0.1 units/kg/hr continuous infusion, or SC 0.1–0.2 units/kg every 6–12?hr. *Children and adults:* 0.5–1 unit/kg/24?hr. Adjust doses to blood glucose and hemoglobin A_{1C} results. *Adolescents (during growth spurt):* 0.8–1.2 units/kg/24?hr. Diabetic ketoacidosis: Continuous infusion IV: 0.1 unit/kg/hr adjusted to serum glucose. Hyperkalemia: Try calcium gluconate and $NaHCO_3$ first, then dextrose 50% 0.5–1?mL/kg and regular insulin 1 unit per 4–5?g dextrose.	*Caution:* Check for drugs that increas effect, do not change insulin types or regulated since dosing requirements new patients on human insulin if poss *Adverse events:* Hypoglycemia (and of dizziness, weakness, paresthesias fatigue, mental confusion, hunger, na problems), hypokalemia. *Monitoring:* Blood glucose (teach pati and make insulin dosing corrections hemoglobin A_{1C}, urine glucose, and

Hyperkalemia: Try calcium gluconate and $NaHCO_3$ first, then dextrose 50% 0.5–1?mL/kg and regular insulin 1 unit per 4–5?g dextrose.

Interferon alfa-2a Roferon-A. Injection.	**In children treat hemangiomas of infancy and pulmonary hemangiomas (inhibits cellular growth, alters cellular differentiation).** *Infants and children:* SC: 1–3 million units/m^2 /24?hr. *Adults:* 3–20 million units/m^2 /dose/24?hr to 3 times/wk depending on the indication.	*Adverse events:* Tachycardia, arrhyth edema, CNS depression, confusion, flu-like symptoms (begin 2–6?hr after 24?hr). *Cautions:* Do not use if: patient is unc reflex, seizures, ingestion of strong ba volatile oils. Do not confuse with ipeca is 14 times more potent.
Ipecac syrup Generic. Syrup: 70?mg/mL.	**Induces vomiting to treat certain toxic ingestions (stimulates medullary chemoreceptor trigger zone).** *Children:* May repeat dose in 20?min one time. *6–12 mo:* 5–10?mL followed by 20?mL/kg of water *1–12 yr:* 15?mL followed by 20?mL/kg of water. *>12 yr and adults:* 30?mL followed by 300?mL of water.	*Adverse events:* Lethargy, persistent
Ipratropium Atrovent. Nebulization solution: 0.02%. Metered-dose inhaler (MDI): 18?µg/puff. Nasal spray: 0.3%, 0.6%.	**Bronchodilator, treatment of rhinitis (anticholinergic).** *Neonates:* Nebulized 100?µg/dose or MDI 1–2 puffs tid–qid. *Infants and children:* Nebulized 125–250?µg or MDI 1–2 puffs 3–6 times/24?hr. *Adults:* Nebulized 500?µg or MDI 2 puffs tid–qid. Nasal spray for rhinitis: 1–2 sprays in each nostril bid–tid.	*Adverse events:* Dry mouth, nervousr headache, blurred vision, urinary rete

Iron Iron dextran complex (injection). Ferrous sulfate, gluconate, etc. (oral).	**Treatment of iron deficiency, hypochromic, microcytic anemia (replacement therapy).** Injection: IM, IV: Give 0.25–0.5?mL test dose 1?hr before starting iron dextran therapy Dose (mL/kg) = Hgb (normal - actual) × 0.0476 + 1?mL/5?kg max: <5?kg = 25?mg, 5–10?kg = 50?mg >10?kg = 100?mg. PO (mg iron): *Children:* Prophylaxis: 1–2?mg/kg/24?hr. Deficiency: 3–6?mg/kg/24?hr in 1–3 divided doses. *Adults:* Prophylaxis 60?mg/24?hr. Deficiency: 60?mg 2–4 times/24?hr.	*Adverse events:* (Oral) Gastrointestin constipation, dark stools: (IV, IM) hyp dizziness, fever, headache, metallic t anaphylaxis. *Monitoring:* Hemoglobin (normal <15? >15?kg = 14.8?mg%), reticulocyte co
Isoetharine Generic. Metered-dose inhaler (MDI), inhalation solution.	**Bronchodilator (ß-agonist stimulation).** *Children:* Nebulize 0.01?mL/kg of 1% solution. *Adults:* Nebulize 0.5–1?mL of 0.5–1% solution; MDI 1–2 puffs q4h as needed.	*Adverse events:* Tachycardia, headac excitement, restlessness, nausea.

Isoproterenol Generic. Injection, sublingual tablets, nebulizer solution, metered-dose inhaler (MDI).	**Asthma or chronic obstructive pulmonary disease, ventricular arrhythmias due to AV node block, low-output shock states (stimulate ß$_1$ - and ß$_2$ -receptors).** *Neonates, infants, and children:* IV infusion 0.05–2?µg/kg/min *Children:* MDI 1–2 puffs every 4?hr as needed; nebulize 0.01?mL of 1% solution; SL tablets 5–10?mg every 3–4?hr (max: 30?mg/24?hr). *Adults:* MDI 1–2 puffs 4–6 times/24?hr; nebulize 0.25–0.5?mL of 1% solution; SL tablets 10–20?mg q3–4h (max: 60?mg/24?hr); IV infusion 2–20?µg/min	*Adverse events:* Tachycardia, palpita nervousness, restlessness, anxiety, h tremor, gastrointestinal distress, naus bronchospasm.
Kaolin and pectin Generic. Oral suspension.	**Treatment of uncomplicated diarrhea (absorbent action).** *Children:* *3–6 yr:* 15–30?mL/dose. *6–12 yr:* 30–60?mL/dose. *>12 yr:* 60–120?mL/dose.	*Cautions:* Some products contain bis and may cause bleeding disorders. A toxigenic diarrheas.
Ketamine Ketalar. Injection: 10?mg/mL, 50?mg/mL, 100?mg/mL.	**Anesthesia for short procedures (direct action on cortex and limbic system to produce dissociative anesthesia).** *Children:* Give 30?min before procedure. PO: 6–10?mg/kg; IM: 3–7?mg/kg; IV: 0.5–2?mg/kg. *Adults:* 3–8?mg/kg; IV: 1–4.5?mg/kg (supplemental doses are ? of initial dose).	*Adverse events:* Hypertension, tachyc bradycardia, increased cerebral blood pressure, hallucinations, delirium, ton increased metabolic rate, hypersaliva vomiting, respiratory depression, apn resistance, cough, emergence reactic

Ketorolac Acular. Ophthalmic. Toradol. Tablet, injection.	**Treatment of pain; ocular itching with conjunctivitis (NSAID, inhibits prostaglandin).** *Children 2–16 yr*: IM, IV: 0.4–1?mg/kg/dose PO: 1?mg/kg/dose q6h if needed. *Adults:* IM: 60?mg; IV: 30?mg up to q6h as needed. Ophthalmic: 1 drop in eye 4 times/24?hr for up to 7 days.	*Adverse events:* Edema, somnolence dyspepsia, nausea, diarrhea, gastroir gastrointestinal bleeding, peptic ulcer aggregation, oliguria, acute renal failu wheezing, pain at injection site.
Labetalol Normodyne, Trandate. Injection: 5?mg/mL. Tablet: 100, 200, 300?mg.	**Treatment of mild to severe hypertension (blocks a- and ß-adrenergic receptors).** *Children:* PO: Start 4?mg/kg/24?hr in 2 doses, then gradually increase (max: 40?mg/kg/24?hr). IV: Start 0.2–1?mg/kg/dose (max: 20?mg/dose), continuous IV infusion 0.4–1?mg/kg/hr (max: 3?mg/kg/hr). *Adults:* PO: 100?mg bid; may increase every 2–3 days (max: 2.4?g/24?hr). IV: Start 20?mg; repeat boluses 40?mg q 10?min (max: total dose 300?mg), continuous IV infusion 2?mg/min and titrate to response.	*Adverse events:* Orthostatic hypotens failure, conduction disturbance, brady fatigue, headache, dry mouth, nasal c bronchospasm.
Lactulose Generic. Syrup: 10?g/15?mL.	**Treatment of constipation, hepatic encephalopathy (osmotic effect on stool in colon, acidification of stool promotes NH_4^+** elimination). *Infants:* 2.5–10?mL/24?hr in 3–4 doses. *Children:* 40–90?mL/24?hr in 3–4 doses. *Adults:* 30–45?mL/dose 3–4 times/24?hr.	*Adverse events:* Flatulence, abdomin diarrhea, nausea, vomiting. *Monitoring:* Target 2–3 soft stools per

Lamotrigine Lamictal. Tablet: 25, 100, 150, 200?mg. Chewable dispersible tablet: 2, 5, 25?mg.	**Treatment of partial seizures (blocks sodium channels and inhibits presynaptic release of glutamate and aspartate).** *Children 2–12 yr:* 0.6?mg/kg/24?hr in 1–2 doses for 2 wk, then 1.2?mg/kg/24?hr in 2 doses for 2 wk, then 5–15?mg/kg/24?hr in 2 doses per response (max: 400?mg/24?hr). *If patient is on valproate:* 0.15?mg/kg/24?hr in 1–2 doses for 2 wk, then 0.3?mg/kg/24?hr in 2 doses for 2 wk, then 1–5?mg/kg/24?hr in 2 doses (max: 200?mg/24?hr). *Adults:* Start 50?mg/24?hr for 2 wk, then 100?mg/24?hr, then increase by 100?mg/24?hr at weekly intervals to response (max: 500?mg/24?hr). If patient is on *valproate:* 25?mg every other day for 2 wk, then 25?mg/24?hr for 2 wk, then increase by 25?mg/24?hr every wk to response (max: 150?mg/24?hr).	*Caution:* Serious rashes (potentially f are particularly common in children a are increased too quickly. Slow increa especially important for patients on va *Adverse events:* Dizziness, sedation, exacerbation of seizures, rashes (ma erythematous eruptions), angioedema nystagmus, amblyopia, nausea, vomi
Lansoprazole Prevacid. Capsule: 15, 30?mg.	**Treatment of gastric or duodenal ulcer (proton pump inhibitor).** *Children*: *Adults:* 15–30?mg/24?hr.	

Leucovorin Wellcovorin, generic. Tablet: 5, 15?mg. Injection.	**Antidote for folic acid antagonists, e.g., methotrexate, treatment of folate-deficient megaloblastic anemias of infancy, nutritional folate deficiency when oral folate cannot be used (reduced form of folic acid so conversion is not necessary, replacement therapy).** *Children and adults:* Methotrexate rescue: IV: 10?mg/m^2 to start then 10?mg/m^2 PO q6h for 72?hr; increase dose to 100?mg/m^2 q3h if 24?hr after methotrexate dose the serum creatinine is increased by >50%, or methotrexate serum level is >5 × 10^{-6} M (continue until level <1 × 10^{-8} M). High-dose methotrexate rescue: IV 100–1000?mg/m^2 /dose Intrathecal methotrexate: IV 12?mg/m^2 as single dose Megaloblastic anemia of infancy: IM 3–6?mg/24?hr.	*Adverse events:* Rash, itching erythe *Monitoring:* Plasma methotrexate leve dosing nomogram is available based levels at various times after the dose.
Leuprolide Lupron. Injection.	**Treatment of precocious puberty, prostate cancer (decreases levels of luteinizing hormone and follicle-stimulating hormone).** 0.15–0.3?mg/kg/dose q 28 days (min: 7.5?mg); SC: 20–45?µg/kg/24?hr. *Adults:* Prostate cancer: IM: 7.5?mg/dose/mo; SC: 1?mg/24?hr.	*Adverse events:* Weight gain, hot flas nausea, vomiting, gastrointestinal ble pain, weakness, blurred vision, estro
Levothyroxine Synthroid, generic. Injection, tablet.	**Thyroid replacement therapy.** PO: *0–6 mo:* 8–10?µg/kg/24?hr. *6–12 mo:* 6–8?µg/kg/24?hr. *1–5 yr:* 5–6?µg/kg/24?hr. *6–12 yr:* 4–5?µg/kg/24?hr. *>12 yr:* 2–3?µg/kg/24?hr. *Adults:* 12.5–50?µg/kg/24?hr (max: 200?µg/kg/24?hr). IV, IM: 50–75% of PO dose. Myxedema coma: 200–500?µg for one dose. Thyroid suppression therapy: 2–6?µg/kg/24?hr for 7–10 days.	*Adverse events:* Tachycardia, cardiac hypertension, nervousness, headach increased appetite, weight loss, trem
Lidocaine Generic. Injection. Topical (alone or in combination with prilocaine [EMLA]).	**Treatment of ventricular arrhythmias, local anesthetic (class 1B antiarrhythmic, blocks initiation and conduction of impulses).** *Children and adults:* Topical: Apply to affected area (max: 3?mg/kg/dose) at least 2?hr apart. Local anesthetic injection: doses as needed, max: 4.5?mg/kg not closer than 2?hr apart. Arrhythmias: *Children:* Load 1?mg/kg (may repeat q 5–10?min to maximum of 3?mg/kg), IV continuous infusion: 20–50?µg/kg/min (½ dose if liver disease or poor cardiac output). *Adults:* Load 1–1.5?mg/kg (may repeat to maximum of 3?mg/kg), IV continuous infusion: 2–4?mg/min (½ dose for liver disease or heart failure). ET route: 2–2.5 times IV dose. Pre-hospital post–myocardial infarction: 300?mg IM.	*Caution:* Avoid lidocaine with epineph arrhythmias. *Adverse events:* Arrhythmias, heart b seizures, nausea, vomiting, paresthe diplopia, local skin irritation or rash. *Monitoring:* Lidocaine serum levels (t toxic >6?µg/mL

Liothyronine Cytomel (oral), Triostat (injection), generic.	**Replacement therapy in hypothyroidism.** *Neonates, infants, and children <3 yr:* Congenital hypothyroidism (cretinism): PO: 5?µg/24?hr initially then may increase 5?µg q 3 days to maximum of 20?µg/24?hr (50?µg/24?hr for children age 1–3 yr). Hypothyroidism: *Children:* 5?µg/24?hr; increase by 5?µg q 1–2 wk (usual 15–20?µg/24?hr). *Adults:* Start 5?µg/24?hr; increase by 5?µg/24?hr q 1–2 wk to 25?µg then by 12.5–25?µg q 1–2 wk to maximum of 100?µg/24?hr.	*Adverse events:* Palpitations, tachyca nervousness, insomnia, headache, h abdominal cramps, tremor, sweating. *Monitoring:* Thyroid function, T_3 , thyr hormone.
Lithium Generic. Syrup: 300?mg/5?mL. Tablet: 300?mg. Capsule: 150, 300, 600?mg.	**Management of acute mania, bipolar disorders, and depression (alters cation exchange across cell membranes).** *Children:* 15–60?mg/kg/24?hr in 3–4 doses (start low and increase at weekly intervals). *Adolescents:* 600–1,800?mg/24?hr in 3–4 doses at regular intervals. *Adults:* 300?mg 3–4 times/24?hr to start; may gradually increase per blood levels (max 2.4?g/24?hr). **May use twice-daily dosing if sustained-release product used.** *Renal impairment:* CrCl 10–50?mL/min 50–75% of normal dose; CrCl <10?mL/min 25–50% of normal dose.	*Adverse events:* Polydipsia, nausea, taste, bloated feeling, weight gain, tre twitching, weakness, fatigue, diabete nonspecific nephron atrophy, renal tu leukocytosis, vision problems, hypoth eruptions, acne. *Monitoring:* Serum lithium concentrati proper use of lithium, must be drawn (therapeutic: acute mania 0.6–1.2?m against future episodes 0.6–1?mEq/L seizures >2.5?mEq/L. Watch for accu loss and dehydration states.

Lomustine, CCNU CeeNu. Capsule: 10, 40, 100?mg.	**Treatment of various cancers (alkylating agent, inhibits DNA and RNA synthesis).** *Children:* 75–100?mg/m^2 as single dose every 6 wk. *Adults:* 100–130?mg/m^2 as single dose every 6 wk.	*Adverse events:* Nausea, vomiting, m (onset, 14 days; nadir, 4–5 wk; recov neurotoxicity, stomatitis, diarrhea, an hepatotoxicity, renal failure, pulmona cumulative doses >600?mg). *Monitoring:* Reduce dose if CrCl <50? and WBC counts remain low beyond
Loperamide Imodium, generic. Liquid: 1?mg/5?mL. Tablet: 2?mg. Capsule: 2?mg.	**Treatment of acute and chronic diarrhea (directly inhibits intestinal peristalsis).** *Children:* *2–5 yr:* 1?mg tid. *6–8 yr:* 2?mg bid. *8–12 yr:* 2?mg tid. *Adults:* 4?mg initially, then 2?mg after each loose stool (max: 16?mg/24?hr).	*Adverse events:* Sedation, fatigue, di vomiting, constipation.
Loratadine Tablet: 10?mg. Claritin. Syrup: 1?mg/mL.	**Treatment of allergic symptoms (antihistamine, H_1 -receptor antagonist).** *Children >3 yr:* <30?kg 5?mg/24?hr, >30?kg 10?mg/24?hr. *Adults:* 10?mg/24?hr.	*Caution:* Prolonged QT intervals may with drugs that inhibit liver enzymes; interactions. *Adverse events:* Somnolence, fatigue headache.

Lorazepam Ativan, generic. Injection. Tablet: 0.5, 1, 2?mg. Oral solution: 2?mg/mL.	**Treatment for anxiety, sedation, and seizures; adjunct to antiemetic therapy (benzodiazepine, increase action of ?-aminobutyric acid).** Antiemetic therapy: *Children:* IV 0.04–0.08?mg/kg/dose q6h as needed. Anxiety/sedation: *Neonates:* IV: 0.1–0.4?mg/kg/dose q4–6h as needed. *Infants and children:* IV: 0.05–0.1?mg/kg/dose q4–8h. *Adults:* PO: 1–10?mg/24?hr in 2–3 divided doses. Insomnia: *Adults:* 2–4?mg at bedtime. Status epilepticus: *Neonates:* IV: 0.05–0.2?mg/kg/dose over 2–5?min; may repeat in 10–15?min. *Infants and children:* IV: 0.1?mg/kg load over 2–5?min; may give additional 0.05?mg/kg bolus in 10–15?min. *Adolescents:* IV: 0.07?mg/kg/dose over 2–5?min; may repeat in 10–15?min. *Adults:* IV: 4?mg/dose over 2–5?min; may repeat in 10?min.	*Caution:* Do not discontinue abruptly avoid possible abstinence symptoms. *Adverse events:* Several cases of my reported in neonates, tachycardia, dr confusion, paradoxical excitement, bl diplopia.
Magnesium citrate, citrate of magnesia Generic. Solution: 300?mL.	**Evacuation of bowel (osmotic retention of fluid and increased peristalsis).** *Children <6 yr:* 2–4?mL/kg. Children 6–12 yr: 100–150?mL. *>12 yr and adults:* 150–300?mL.	*Adverse events:* Hypermagnesemia, abdominal cramps, muscle weakness *Monitoring:* Toxicity related to serum (>3?mg/dL, depressed CNS; >5?mg/ depressed deep tendon reflexes; >12 paralysis and heart block).

Magnesium gluconate Generic. Tablet: 500?mg.	**Magnesium replacement therapy.** *Children:* 10–20?mg/kg/dose elemental magnesium qid. *Adults:* 300?mg elemental magnesium qid.	*Adverse events:* Hypermagnesemia (*citrate*). *Monitoring:* Serum magnesium conce children, 1.5–1.9?mg/dL; adults, 2.2–
Magnesium oxide Generic. Tablet: 400, 420, 500?mg. Capsule: 140?mg.		
Magnesium hydroxide, milk of magnesia Generic. Liquid, tablet.	**Short-term treatment of constipation (osmotic retention of fluid promotes peristalsis).** *Children:* *<2 yr:* 0.5?mL/kg/dose. *2–5 yr:* 5–15?mL once daily. *6–12 yr:* 15–30?mL once daily. *>12 yr and adults:* 30–60?mL once daily.	*Adverse events:* (see *Magnesium citr*
Magnesium sulfate Generic. Granules: 40?mEq/5?g. Injection: 50% solution.	**Treatment of hypomagnesemia, and seizures associated with acute nephritis in children, also used as a cathartic (cofactor for many enzymes in the body and is important in calcium and potassium hemostasis).** Hypomagnesemia: *Neonates:* IV: 25–50?mg/kg/dose q8h for 2–3 doses. *Children:* PO: 100–200?mg/kg/dose qid; IM, IV: 25–50?mg/kg/dose q6h for 3–4 doses. *Adults:* PO: 3?g q6h for 4 doses; IM, IV: 1?g q6h for 4 doses. Daily maintenance magnesium: *Neonates, infants, and children:* IV: 30–60?mg/kg/24?hr. *Adolescents:* IV: 42–54?mg/kg/24?hr.	*Caution:* Magnesium may accumulate renal insufficiency. *Adverse events:* (see *Magnesium citr*

	magnesium: *Neonates, infants, and children:* IV: 30–60?mg/kg/24?hr. *Adolescents:* IV: 42–54?mg/kg/24?hr. *Adults:* IV: 0.5–3?g/24?hr. Infuse IV doses over 2–4?hr (max: 125?mg/kg/hr). Management of seizures and hypertension: *Children:* IM, IV: 20–100?mg/kg/dose q4–6h as needed. Cathartic: *Children:* PO: 0.25?g/kg/dose. *Adults:* PO: 10–30?g.	
Manganese Injection: 0.1?mg/mL.	**Trace element added to parenteral nutrition (cofactor in many enzyme systems).** *Infants:* 2–10?µg?hr in TPN solutions. *Adults:* 150–800?µg?hr in TPN solutions.	*Monitoring:* Reference manganese pl 4–14?µg/L.
Mannitol Generic. Injection.	**Promotion of diuresis, reduction of increased intracranial pressure.** *Children and adults:* IV: 200?mg/kg test dose; initial, 0.5–1?g/kg; maintenance, 0.25–0.5?g/kg q4–6h.	*Adverse events:* Circulatory overload failure, headache, chills, seizures, flui imbalance. *Monitoring:* After test dose evaluate u 1?mL/kg/hr (children) or 30–50?mL/h for increased intracranial pressure ma osmolality 310–320?mOsm/kg.
Mechlorethamine, nitrogen mustard Mustargen Hydrochloride. Injection.	**Cancer chemotherapy (alkylating agent, inhibits DNA and RNA synthesis).** *Children:* As part of MOPP regimen, IV 6?mg/m^2 on days 1 and 8 of 28-day regimen. *Adults:* IV: 0.4?mg/kg (12–16?mg/m^2) as single monthly dose.	*Caution:* Extravasation should be trea sterile sodium thiosulfate (? M) and a 6–12?hr. *Adverse events:* Nausea, vomiting, di myelosuppression (onset, 4–7 days; r recovery, 21 days), ototoxicity, precip zoster, alopecia, hyperuricemia.
Meclizine Generic. Tablet, capsule.	**Prevention and treatment of motion sickness, and treatment of vertigo (anticholinergic and CNS depressant effects).** *Children and adults:* PO: 25–50?mg taken 1?hr before travel for motion sickness; 25–100?mg/24?hr in divided doses for vertigo.	*Adverse events:* Drowsiness, headac increased appetite, weight gain

Medium chain triglycerides MCT Oil. Oil: 14?g/15?mL.	**Dietary supplement for those who cannot digest long-chain fats, ketogenic diet for seizure disorders (nutritional supplement).** *Infants:* 0.5?mL every other feed and may advance by 0.5?mL q 2–3 days as tolerated. *Children:* Ketogenic diet for seizures: 50–70%of total calories (usually about 40?mL with each meal); cystic fibrosis: 1 tablespoon tid. *Adults:* 15?mL tid–qid.	*Adverse events:* Nausea, vomiting, al
Medrysone HMS Liquefilm. Ophthalmic solution.	**Treatment of conjunctivitis (inhibits inflammatory response).** *Children and adults:* Ophthalmic: Instill 1 drop in conjunctival sac bid–qid (may use q1–2h for 1–2 days).	*Adverse events:* Local stinging and bu intraocular pressure, cataracts.
Melphalan Alkeran. Injection. Tablet: 2?mg.	**Cancer chemotherapy (alkylating agent, inhibits DNA and RNA synthesis).** *Children:* IV: 10–35?mg/m^2 /dose q 21–28 days; high-dose: 140–220?mg/m^2 before bone marrow transplantation. PO: 4–20?mg/m^2 /24?hr for 1–21 days. *Adults:* IV 16?mg/m^2 /dose q 2 wk for 4 doses monthly. PO: 0.15?mg/kg/24?hr for 7 days or 0.25?mg/kg/24?hr for 4 days, repeat q 4–6 wk.	*Adverse events:* Myelosuppression (c 8–10 days and 27–32 days; recovery secondary malignancy, alopecia, vesi syndrome of inappropriate secretion c hormone, nausea, vomiting, diarrhea, hemorrhagic cystitis, pulmonary fibros pneumonitis, vasculitis.
Meperidine Generic. Injection, syrup: 50?mg/5?mL. Tablet: 50, 100?mg.	**Narcotic analgesic, adjunct to anesthesia (binds to opiate receptors in CNS).** *Children:* IM, IV, SC: 1–1.5?mg/kg/dose q3–4h. *Adults:* IM, IV, SC: 50–100?mg/dose q3–4h as needed (equipotent oral dose is 3 times IV dose).	*Caution:* Scheduled use may result in accumulation in diminished renal func to CNS stimulation or seizures. *Adverse events:* Hypotension, weakn headache, anorexia, stomach cramps paradoxical excitation, seizures, phys dependence. *Comment:* Equianalgesic dose to mor meperidine 100?mg IV, IM, or 300?m

Mephenytoin Mesantoin. Tablet: 100?mg.	**Treatment of tonic-clonic and partial seizures (decreases sodium ion influx across cell membranes)** *Children:* 3–15?mg/kg/24?hr in 3 divided doses. *Adults:* Start 50–100?mg/24?hr; then increase weekly by 50–100?mg (max: 800?mg/24?hr).	*Adverse events:* Drowsiness, slurred changes, confusion, nausea, vomiting leukopenia, hepatitis, blurred vision, r photophobia, and lymphadenopathy. *Monitoring:* Total mephenytoin level (
Mephobarbital Mebaral. Tablets: 32, 50, 100?mg.	**Sedative, treatment of epilepsy (increases seizure threshold).** *Children:* 4–10?mg/kg/24?hr in 2–4 doses. *Adults:* 200–600?mg/24?hr in 2–4 doses.	*Adverse events:* Drowsiness, lethargy depression, paradoxical excitement, p physical dependence, constipation, n *Monitoring:* Phenobarbital concentrati 10–40?µg/mL).
Mercaptopurine Purinethol. Injection, tablet. Extemporaneous formulations.	**Treatment of leukemias and non-Hodgkin lymphoma (antimetabolite, blocks purine synthesis).** *Children:* PO: Induction: 2.5–5?mg/kg once daily; maintenance: 1.5–2.5?mg/kg/24?hr. IV continuous infusion: 50?mg/m^2 /hr for 24–48?hr *Adults:* PO: Induction: 2.5–5?mg/kg once daily; maintenance: 1.5–2.5?mg/kg/24?hr. *Renal function CrCl <50?mL/min:* dose every 48?hr.	*Adverse events:* Hepatotoxicity (chole nausea, anorexia, vomiting, diarrhea, stomatitis, mucositis, rash, hyperpigm myelosuppression (onset, 7–10 days; recovery, 21 days), renal toxicity, hyp eosinophilia, drug fever

Mesna Mesnex. Injection: 100?mg/mL.	**Protects against hemorrhagic cystitis from ifos-famide and cyclophosphamide therapy (binds and detoxifies urotoxic metabolites via active sulfhydryl group).** *Children and adults:* IV: 20% w/w of ifosfamide or cyclophosphamide dose started 15?min before alkylating agent dose, and repeat same mesna dose at 3, 6, 9, and 12?hr after alkylating agent dose. PO: 40% w/w of alkylating agent in 3 doses 4?hr apart.	*Adverse events:* Hypotension, heada bad taste in mouth, limb pain. *Monitoring:* Urinalysis.
Metaproterenol, orciprenaline Alupent, Metaprel, generic. Metered-dose inhaler (MDI). Inhalation solution. Tablet: 10, 20?mg. Syrup: 10?mg/5?mL.	**Bronchodilator (stimulates ß$_2$ -receptors).** *Children:* PO: *<2 yr:* 0.4?mg/kg/dose tid–qid. *2–6 yr:* 1.3–2.6?mg/kg/24?hr divided q6h. *6–9 yr:* 10?mg/dose qid. *>9 yr and adults:* 20?mg/dose tid–qid. MDI: 2–3 puffs q4h. Nebulizer: *Infants and children:* 0.01–0.02?mL/kg of 5% solution q4–6h. *Adolescents and adults:* 0.3?mL of 5% solution q4–6h.	*Caution:* Some generic nebulizer solu that may exacerbate asthma. *Adverse events:* Tremor, nervousnes tachycardia, hypotension, headache. *Comment:* Dilute nebulizer solution in saline.

Methadone Dolophine, generic. Injection: 10?mg/mL. Tablet: 5, 10?mg. Oral solution: 5?mg/mL.	**Management of severe pain, narcotic detoxification (binds to opiate receptors in CNS).** *Neonates (abstinence syndrome):* 0.05–0.2?mg/kg/dose q12h; then adjust/taper based on abstinence scores. *Children:* Analgesia: IV, IM, PO: 0.1?mg/kg/dose q4h for 2–3 doses, then q6–12h as needed. Narcotic abstinence: Start 0.05–0.1?mg/kg/dose q6h and taper per abstinence scores. *Adults:* IV, IM, SC, PO. Analgesia: 2.5–20?mg q6–8h. Detoxification: 15–40?mg/24?hr.	*Adverse events:* Weakness, drowsine vomiting, constipation, ileus. *Monitoring:* Methadone accumulates and patients should be monitored for depression.
Metformin Glucophage. Tablet: 500, 850, 100?mg.	**Treatment of type 2 diabetes; increases insulin sensitivity and improves glucose tolerance; hypoglycemic effect.** *Children 10–16 yr:* Start with 500?mg bid with meals; increase in 500-mg increments weekly to response (max: 2,000?mg/24?hr). *Adults:* Start with 850?mg q24h or 500?mg bid; titrate by 500?mg once/wk or 850?mg q 2 wk to response or maximum dose 2550?mg/24?hr.	*Caution:* Avoid use if creatinine clear serum creatinine >1.5?mg/dL (males) (females). Monitor for lactic acidosis. process that may predispose to meta dysfunction until the situation is resol *Adverse events:* Nausea, vomiting, di flatulence.

Methimazole Tapazole. Tablet: 5, 10?mg.	**Treatment of hyperthyroidism (blocks iodine synthesis in the thyroid gland, inhibits synthesis of thyroid hormone).** *Children:* Start 0.4?mg/kg/24?hr, then maintenance 0.2?mg/kg/24?hr. *Adults:* Start 5?mg/kg q8h; maintenance dose: 5–15?mg/24?hr (max: 60?mg/24?hr).	*Adverse events:* Fever, rash, leukope SLE-like syndrome, nausea, vomiting taste, cholestatic jaundice, constipatio *Monitoring:* Thyroid function tests for hyperthyroidism.
Methocarbamol Robaxin, generic. Injection: 100?mg/mL. Tablet: 500, 750?mg.	**Treatment of muscle spasm (skeletal muscle relaxant through CNS depressive effects).** *Children:* Treatment of tetanus: IV: 15?mg/kg/ dose q6h for 3 days only. *Adults:* IV: 1–2?g q6h. PO: 1.5?g tid–qid for 2–3 days, then decrease to 4–4.5?g/24?hr.	*Adverse events:* Syncope, bradycardi drowsiness, dizziness, headache, nau
Methohexital Brevital. Injection.	**Induction and maintenance of general anesthesia (ultra-short-acting barbiturate).** *Children:* IM (preoperative): 5–10?mg/kg/dose; IV: (induction) 1–2?mg/kg/dose. Rectal: 20–35?mg/kg/dose. *Adults:* IV (induction): 50–120?mg, then 20–40?mg q 4–7?min.	*Adverse events:* Apnea, respiratory d laryngospasm, hypotension, skeletal rigidity, tremor, seizures, headache, r

Methotrexate Generic. Injection. Tablet: 2.5?mg.	**Treatment of neoplasms, psoriasis, rheumatoid arthritis (antimetabolite, inhibition of DNA and purine synthesis).** *Children:* Juvenile rheumatoid arthritis: PO, IM: 5–15?mg/m^2 /wk as a single dose. Antineoplastic: PO, IM: 7.5–30?mg/m^2 q 1–2 wk; IV: 10–33?g/m^2 bolus dose or infused over 6–42?hr. *Adults:* Rheumatoid arthritis: PO: 7.5?mg once wk. Psoriasis: PO, IM: 10–25?mg/dose once/wk. Antineoplastic: PO, IM, IV: 25–50?mg/m^2 /wk. Reduced renal function: CrCl 61–80?mL/min = reduce 25%. CrCl 51–60?mL/min = reduce 33%. CrCl 10–50?mL/min = reduce dose by 50–70%.	*Caution:* Avoid if severe renal or hepa *Adverse events:* Hepatotoxicity, neph malaise, fatigue, encephalopathy, hea chills, fever, cystitis, stomatitis, enteri diarrhea, alopecia, photosensitivity, ir skin pigmentation, urticaria, arthralgia myelosuppression (onset, 7 days; nad 21 days). *Monitoring:* Methotrexate concentratio mol/L for more than 40?hr. Ensure ac urinary alkalinization.
Methsuximide Celontin. Capsule: 150, 300?mg.	**Control of absence seizures, and adjunct in partial complex seizure management (increases seizure threshold, suppresses nerve transmission).** *Children:* 10–15?mg/kg/24?hr divided in 3–4 doses; may increase at weekly intervals (max: 30?mg/kg/24?hr). *Adults:* Start 300?mg/24?hr; may increase by 300?mg/24?hr at weekly intervals (max: 1,200?mg/24?hr).	*Adverse events:* Dizziness, drowsines headache, ataxia, aggressiveness, de nausea, vomiting, hiccups, agranuloc anemia, leukopenia, thrombocytopen *Monitoring:* Methsuximide concentrati 10–40?µg/mL toxic >4?µg/mL).
Methyldopa Aldomet, generic. Injection: 50?mg/mL. Tablet: 125, 250, 500?mg. Oral suspension: 250?mg/5?mL.	**Treatment of hypertension (false a-neurotransmitter metabolite stimulates inhibitory a-adrenergic receptors).** *Children:* PO: Start 10?mg/kg in 2–4 doses; may increase q 2 days (max: 65?mg/kg/24?hr or 3?g/24?hr). IV: Start 2–4?mg/kg/dose; may increase to 5–10?mg/kg/dose per response (max: 65?mg/kg/24?hr). *Adults:* PO: Start 250?mg 3 times/24?hr; may increase to max 3?g/24?hr. IV: 0.25–1?g q6h (max: 4?g/24?hr). Renal dysfunction: Extend interval.	*Caution:* Tolerance to effects occurs, requires concurrent diuretic. *Adverse events:* Drowsiness, mental headache, dry mouth, fever, chills, ve edema, hepatocellular injury, cholesta cirrhosis, pancreatitis, nausea, vomiti hemolytic anemia, positive Coombs te thrombocytopenia, paresthesias, wea bradycardia. *Monitoring:* Blood pressure, liver enzy (direct).
Methylene blue Urolene Blue. Injection: 10?mg/mL. Tablet: 65?mg.	**Antidote for cyanide poisoning and drug-induced methemoglobinemia (promotes conversion of methemoglobin to hemoglobin, combines with cyanide to form cyanmethemoglobin).** *Children and adults:* Methemoglobinemia: IV: 1–2?mg/kg; may repeat after 1?hr if needed. NADPH-methemoglobin reductase deficiency: PO: 1–1.5?mg/kg/24?hr (given with 5–8?mg/kg/ 24?hr of ascorbic acid).	*Caution:* Avoid in glucose-6-phospha deficiency and renal insufficiency. *Adverse events:* Urine and feces turn

Methylphenidate Ritalin, generic. Tablet: 5, 10, 20?mg. Tablet, sustained release: 20?mg.	**Attention deficit disorder (ADD), narcolepsy, adjunct for pain management (CNS stimulant).** *Children >5 yr:* 0.3–0.6?mg/kg/dose (max: 2?mg/kg/24?hr). *Adults:* 10?mg bid–tid (max: 60?mg/24?hr).	*Cautions:* Avoid in patients with moto syndrome, or marked agitation or psy addictive if used in high doses at freq *Adverse events:* Nervousness, insom anorexia, disorders, tics, growth retar and minimal if real), addiction (not a c ADD dosing).
Methylprednisolone Solu-Medrol (injection). Depo-Medrol (injection, IM). Medrol (tablets), generic. Topical ointment.	**Anti-inflammatory and immunosuppressant glucocorticoid used in allergic, inflammatory, and neoplastic disorders, and acute spinal cord injury.** *Children:* Anti-inflammatory and immunosuppressant: PO, IM, IV: 0.5–2?mg/kg/24?hr divide q6–12h. Lupus nephritis: IV: 30?mg/kg every other day for 6 doses. Acute spinal cord injury: 30?mg/kg over 15?min, followed in 45?min by continuous infusion of 5.4?mg/kg/hr for 23?hr. PO: 2–60?mg/24?hr in 1–4 doses. IV: 40–250?mg q4–6h. IM: 10–80?mg/24?hr.	*Caution:* Avoid if live virus vaccine giv fungal infection present. *Adverse events:* Hypertension, edem agitation, psychosis, pseudomotor ce swing, delirium, euphoria, hyperglyce alkalosis, HPA-axis (adrenal) suppres syndrome, skin atrophy, bruising, hyp ulcer disease, muscle weakness, bon growth retardation, cataracts, glaucor immunosuppression. *Comment:* See comparison of cortico *Hydrocortisone.*

Metoclopramide Reglan, generic. Injection: 5?mg/mL. Tablet: 5, 10?mg. Oral solution: 10?mg/mL. Syrup: 5?mg/5?mL.	**Treatment of diabetic gastroparesis, gastroesophageal reflux, and nausea associated with chemotherapy and surgery (blocks dopamine receptors in chemoreceptor trigger zone, enhances gastrointestinal motility and gastroduodenal sphincter tone).** *Neonates infants, and children:* Gastroesophageal reflux: IV, PO: 0.033–0.1?mg/kg/dose q8h. *Children:* Postoperative antiemetic: IV: 0.1–0.2?mg/kg/ dose q6–8h as needed. Chemotherapy antiemetic: PO, IV: 1–2?mg/kg/ dose q2–4h (pre-treat with diphenhydramine to avoid extrapyramidal reactions). *Adults:* Antiemetic: PO, IV: 1–2?mg/kg/dose q2–4h. Gastroesophageal reflux: PO: 10–15?mg qid. Renal dysfunction: Decrease dose.	*Cautions:* May precipitate seizures, c reactions, and worsen asthma (if sulfi formulation). In elderly, chronic use is increased risk and earlier onset of Pa (pediatric studies lacking). *Adverse events:* Weakness, drowsine stimulation, breast tenderness, extrap administration is associated with an ir anxiety and restlessness followed by *Comment:* Administer oral doses 30? at bedtime. *Monitoring:* Creatinine clearance: CrC 75% of recommended dose; CrCl <4(recommended dose; CrCl <10?mL/m recommended dose.
Metolazone Zaroxolyn, Mykrox. Tablet.	**Treatment of fluid overload states (diuresis, inhibits sodium reabsorption at distal tubules).** *Children:* 0.2–0.4?mg/kg/24?hr in 1–2 doses. *Adults:* 2.5–20?mg/24?hr.	*Adverse events:* Fluid and electrolyte hyperglycemia, hypocalcemia, hypom vomiting, blood dyscrasias.

Metoprolol Lopressor. Injection: 1?mg/mL. Tablet: 50, 100?mg.	**Treatment of hypertension, tachyarrhythmias, idiopathic hypertrophic subaortic stenosis, migraine prophylaxis (selective blocker of ß$_1$ -receptors).** *Children:* PO: 1–5?mg/kg/24?hr. *Adults:* PO: 100–450?mg/24?hr in 2–3 doses; IV: 5?mg q 2?min for 3 doses.	*Adverse events:* Mental depression, t bradycardia, reduced peripheral circu diabetes mellitus, worsens asthma, ir
Mexilitene Mexitil, generic. Capsule: 150, 200, 250?mg. Extemporaneous formulation.	**Treatment of ventricular arrhythmias, neuropathic pain (class 1B antiarrhythmic).** *Children:* 1.4–5?mg/kg/dose q8h. *Adults:* 200?mg q8h (max: 1,200?mg/24?hr). Renal dysfunction: CrCl <10?mL/min: give 50% of dose.	*Adverse events:* Atrial and ventricular bradycardia, hypotension, confusion, nervousness, tremor, ataxia, numbne weakness, blurred vision, tinnitus, inc gastrointestinal discomfort. *Monitoring:* Mexiletine concentrations 0.5–2?µg/mL, toxic >2?µg/mL.

Midazolam Versed. Injection: 1?mg/mL, 5?mg/mL. Extemporaneous formulation.	**Sedation, anticonvulsant (benzodiazepine, increase ?-aminobutyric acid).** *Neonates:* IV: Continuous infusion 0.15–0.5?µg/kg/min for sedation; IV bolus 0.05–0.15?mg/kg q2–4h. *Infants and children:* Status epilepticus: IV load 0.15?mg/kg followed by continuous infusion 1?µg/kg/min. Sedation: IV: 0.05–0.2?mg/kg load, then either same dose q1–2h or continuous infusion 1–2?µg/kg/min. Intranasal: 2.5?mg (0.5?mL) in each naris (total, 5?mg) using 5?mg/mL injection. *>12 yr:* 0.5?mg q 3–4?min to effect. *Adults:* 0.5–2?mg q 2?min to effect (usually 2–5?mg).	*Adverse events:* Several cases of my prolonged movement disorders have neonates treated with midazolam. Wi may occur if abrupt discontinuation. S paradoxical excitation, blurred vision, burning, apnea, respiratory depressio
Mitomycin Mutamycin. Injection.	**Cancer chemotherapy (antibiotic type alkylating agent inhibits DNA and RNA synthesis).** *Children and adults:* Depends on protocol; typically IV 3?mg/m^2 /24?hr for 5 days q4–6 wk; up to 40–50?mg/m^2 single dose for bone marrow transplant.	*Adverse events:* Nausea, vomiting, m (onset, 21 days; nadir, 36 days; reco tingling of extremities, paresthesias, a discoloration, mouth ulcers, cardiac fa >30?mg), interstitial pneumonitis, pul

Mitoxantrone, DHAD Novantrone. Injection.	**Cancer chemotherapy (anthracycline analog inhibits DNA and RNA synthesis throughout entire cell cycle).** Acute nonlymphocytic leukemias: *Children <2 yr:* 0.4?mg/kg/24?hr for 3–5 days. *>2 yr and adults:* 8–12?mg/m^2 /24?hr for 5 days. Solid tumors: *Children:* 18–20?mg/m^2 q 3–4 wk or 5–8?mg/m^2 weekly. *Adults:* 12–14?mg/m^2 q 3–4 wk (max: total 80–120?mg/m^2).	*Adverse events:* Cardiotoxicity (less t anthracyclines), seizures, headache, enzymes, renal failure, conjunctivitis, (onset, 7–10 days; nadir, 14 days; re
Molindone hydrochloride Moban. Tablet: 5, 10, 25, 50, 100?mg. Oral concentrate: 20?mg/mL.	**Management of psychotic disorder (actions similar to chlorpromazine but more extrapyramidal effects and less sedation).** *Children:* *3–5 yr:* 1–2.5?mg/kg/24?hr in 4 doses. *5–12 yr:* 0.5–1?mg/kg/24?hr in 4 doses. *Adults:* 50–225?mg/24?hr.	*Adverse events:* Extrapyramidal effec dyskinesias, constipation, blurred visi hypotension, seizures, neuroleptic m mouth, weight gain, galactorrhea, uri agranulocytosis, leukopenia, retinal p
Montelukast Singulair. Tablet: 4 (chewable), 5 (chewable), 10?mg.	**Prophylaxis and chronic treatment of asthma (leukotriene receptor blocker for LTD4).** *Children 2–5 yr:* 4?mg once daily in evening. *Children: 6–14 yr:* 5?mg once daily in the evening. *>15 yr and adults:* 10?mg once daily in the evening.	*Adverse events:* Headache, dizziness elevated liver enzymes.
Morphine Generic. Injection, oral solution, suppository. Tablet, sustained-release (SR). Tablet, controlled-release (CR). Tablet.	**Relief of moderate to severe pain (narcotic analgesic).** *Neonates:* IV, IM, SC. Analgesia: 0.05–0.2?mg/kg/dose q 2–4?hr; continuous infusion 0.025–0.05?mg/kg/hr. *Infants and children:* IV, IM, SC: 0.1–0.2?mg/kg/ dose q 2–4?hr; PO: 0.2–0.5?mg/kg/dose q4–6h. *Adolescents >12 yr:* IV: 3–4?mg; may repeat in 5?min if needed. *Adults:* PO: 10–30?mg q4h or CR tablet 15–30?mg q8–12h. IV, IM, SC: 2.5–20?mg/dose q2–6h as needed or continuous infusion 0.8–10?mg/hr.	*Cautions:* May develop physical depe days continuous use; if so, taper dose contain sulfites. *Adverse events:* Hypotension, bradyc vomiting, constipation, sedation, conf urination, respiratory depression.
Mupirocin Bactroban. Ointment: 2%.	**Topical treatment of impetigo and other gram-positive skin infections (inhibit bacterial protein and RNA synthesis).** *Children and adults:* Apply to affected area 4–5 times daily. Intranasal (eliminate nasal carriage of *Staphylococcus aureus*): Apply small amount bid–qid for 5–14 days.	*Adverse events:* Stinging and irritatio

Muromonab-CD3, OKT3 Orthoclone OKT3. Injection: 5?mg/5?mL.	**Treatment of acute allograft rejection in renal transplant patients (coats circulating T lymphocytes facilitating their opsonization by the reticuloendothelial system, and promotes removal of all CD3 molecules from T lymphocyte antigen receptor complex).** *Children <12 yr:* 0.1?mg/kg/24?hr for 10–14 days; or if <30?kg, give 2.5?mg/24?hr for 10–14 days. *>12 yr and adults:* 5?mg/24?hr for 10–14 days.	*Cautions:* Severe first-dose reactions recommend methylprednisolone 1?m first OKT3 dose and hydrocortisone 1 after each OKT3 dose and as neede *Adverse events:* Shortness of breath, fever, chills, trembling, nausea, vomit headache, stiff neck, photophobia, flu *Monitoring:* OKT3 serum trough level 1?µg/mL then CD3 counts remain lov
Mycophenolate mofetil CellCept. Capsule: 250?mg.	**Prevent rejection of allograph transplants, used in conjunction with other drugs (active metabolite MPA inhibits T- and B-cell proliferation, T-cell generation, and antibody secretion).** *Children:* 600?mg/m^2 /dose bid. *Adults:* 1,000?mg/dose bid.	*Adverse events:* Hypertension, insom headache, bone marrow suppression myalgia, dyspnea, cough, pharyngitis tubular necrosis, lymphoproliferative
Nadolol Corgard. Tablet: 20, 40, 80, 120, 160?mg.	**Antiarrhythmic, antihypertensive, and migraine prophylaxis: (nonselective ß-adrenergic receptor antagonist).** *Children:* 0.5–2.5?mg/kg PO q24h for supraventricular tachycardia. *Adults:* 40?mg q24h; titrate upward to desired effect (usual dose: 40–80?mg/24?hr up to 640?mg/24?hr).	*Cautions:* Should not be used in patie bronchoconstriction, or uncontrolled h dose with renal dysfunction (CrCl <50 *Adverse effects:* Bradycardia, heart fa *Drug interactions:* Other hypotensive Antagonizes ß-sympathomimetic drug .

Nalbuphine Nubain. IV, IM, SQ: 10?mg/mL.	**Analgesic (opiate agonist with partial opiate antagonistic activity for treatment of moderate to severe pain).** *Children =1 yr:* 0.1–0.2?mg/kg IV, IM, SC, q3–4h. Maximal single dose: 20?mg; maximal daily dose: 160?mg.	*Cautions:* Like most opiate analgesics histamine release and cause CNS an depression. Use with caution in hepa other respiratory depressants. Depen *Adverse effects:* Hypotension, sedatio depression. Naloxone reverses effect
Naloxone Narcan, generic. Injection: 0.4?mg/mL. Injection neonate: 0.02?mg/mL.	**Opiate antagonist: antagonizes all opiate receptors—used in the treatment of opiate excess (overdose, poisoning).** *Neonates and children:* 0.1?mg/kg IV (max dose: 2?mg). If no response, repeat q 2–3?min until desired effect. May give by continuous IV infusion.	*Cautions:* May precipitate acute opiat of effect of many opiates may be long requiring individualized naloxone dos push.
Naproxen Aleve, Anaprox, Naprosyn, generic. Tablet: 220, 250, 275, 375, 550?mg. Suspension: 125?mg/5?mL.	**Nonsteroidal anti-inflammatory drug for the treatment of mild to moderate pain, inflammation, fever (inhibits prostaglandin synthesis).** *Neonates:* Do not use owing to probably negative effects on renal function. *Children:* 5–7?mg/kg PO q8–12h. *Adults:* 250–375?mg PO q8–12h (max: 1,250?mg/24?hr).	*Cautions:* Gastrointestinal upset/irrita interference with platelet aggregation infants <3 mo of age. *Adverse effects:* Dizziness, gastrointe age-related decreased renal function.
Nedocromil Tilade. Aerosol: 1.75?mg/activation.	**Chronic treatment of asthma/allergic disorders. Mast cell stabilizer (also stabilizes other cells to mediator release—neutrophils, eosinophils, platelets), nonsteroidal.** *Children and adults:* 1–2 puffs 2–4 times/24?hr. Dose titrated to clinical response.	*Cautions:* Only effective as chronic th bronchodilatation. *Adverse effects:* Dysphonia, chest irri

Neostigmine Prostigmin, generic. Tablet: 15?mg (as bromide). Injection: 0.25, 0.5, 1?mg/mL (as methylsulfate).	**Treatment of myasthenia gravis, reversal of nondepolarizing neuromuscular blocking agents (NDNM). Competitively inhibits acetylcholine esterase augmenting effects of endogenous acetylcholine.** *Children:* 0.01–0.04?mg/kg IV, IM, SC q2–4h; titrate dose to desired effect. To reverse NDNM 0.025–1?mg/kg/dose (max adult dose: 5?mg).	*Cautions:* Patients with asthma/bronc bradycardia. Does not antagonize suc *Adverse effects:* Bradycardia, abdom frequency.
Niacin Nicobid, generic. Tablet: 25, 50, 100, 250, 500?mg. Tablet, timed-release: 150, 250, 500, 750?mg. Capsule, timed-release: 125, 250, 300, 400, 500?mg. Elixir: 50?mg/5?mL. Injection: 100?mg/mL.	**Vitamin supplementation (vitamin B_3), hyperlipidemia, vasodilator.** *Children:* IV, IM, SC, PO titrated to desired effect (max: 10?mg/kg/24?hr).	*Cautions:* Titrate dose upward and ac avoid/minimize flushing. *Adverse effects:* Flushing, tachycardi hyperuricemia. *Drug interactions:* Augments hypoten antihypertensives.
Nifedipine Adalat, Procardia, generic. Capsule (liquid filled): 10, 20?mg. Tablet, timed-release: 30, 60, 90?mg. Capsule, timed-release: 30, 60, 90?mg.	**Antihypertensive, antiarrhythmic calcium channel antagonist.** *Infants and children:* Hypertensive emergency 0.25–0.5?mg/kg/dose PO/SL: q4–6h (max: 10?mg). Hypertropic cardiomyopathy: 0.2–0.3?mg/kg PO q8h. *Adults:* 10?mg/dose titrated to effect (max: 120–180?mg/24?hr).	*Caution:* Do not crush or break timed *Adverse effects:* Profound, acute hyp dizziness. More rapid effect if drug is food. Concurrent grapefruit juice may bioavailability and effects. *Drug interactions:* Cimetidine, cyclosp possibly digoxin. *Comment:* Preferred route is oral, not due to swallowing. Capsule content a 0.34?mL and 20?mg in 0.45?mL.
Nitric oxide **Nitroprusside** Nipride, generic. Injection: 10?mg/mL, 25?mg/mL.	**Antihypertensive, congestive heart failure: controlled, titratable blood pressure control.** *Children and adults:* 0.3–0.5?µg/kg/min; titrate dose to desired effect; rarely requires >6?µg/kg/min (probable max: 8?µg/kg/min	*Cautions:* Metabolized to thiocyanate accumulates with renal dysfunction. *Adverse effects:* Profound hypotensic suppression, acidosis, seizures. Cyar metabolic acidosis, pink skin methem Administer by continuous IV infusion. direct light. Thiosulfate co-administrat (10?mg thiosulfate for each 1?mg nitr

Norepinephrine bitartrate Levophed. Injection: 1?mg/mL base.	**Hypotension/shock. Sympathomimetic/ adrenergic agonist.** *Children:* 0.05–0.1?µg/kg/min; titrate dose to desired effect (max dose: 2?µg/kg/min).	*Cautions:* Extravasation may cause s Administer into large vein by continuc patient fluid status. May cause profou *Adverse effects:* Hypertension, cardia headache. Drug dose based on norep
Nortriptyline Aventyl, Pamelor, generic. Capsule: 10, 25, 50, 75?mg. Solution: 10?mg/5?mL.	**Tricyclic antidepressant, nocturnal enuresis: central synaptic norepinephrine/serotonin reuptake inhibitor.** *Children:* Nocturnal enuresis: 10–20?mg/24?hr; titrate upward to maximum of 40?mg/24?hr. Depression: 1–3?mg/kg PO/24?hr (bedtime) titrated to effect. May give in divided doses q6h (usual max dose: 150?mg/24?hr).	*Cautions:* Avoid in patients with cardi abnormalities, cardiac disease. Slow patients with hepatic dysfunction. *Adverse effects:* Anticholinergic effec tachycardia, blurred vision, urinary re *Drug interactions:* Clonidine, MAO inh
Octreotide Sandostatin. Injection: 0.05, 0.1, 0.2, 0.5, 1?mg/mL.	**Antisecretory somatostatin analog.** *Children:* Secretory diarrhea: 1–10?µg/kg IV, SC q12?hr; titrate dose to effect. May give via continuous IV infusion *Adults:* For treatment of vasoactive intestinal peptide secreting tumors: 100–150?µg IV, SC q12h.	*Cautions:* Continuous long-term use (cholelithiasis, hypothyroidism. *Adverse effects:* Flushing, dizziness, Infuse IV over 20–30?min, IV push ov

Olanzapine Zyprexa Tablet: 2.5, 5, 7.5, 10, 15, 20?mg.	**Atypical antipsychotic, monaminergic antagonist with high affinity for serotonin, dopamine, histamine, muscarinic, and a_1 -adrenergic receptors. Actual mechanism of action is unknown.** *Children:* Start 2.5–5?mg q24h; titrate weekly by 2.5–5?mg to 15–20?mg/24?hr as q24h dosing. *Adults:* Start 5–10?mg/24?hr; increase by 5?mg weekly to response (max: 20?mg/24?hr).	*Adverse events:* Postural hypotensior dizziness, akathisia, asthenia, dry mc dyspepsia, increased appetite, weigh amenorrhea and vaginitis in females.
Olsalazine Dipentum. Capsule: 10, 20, 250?mg.	**Inflammatory bowel disease, anti-inflammatory drug, 5-aminosalicylic acid derivative.** *Adults:* 500?mg q12h.	*Cautions:* Administer with food. *Adverse effects:* Headache, cramps, rash, cholestasis.
Omeprazole Prilosec. Capsule: 10, 20?mg.	**Gastric acid hypersecretion/ulcer disease. Proton pump inhibitor of parietal cell hydrogen ion secretion.** *Children:* 0.6–0.7?mg/kg PO q24h. Dose titrated to desired gastric pH. *Adults:* Usual 20–40?mg/24?hr PO.	*Caution:* Drug granules in capsule mu whole; do not chew *Drug interactions:* May decrease diaz clearance. May reduce itraconazole,

Ondansetron Ondansetron. Tablet: 4, 8?mg. Injection: 2?mg/mL.	**Antiemetic. Treatment of nausea/vomiting associated with cancer chemotherapy/ surgery and other causes (drug toxicity). Selective serotonin-3 receptor antagonist.** *Infants and children:* 0.15?mg/kg IV q8h; may give as continuous IV infusion 0.45?mg/kg/24?hr (max: 24–32?mg/24?hr). Child PO dose for mild to moderate nausea/vomiting: 4–8?mg q8–12h).	*Adverse effects:* Headache, chest pai dystonia/sedation. *Comment:* Oral bioavailability ~50%. before starting chemotherapy.
Oxcarbazepine Trileptal. Tablet (film-coated): 150, 300, 600?mg. Suspension: 300?mg/5?mL.	**Used for seizure disorders (except absence).** *Children 3–17 yr:* Start 8–10?mg/kg/24?hr divided bid (max: 600?mg/24?hr); increase over 2 wk to 30–45?mg/kg/24?hr divided bid per response. *Adults:* Start at 600?mg/24?hr divided bid, then gradually increase over 2–4 wk to 1,200?mg/24?hr divided bid (max: 2,400?mg/24?hr).	*Cautions:* Cut dose in half if creatinin <30?mL/min. Toxicities are mainly CN somnolence, dizziness, etc), diplopia, (nausea, vomiting, diarrhea) and hyp
Oxybutynin Ditropan, generic. Tablet: 5?mg. Syrup: 5?mg/5?mL.	**Urinary antispasmodic. Relaxes smooth muscle by antagonizing acetylcholine.** *Children:* 0.2?mg/kg PO q6–12h (max: 5?mg PO q8h). *Adults:* 5?mg per dose up to 4 times daily.	*Cautions:* Patients with renal and/or li *Adverse effects:* Tachycardia, drowsi mouth, blurred vision. *Drug interactions:* Additive anticholine depression, e.g., antihistamines.
Oxycodone (Various brands, generic). Tablet: 5?mg.	**Analgesic. Opiate analgesic for the treatment of moderate to severe pain.** *Children:* 0.05–0.15?mg/kg PO q4–6h (max: 5?mg). *Adults:* 5?mg per dose PO q4–6h (max: 5?mg.)	*Cautions:* Like most opiate analgesics histamine release and may cause CN depression. Use with caution in hepa other respiratory depressants. Depen *Adverse effects:* Hypotension, sedatic depression. Naloxone reverses effect

Pamidronate disodium Aredia. Injection: 30, 60, 90?mg.	**Treatment of hypercalcemia, Paget disease. Osteogenesis Imperfecta, Osteopenia Bisphosphonate derivative binds to bone inhibiting osteoclast-mediated calcium resorption. Dose based on serum calcium concentration.** *Children:* 1?mg/kg/24?hr for consecutive days q 3 mo; 10–40?mg/m^2 over 5–8?hr q mo. *Adults:* Serum calcium 12–13.5?mg/dL: 60–90?mg; serum calcium >13.5?mg/dL: 90?mg. Wait 7 days to assess full effect of dose before re-treatment. Paget disease: 30?mg/24?hr for 3 consecutive days.	*Cautions:* Leukopenia, thrombophleb with calcium containing IV solutions. *Adverse effects:* Hypertension, synco hypophosphatemia, hypothyroidism, l
Pancreatin Various brands. Capsule, tablet, timed-release capsule, powder.	**Pancreatic enzyme replacement. Individual products contain different amounts of lipase, amylase, and protease.** *Children and adults:* Dose titrated to desirable stool frequency and consistency.	*Cautions:* Excessive dosing may leac inadequate dosing may lead to steatc pancreatic enzymes inactivated by ga microencapsulated forms when possi *Drug interactions:* Reduction of gastri -receptor antagonists/omeprazole/ant effectiveness. *Adverse effects:* Rash, abdominal co hyperuricemia, allergy.
Pancuronium Pavulon, generic. Injection: 1?mg/mL, 2?mg/mL.	**Anesthetic/skeletal muscle relaxant. Nondepolarizing neuromuscular antagonist.** *Children and adults:* 0.04–0.1?mg/kg IV q20–30?min. Dose titrated to desired effects.	*Cautions:* Ventilation must be suppor neuromuscular blockade. Dose adjus dysfunction. *Adverse effects:* Tachycardia, hyperte muscle weakness. *Drug interactions:* Possible augmente with aminoglycosides, anesthetics, ar

Papaverine hydrochloride Cerespan, Pavabid, generic. Capsule: 150?mg. Tablet, time-released. Injection.	**Vasodilator, antimigraine. Generalized smooth muscle relaxant. Common pediatric use for preservation of arterial catheters to prolong function.** *Children:* 30?mg papaverine plus 250 units heparin per 250?mL IV solution (0.45–0.9% NaCl) infused.	*Cautions:* Avoid in neonates because vasodilatation predisposing to CNS h *Adverse effects:* Flushing, tachycardi dizziness. *Drug interactions:* Additive hypotensiv
Paraldehyde Paral, generic. Liquid: 1?g/mL.	**Anticonvulsant, sedative. Generalized CNS depressant used as adjunct treatment for refractory status epilepticus, alcohol withdrawal.** *Children:* 0.15?mL/kg/dose PO, PR. May repeat once in 4–6?hr. IM formulation not available in United States. *Adults:* 5–10?mL per dose.	*Cautions:* May give IM but inject remo to risk of damage. Use glass syringe/ reacts with plastic. Rectal route prefe rectal solution 2:1 in oil (e.g., olive oil) *Adverse effects:* Sedation, gastric irrit thrombophlebitis.
Paregoric Generic. Liquid: 2?mg morphine equivalent per 5?mL.	**Antidiarrheal, analgesic. Camphorated tincture of opium.** *Children:* 0.25–0.5?mL/kg PO q6–12h. *Adults:* 5–10?mL PO q6–12h. Neonatal abstinence syndrome: dose titrated to desired effect.	*Comments:* Each 5?mL of paregoric c morphine equivalent, 20?mg campho acid. Final alcohol content 45%.

Drug	Indication and dosage	Cautions, adverse effects, interactions
Paroxetine Paxil. Tablets: 10, 20, 40?mg Oral suspension: 10?mg/5?mL.	**Serotonin reuptake inhibitor. Effective for treatment of depression, obsessive-compulsive disorder, panic disorder, and social anxiety disorder.** *Children:* Start 10?mg q24h; increase at weekly intervals by 10?mg/24?hr to maximum 60?mg/24?hr. *Adults:* Start 20?mg q24h, increase by 10?mg/24?hr at weekly intervals to response or maximum 60?mg q 24?hr.	*Cautions:* Do not discontinue abruptly syndrome may occur. Taper by 10?m days to avoid problems. Avoid use wi inhibitors except in extreme situations *Adverse events:* Somnolence, dizzine nervousness, decreased appetite, as constipation. *Drug interactions:* Paroxetine inhibits isoenzyme and may interact with phe 1C antiarrhythmics. Concurrent use w elevate thioridazine levels causing pr and predispose to torsades de pointe
Pegaspargase Oncaspar. Injection.	**Antineoplastic agent used in combination for induction of acute lymphoblastic leukemia. Also called PEG-ı-asparaginase.** *Children and adults:* IM, IV: 2,500 units/m^2 q 14 days. Dose usually dictated by specific protocol.	*Cautions:* Hepatotoxic, allergic reacti in patients with pancreatitis, significar events associated with ı-asparaginase *Drug interactions:* Possible interactior vincristine, corticosteroids.
Pemoline Cylert. Tablet: 18.75, 37.5, 75?mg. Tablet, chewable: 37.5?mg.	**Central nervous system stimulant used in the treatment of attention deficit disorder. Structurally unique from methylphenidate.** *Children:* 1?mg/kg/24?hr PO as single dose each morning. Titrate to effect 0.5?mg/kg/24?hr q 1–2 wk. Usual max dose 3?mg/kg/24?hr (~112.5?mg/24?hr).	*Cautions:* Insomnia, anorexia, weight *Adverse effects:* Central nervous syst seizures, hypertension, increased live hepatitis, movement disorders. *Drug interactions:* Possible with other system stimulants, sympathomimetic

Drug	Indication and dosage	Cautions, adverse effects, interactions
Penicillamine Cuprimine, Depen. Capsule: 12, 250?mg. Tablet: 250?mg.	**Metal chelating agent with affinity for copper (Wilson disease) and lead. Also used as an adjunct for the treatment of severe rheumatoid arthritis.** **Wilson disease:** Dose titrated to maintain >1?mg/24?hr urinary copper excretion. *Infants and children:* 20?mg/kg/24?hr PO q6–12h (max: 1?g/24?hr). *Adults:* 1?g/24?hr PO q6–12h (max: 2?g). **Lead intoxications** *Infants and children:* 30–40?mg/kg/24?hr PO q8–12h (max: 1.5?g/24?hr). *Adults:* 1–1.5?g/24?hr PO q8–12h. **Rheumatoid arthritis** *Children:* 3?mg/kg/24?hr PO q12h, increasing by 3?mg/kg/24?hr q 2–3 mo to max 10?mg/kg/24?hr.	*Cautions:* Cross allergen in patients a not administer with food or iron/zinc c *Adverse effects:* Rash, pruritus, naus bone marrow suppression, nephrotic lupus erythematosus–like syndrome. *Drug interactions:* Other metals, iron, antimalarials.
Pentazocine Talwin. Tablet: 50?mg with 50?mg naloxone (parenteral deterrent). Injection: 30?mg/mL.	**Opiate analgesic of the benzo orphan type for the treatment of moderate to severe pain.** *Children >14 yr of age and adults:* 50?mg PO q3–4h; titrate to effect to 100?mg dose not to exceed 600?mg/24?hr. May give IM or IV reducing oral dose by one third.	*Cautions:* Generalized CNS depressa antagonistic action and may precipita *Adverse effects:* CNS depression, na respiratory depression, histamine rele

Pentobarbital Nembutal, generic. Capsule: 50, 100?mg. Elixir: 18.2?mg/5?mL. Suppository: 30, 60, 120, 200?mg. Injection.	**Short-acting barbiturate used as an anticonvulsant, sedative/hypnotic, anesthetic.** **Sedation** *Children:* 2–6?mg/kg/24?hr PO, IM q6h. May give rectally dosed by body weight: 4.5–10?kg: 30?mg; 10–18?kg: 30–60?mg; 18–36?kg: 60?mg; 36–50?kg: 60–120?mg. **Pentobarbital coma** *Children:* Loading dose 10–15?mg/kg IV slowly over 1–2?hr monitoring blood pressure and heart rate. Maintenance infusion 1?mg/kg/hr increasing up to 5?mg/kg/hr to maintain burst suppression on EEG.	*Cautions:* Hypotension in hypovolemi contain propylene glycol. *Adverse effects:* Arrhythmias, bradyca respiratory depression, laryngospasm *Drug interactions:* May increase meta hepatically cleared drugs; oral contra corticosteroids. *Monitoring:* Pentobarbital concentratio 1–5?μg/mL coma 20–40?μg/mL.
Pentoxifylline Trental. Tablet, timed-release: 400?mg.	**Used in the treatment of peripheral vascular disease (Raynaud syndrome) and investigationally in reducing tumor necrosis factor, neutrophil adhesion, and platelet aggregation.** *Children:* Antiplatelet effect in Kawasaki disease: 20?mg/kg/24?hr PO q8h. *Adults:* 400?mg PO tid.	*Cautions:* Administer with meals to re upset. *Adverse effects:* Hypotension, tachyc nausea, vomiting. *Drug interactions:* Cimetidine, possibl warfarin, heparin effects.
Phenazopyridine Pyridium, generic. Tablet: 100, 200?mg.	**Urinary anesthetic for possible symptomatic relief of urinary burning and itching associated with urologic procedures or urinary tract infection.** *Children:* 12?mg/kg/24?hr PO q8h. *Adults:* 100–200?mg PO q6–8h.	*Caution:* Discolors urine to orange or *Adverse effects:* Headache, rash, me Administer with food to decrease gas effects.

Phenobarbital Generic. Elixir: 15?mg/5?mL; 20?mg/5?mL. Tablet: 8, 15, 30, 60, 100?mg. Injection: 30?mg/mL, 60?mg/mL, 130?mg/mL.	**Barbiturate CNS depressant used as a sedative, hypnotic, anticonvulsant, anesthetic.** **Anticonvulsant: loading dose** *Children and adults:* 15–20?mg/kg PO, IV. **Maintenance dose** *Neonates:* 3–4?mg/kg/24?hr PO, IV, q12–24h. *Children:* 5–6?mg/kg/24?hr PO, IV, q12–24h. *Adults:* 1–3?mg/kg/24?hr PO, IV, q12–24h. **Sedation** *Children:* 2?mg/kg per dose. **Hyperbilirubinemia** *Children:* 3–8?mg/kg/24?hr PO, IV q12–24h. *Adults:* 90–180?mg/24?hr PO, IV q12–24h.	*Cautions:* Dose titrated to desired eff =30?mg/min in infants and children a adults. *Adverse effects:* Hypotension, drowsi depression, paradoxical hyperactivity *Drug interactions:* May increase meta hepatically cleared drugs; oral contra corticosteroids. Certain drugs may int phenobarbital metabolism: valproic a felbamate. *Target serum concentrations:* 15–40? 60?μg/mL. *Monitoring:* Phenobarbital concentrati 15–40?μg/mL; coma >60?μg/mL.
Phenoxybenzamine Dibenzyline. Capsule: 10?mg.	**a-Adrenergic receptor antagonist used for symptomatic treatment of pheochromocytoma.** *Children:* 0.2–2?mg/kg/24?hr PO q24h. Titrate dose to desired effect (e.g., blood pressure). *Adults:* 10?mg per dose PO q12h; titrate dose to effect.	*Cautions:* Long-acting a-receptor ant *Adverse effects:* Postural hypotensio *Drug interactions:* Sympathomimetics

Phentolamine Regitine. Injection: 5?mg/mL.	**a-Adrenergic antagonist used in the diagnosis/ treatment of pheochromocytoma and for extravasation of drugs with a-adrenergic effects (e.g., dopamine, dobutamine, epinephrine, norepinephrine, phenylephrine).** Pheochromocytoma Diagnosis: *Children:* 0.05–0.1?mg/kg/dose (usual max dose: 5?mg). *Adults:* 5?mg per dose. Preoperatively: *Children:* 0.05–0.1?mg/kg/dose q1–2h titrating to effect and needed duration. Usual max dose: 5?mg. **Extravasation** 5–10?mg in 10?mL 0.95 normal saline. Infiltrate area with small volume using 27–30 gauge needle not to exceed total dose of 0.1?mg/kg.	*Cautions:* Short-acting a-receptor ant *effects:* Hypotension, dizziness, gastr *Drug interactions:* Sympathomimetics
Phenylephrine hydrochloride Neo-Synephrine, generic. Injection: 10?mg/mL. Nasal drops/spray: 0.16–1%. Eye drops.	**a-Adrenergic receptor agonist, peripheral vasoconstrictor; used in treatment of hypotension in shock and in many nasal decongestants.** **Nasal decongestant** *Infants:* 1–2 drops per naris q3–4h 0.16% solution. *Children 1–6 yr:* 1–2 drops/spray per naris q3–4h 0.125% solution. *6–12 yr:* 1–2 drops/spray q3–4h 0.25% solution. *>12 yr and adults:* 1–2 drops/spray per naris q3–4h 0.25–0.5% solution. **Hypotension/shock** *Children:* 5–20?µg/kg per dose IV q10–15?min. May give by continuous IV infusion 0.1–0.5?µg/kg/min titrated to desired effects (e.g., blood pressure). *Adults:* 0.1–0.5?mg/dose q10–15?min continuous IV infusion 100–180?µg/min titrating to desired effect. **Paroxysmal supraventricular tachycardia** *Children:* 5–10?µg/kg IV over 20–30?sec. *Adults:* 0.25–0.5?mg IV over 20–30?sec.	*Cautions:* Patients with hypertension. sulfites. Rebound nasal stuffiness wit use/abuse. *Adverse effects:* Hypertension, angin restlessness, necrosis if IV infiltrates. *Drug interactions:* Sympathomimetics antagonists, monoamine oxidase inhi

Phenytoin Dilantin; generic (use cautiously). Capsule, slow (extended) release: 30, 100?mg. Capsule, prompt release: 30, 100?mg. Suspension: 125?mg/5?mL. Injection: 50?mg/mL.	**Anticonvulsant and antiarrhythmic.** **Status epilepticus: loading dose** *Neonate:* 15–20?mg/kg IV; do not exceed 0.5?mg/kg/min. *Children and adults:* 15–18?mg/kg IV; do not exceed 1–3?mg/kg/min. **Maintenance dose** *Neonate:* 5?mg/kg/24?hr PO, IV q12–24h. *Children 0.5–6 yr:* 8–10?mg/kg/24?hr *7–9 yr:* 6–8?mg/kg/24?hr PO, IV q12–24h *10–16 yr:* 6–7?mg/kg/24?hr PO, IV q12–24h. *Adults:* 300–600?mg/24?hr q12–24h. **Arrhythmias: loading dose** *Children and adults:* 1.25?mg/kg IV q5? min until desired effect or total dose 15?mg/kg. **Maintenance dose** *Children:* 5–10?mg/kg/24?hr q8–12h. *Adults:* 250?mg per dose q6–8h.	*Cautions:* Infuse slowly IV; variable o chewable tablet most consistent. Mus suspension very well before use. Foll (Michaelis-Menten) pharmacokinetics states (renal failure, acute head traun imbalance between free and protein-b *Adverse effects:* Lethargy, dizziness, hypotension, hirsutism, gingival hyper Stevens-Johnson syndrome, hepatitis *Drug interactions:* May increase meta hepatically cleared drugs; oral contra corticosteroids, cyclosporin; highly pr cause displacement interaction. *Monitoring:* Phenytoin concentrations 8–20?µg/mL If necessary, measure fr concentration: therapeutic 1–2?µg/ml
Physostigmine Antilirium. Injection, ophthalmic solution, and ointment.	**Competitive antagonist of acetylcholine. Unlike neostigmine, crosses the blood-brain barrier with central effects. Used with extreme caution in the reversal of anticholinergic effects.** *Children:* 0.001–0.03?mg/kg/dose IM, IV, SQ, repeated q15–20?min to desired effect (max total dose: 2?mg). *Adults:* 0.5–2?mg IM, IV, SQ repeated q15–20?min until desired effect.	*Cautions:* Patients with bradycardia, asthma, ulcer disease. Should be use in life-threatening situations by experi *Adverse effects:* Palpitations, restless salivation, secretions, muscle fascicu bronchospasm.

Phytonadione AquaMEPHYTON, Mephyton. Tablet: 5?mg. Injection.	**Vitamin K_1 for nutritional supplementation and treatment of hemorrhagic disease of the newborn or from warfarin-like compound anticoagulant toxicity.** *Children:* 1–2?mg/dose IM, IV, SQ dosed to effect; PO dose may increase to 2.5 to 5?mg. *Adults:* 10?mg/24?hr IM, IV, SQ; 5–25?mg/24?hr PO. Higher doses may be required for reversal of warfarin-like anticoagulant toxicity.	*Cautions:* Infuse slowly IV (over 15–3 flushing. Multiple doses may be need period depending on type of coumarin *Adverse effects:* Flushing, hypotensic
Piroxicam Feldene. Capsule: 10, 20?mg.	**Nonsteroidal anti-inflammatory agent used as an analgesic and in therapy for rheumatoid disorders.** *Children:* 0.2–0.3?mg/kg q 24?hr PO (max dose: 15?mg/kg/24?hr). *Adults:* 10–20?mg q24h.	*Cautions:* Limited data in infants and more frequent daily dosing in pediatri food/milk to decrease gastrointestinal use in young infants. *Adverse effects:* Dizziness, gastrointe nausea/vomiting, ulcer, hepatitis, dec
Polyethylene glycol-electrolyte solution Golytely, Colovage, Colyte. Powder for reconstitution.	**Bowel lavage solution used before bowel radiology or in poisonings.** *Children:* 25–40?mL/kg/hr up to 1.5–2?L/hr until rectal effluent clear; usual max dose 4?L for x-ray may go much higher if used for poisonings (e.g., iron). *Adults:* 2,400?mg q10–20?min until 4?L consumed. May go higher for poisonings.	*Caution:* In patients with bowel diseas obstruction. *Adverse effects:* Nausea, cramps, blo

Poractant alfa Curosurf Intratracheal suspension of porcine lung extract, surfactant (80?mg phospholipids, 1?mg protein, 0.3?mg SP-B/mL).	**Prophylaxis or treatment of respiratory distress syndrome, treatment of persistent pulmonary hypertension.** *Neonates:* 2.5?mL/kg (200?mg/kg) for dose #1, may repeat dose of 1.25?mL/kg (100?mg/kg) 2 times q12h *Children and adults:* Not indicated.	*Caution:* Monitor ventilator status clos weaning within minutes of the dose. *Adverse events:* Bradycardia, airway cyanosis.
Pralidoxime Protopam (2-PAM). Tablet: 500?mg. Injectable.	**Acetylcholinesterase reactivator used in the treatment of organophosphate poisoning; possible treatment of toxicity from cholinergic drugs.** *Children:* 20–50?mg/kg/dose IM, IV repeated in 1–2?hr if muscle weakness has not been relieved; when desired effect obtained dose q12h. *Adults:* 1–2?g IM, IV q5–6h (dose based on clinical response).	*Caution:* As antidote for organophosp combination with atropine. Excessive cholinergic effects. Too-rapid IV admi with tachycardia, laryngospasm. Infus *Adverse effects:* Hypertension, dizzin weakness/rigidity.
Prazosin Minipress, generic. Capsule: 1, 2, 5?mg.	**Competitive antagonist of postsynaptic a-adrenergic receptors used in the treatment of hypertension/heart failure.** *Children:* 0.1?mg/kg/24?hr PO q6h titrating dose to desired blood pressure. Usual max dose: 0.4?mg/kg/24?hr or 15?mg total dose. Consider additive/synergistic combinations with diuretics. *Adults:* 3?mg/24?hr PO q8–12h, titrating dose to desired blood pressure. Usual dose range: 3–15?mg/24?hr.	*Caution:* Profound hypotension may c ("first-dose phenomenon") more comı salt-depleted patients. *Adverse effects:* Syncope, palpitation retention. *Drug interactions:* Other hypotensive ß-receptor antagonists).

Prednisolone DeltaCortef, Hydeltrasol, Predalone, generic. Tablet: 5?mg. Suspension. Injection.	**Glucocorticosteroid used in the treatment of inflammatory disorders including allergic, respiratory, rheumatic, endocrine, and neoplastic disorders.** **Asthma** *Children:* 0.5–4?mg/kg/24?hr PO, IV q6–12h. *Adulst:* 5–60?mg/24?hr PO, IV. **Anti-inflammatory** *Children:* 0.1–2?mg/kg/24?hr PO, IV q6h–q day.	*Cautions:* Dose titrated to desired effe treatment course to avoid side effects increase salt retention. *Adverse effects:* Edema, hypertensio syndrome. HPA-axis (adrenal) suppre *Drug interactions:* Barbiturate, phenyt *Comment:* See comparison of cortico *Hydrocortisone.*
Prednisone Deltasone, Liquid Pred, generic. Tablet: 1, 2.5, 5, 10, 20, 50?mg. Syrup: 5?mg/5?mL. Injection.	**Glucocorticosteroid used in the treatment of inflammatory disorders including allergic, respiratory, rheumatic, endocrine, and neoplastic disorders.** **Asthma** *Children:* 0.5–4?mg/kg/24?hr PO, q6–12h. *Adults:* 5–60?mg/24?hr PO. **Anti-inflammatory** *Children:* 0.1–2?mg/kg/24?hr PO, IV q6–24h.	*Cautions:* Dose titrated to desired effe treatment course to avoid side effects increase salt retention. *Adverse effects:* Edema, hypertensio syndrome. HPA-axis (adrenal) suppre *Drug interactions:* Barbiturate, phenyt *Comment:* See comparison of cortico *Hydrocortisone.*
Primidone Mysoline, generic. Tablet: 50, 250?mg. Suspension: 250?mg/5?mL.	**Anticonvulsant used in the treatment of generalized tonic-clonic, complex partial and focal seizures.** *Neonate:* 12–20?mg/kg/24?hr PO, q8–12h. *Children:* 10–25?mg/kg/24?hr PO q8–12h. *Children >8 yr and adults:* 125–1,500?mg/24?hr PO q8–12h (usual max: 2?g/24?hr).	*Caution:* Partially metabolized to pher *Adverse effects:* Sedation, ataxia, ras *Drug interactions:* Valproate, griseofu *Monitoring:* PEMA concentrations: the

Procainamide Pronestyl, Procan. Tablet and capsule: 250, 375, 500?mg. Tablet, sustained-release: 250, 500, 750, 1,000?mg. Injection.	**Class Ia antiarrhythmic; ventricular tachycardia, premature ventricular contractions, paroxysmal atrial tachycardia, atrial fibrillation.** **Loading dose** *Children:* 3–6?mg/kg/dose IV over 5?min not to exceed 100?mg/dose; repeat q5–10?min as needed to max 15?mg/kg total dose. Do not exceed 500?mg in 30?min. **Maintenance dose** *Children:* 15–50?mg/kg/24?hr PO q3–6h; 20–30?mg/kg/24?hr IM, IV; not to exceed 4?g/24?hr; continuous IV infusion 20–80?µg/kg/min, usual max 2?g/24?hr. *Adults:* 250–500?mg/dose q3–6h (max: 2–4?g/24?hr).	*Caution:* Causes positive antinuclear general cardiodepressant. Metabolize *Adverse effects:* Hypotension, arrhyth confusion, agranulocytosis, systemic erythematosus–like syndrome, fever, *Drug interactions:* Cimetidine, ß-antag agents. *Monitoring:* Procainamide concentrati 4–10?µg/mL. Sum of procainamide a 10–30?µg/mL.
Procarbazine Capsule: 50?mg.	**Antineoplastic used in the treatment of Hodgkin lymphoma, bronchogenic carcinoma.** **Hodgkin disease** *Children:* 1.5–3?mg/kg/24?hr (50–100?mg/m^2) PO, q24hr for 10–14 days per 28-day cycle. **Bone marrow transplant preparation** 12.5?mg/kg/dose. **Neuroblastoma and medulloblastoma** *Children:* 100–200?mg/m^2 /dose per protocol.	*Caution:* Dose based on disease-bas concurrent drugs. Avoid alcohol (caus reaction). Possesses some MAO inhi *Adverse effects:* CNS depression, co marrow suppression, alopecia, flu-like *Drug interactions:* Alcohol, tricyclic ar phenothiazines, tyramine-containing f sympathomimetics.
Prochlorperazine Compazine, generic. Tablet: 5, 10, 25?mg. Capsule, sustained-release: 10, 15, 30?mg. Injection. Suppository: 2.5, 5, 25?mg. Syrup: 5?mg/5?mL.	**Piperazine-type phenothiazine antiemetic. Use should be avoided in children.** *Children:* 0.4?mg/kg/24?hr PO; rectal, q6–8?hr; 0.1–0.15?mg/kg/24?hr IM q8–12h. *Adults:* 5–10?mg/dose PO tid–qid.	*Caution:* Acute dystonic reaction com *Adverse effects:* Sedation, extrapyrar photosensitivity, cholestatic jaundice. *Drug interactions:* Additive CNS effec antagonists.
Promethazine Phenergan; generic. Tablet: 12.5, 25, 50?mg. Syrup. Suppository. Injection.	**Phenothiazine with primary antihistaminic activity used in the treatment of nausea, vomiting, motion sickness, allergy.** **Motion sickness** *Children:* 0.5?mg/kg PO, 30–60?min before departure; then q8–12h as needed. **Sedation-antiemetic** *Children:* 0.25–1?mg/kg/dose IM, IV, rectal, q4–6h as needed. **Sedation-antiemetic** *Children*: 0.25–1?mg/kg/dose IM, IV, rectal, q4–6h as needed.	*Caution:* Potentiates anticholinergic e *Adverse effects:* Sedation, hypotensio reactions, blurred vision. *Drug interactions:* Additive sedative e
Propafenone Rythmol. Tablet: 150, 225, 300?mg.	**Class 1c antiarrhythmic agent. Effective against pediatric SVT.** *Children:* 200–600?mg/m^2 /24?hr divided q8h *Adults:* 150?mg q8h (450?mg/24?hr). May titrate at 3–5 day intervals to 300?mg q8h (max: 900?mg/24?hr).	*Cautions:* May worsen or cause arrhy or angina. Also causes dizziness, fati and constipation. *Drug interactions:* Increases digoxin l cyclosporin, and theophylline.
Propantheline bromide ProBanthine, generic. Tablet: 7.5, 15?mg.	**Synthetic anticholinergic antispasmodic used as adjunctive therapy for gastrointestinal or bladder spasm, irritable bowel.** *Children:* 1.5–3?mg/kg/24?hr PO, q4–8h. Dose to desired effect.	*Caution:* Avoid in patients with decrea *Adverse effects:* Sedation, tachycardi vision, mydriasis.

Propofol Diprivan. Injection.	**Nonbarbiturate sedative, hypnotic, general anesthetic.** **Sedation** *Children:* 1.5–3?mg/kg/dose IV over 1–2?min. **Continuous sedation** (mechanical ventilation). *Children:* 5.5?mg/kg for 30?min; increase to 6?mg/kg for 30?min; increase to 8?mg/kg for 1?hr; increase to 10?mg/kg for 1?hr; increase to final infusion rate of 12.5?mg/kg/hr.	*Caution:* Dose titration regimen to per sedation-accommodating drugs comp Pharmacokinetics. Single- use vials ir *Adverse effects:* Hypotension, bradyc questionable metabolic acidosis.
Propoxyphene Darvon. Capsule. Tablet.	**Analgesic for mild to moderate pain. Binds opiate receptors. Less dependence liability than codeine.** *Children:* 2–3?mg/kg/24?hr PO q4–6h. Titrate dose to desired effect. *Adults:* Hydrochloride 65?mg/dose PO, q4–6h (max dose: 390?mg); napsylate salt 100?mg PO, q4–6h (max dose: 600?mg).	*Caution:* Weak opiate agonist with lim *Adverse effects:* Sedation, dizziness, constipation, dependence.

Propranolol Inderal, generic. Tablet: 10, 20, 40, 60, 80?mg. Solution: 4?mg/mL, 8?mg/mL, and concentrate 80?mg/mL. Injection: 1?mg/mL. Sustained-release capsule: 60, 80, 120, 160?mg.	**Nonselective ß-adrenergic receptor antagonist ($ß_1$ and $ß_2$).** *Neonates:* 0.25?mg/kg/dose PO q6–8h; titrate to desired response, increasing dose slowly (max dose 5?mg/kg/24?hr). IV: 0.01?mg/kg over 10–15?min; titrate to desired effect (max dose: 1?mg/kg/24?hr). **Arrhythmias/hypertension** *Children:* 0.5–1?mg/kg/24?hr PO q6–8h titrated upward to 2–5 (mg/kg/24?hr, over 3–5 days). *IV dose:* 0.01–0.1?mg/kg/dose infused over 10–15?min as needed (max dose: 1?mg infants; 3?mg children). *Adults:* 40–80?mg/24?hr, titrating to response; range 40–320?mg/24?hr PO q6–8h. **Thyrotoxicosis** *Neonates:* 2?mg/kg/24?hr PO q6–8h; titrate to response. *Children:* 2–4?mg/kg/24?hr PO q6–8h; titrate to response. **Migraine prophylaxis** *Children:* 0.6–2?mg/kg/24?hr PO q6–8h (usual max: 4?mg/kg/24?hr).	*Caution:* Drug undergoes substantial explaining huge difference between IV cautiously IV and in patients with con asthma, chronic obstructive pulmonar heart rate for drug effect. *Adverse effects:* Decreased cardiac o hypotension, bradycardia, hypoglycer

Propylthiouracil (PTU) Generic. Tablet: 50?mg.	**Antithyroid that inhibits thyroid hormone synthesis by interfering with incorporation of iodine.** *Neonates:* 5–10?mg/kg/24?hr PO q8h and titrate to effect. *Children:* 5–7?mg/kg/24?hr PO q8h titrate to effect. *Adults:* 300–450?mg/24?hr PO q8h increasing to 600–1,200?mg/24?hr.	*Caution:* Marked drug effect usually r *Adverse effects:* Vertigo, rash, blood arthralgia, interstitial pneumonitis.
Protamine sulfate Generic. Injection: 10?mg/mL.	**Heparin antidote, neutralizing its anticoagulant effect.** 1?mg protamine neutralizes 90 USP units of lung-derived heparin and 115 USP units of intestinal-derived heparin. Protamine dose calculated on duration of time since last heparin dose using heparin elimination half-life (~1?hr) to determine estimated heparin body stores.	*Caution:* Calculate dose carefully as p cause anticoagulation. Monitor partial with use. *Adverse effects:* Hypotension, dyspne
Pseudoephedrine Generic. Tablet: 30, 60?mg; timed-release: 120?mg. Capsule: 60?mg; timed-release: 120?mg. Syrup: 15?mg/mL.	**Indirectly acting sympathomimetic used as a nasal decongestant/symptoms of common cold.** *Infants and children:* 4?mg/kg/24?hr PO, q6–12h. *Adults:* 60?mg/dose PO, q6–8h; max: 240?mg/24?hr.	*Caution:* In patients with hypertension *Adverse effects:* Tachycardia, headac tremor. *Drug interactions:* Monoamine oxidas propranolol, pressors.

Pyridostigmine Mestinon. Tablet: 60?mg; sustained-release 180?mg. Syrup: 60?mg/5?mL. Injection: 5?mg/mL.	**Cholinesterase inhibitor used in the treatment of myasthenia gravis; reversal of neuromuscular blocking agents.** **Myasthenia gravis** *Children:* 0.05–0.15?mg/kg/dose IM, IV; max dose 10?mg; titrate to desired effect; PO dose 7?mg/kg/24?hr in 5–6 divided doses. *Adults:* 2?mg IM, IV q2–3h; PO dose 60?mg per dose q8h; titrate to desired effect. **Reversal of neuromuscular blocking agents.** *Children:* 0.1–0.25?mg/kg/dose IM, IV; titrate to effect; may need to co-administer atropine/glycopyrrolate. *Adults:* 10–20?mg per dose with atropine/ glycopyrrolate.	*Caution:* In patients with asthma, card dysfunction/arrhythmias, peptic ulcer. *Adverse effects:* Bradycardia, AV bloc headache, diarrhea, abdominal cramp urinary frequency, muscle weakness, increased bronchial secretions.
Pyridoxine Nestrex, generic. Tablet: 25, 50, 100?mg; sustained-release: 100?mg. Injection: 100?mg/mL.	**Vitamin B_6 used for dietary or drug-induced (e.g., isoniazid, hydralazine) deficiency and B_6 -dependent seizures.** **Pyridoxine-dependent seizures.** *Children:* 50–100?mg PO, IM, IV; maintenance dose 50–100?mg/24?hr. **Dietary deficiency.** *Children:* 5–15?mg/24?hr for 3–4 wk then 2.5–5?mg/24?hr. *Adults:* 10–20?mg/24?hr for 3–4 wk. **Drug-induced neuritis.** *Children:* 1?mg/kg/24?hr PO, IM, IV, q day. *Adults:* 100–200?mg/24?hr PO, IM, IV, q day.	*Caution:* May decrease serum pheno concentrations. Large IV doses may p *Adverse effects:* Nausea, decreased tests.

Quetiapine Seroquel. Tablet: 25, 100, 200, 300?mg.	**Atypical antipsychotic. Antagonist of serotonin, dopamine, and a_1 - and a_2 -adrenergic receptors.** *Children:* Start 12.5?mg bid, then increase in 25–50?mg increments to 300–400?mg/24?hr divided in 2–3 doses. *Adults:* Start 25?mg bid, then increase in 25–50?mg increments q 2–3 days to esponse, 300–400?mg/24?hr divided in 2–3 doses (max: 800?mg/24?hr).	*Adverse events:* Somnolence, dizzine constipation, dry mouth, dyspepsia, p tachycardia.
Quinidine Quinaglute, Quinidex, generic. Tablet (sulfate): 200, 300?mg; sustained-release: 300?mg. Sustained-release gluconate: 324?mg. Injection, gluconate: 80?mg/mL.	**Myocardial depressant used in the treatment of arrhythmias: supraventricular tachycardia, paroxysmal ventricular tachycardia, premature atrial/ventricular contractions.** *Children:* 2?mg/kg PO, IM, IV test dose to exclude idiosyncrasy: 20–50?mg/kg/24?hr sulfate salt q4h PO; gluconate salt 2–10?mg/kg/dose q3–6h IV. *Adults:* 199–600?mg/dose sulfate salt q4–6h PO; 324–972?mg/dose q8–12h gluconate salt; 200–400?mg/dose sulfate IV; titrate to effect.	*Caution:* First-dose syncope; 267?mg 200?mg quinidine sulfate. Infuse IV s *Adverse effects:* Syncope, hypotensic abdominal discomfort, bone marrow s thrombocytopenia, idiopathic thrombc cinchonism. *Drug interactions:* Verapamil, cimetidi phenobarbital, rifampin, digoxin. *Caution:* Dose may be titrated to desi gastric aspirate.

Ranitidine Zantac, generic. Tablet/capsule: 150, 300?mg. Syrup: 15?mg/mL. Injection: 25?mg/mL. Effervescent granules and tablet: 150?mg.	**H_2 -receptor antagonist competitively inhibits gastric acid secretion in gastric/peptic ulcer disease/stress ulcer prophylaxis, gastroesophageal reflux disease.** *Neonates:* 1.5–2?mg/kg/24?hr PO, IV q12h; continuous 24?hr IV infusion 0.04?mg/kg/hr (max: 1?mg/kg/24?hr). *Children:* 1–5?mg/kg/24?hr PO, IM, IV q6–8h; continuous 24?hr IV infusion 2–5?mg/kg/24?hr. *Adults:* 150?mg/dose PO q12?hr or 300?mg PO qhs; 50–100?mg/dose IM, IV q6–8h.	*Adverse effects:* Headache, mental c injection site. *Comment:* Very few if any clinically im interactions.
Risperidone Risperdal. Tablet: 0.25, 0.5, 1, 2, 3, 4?mg Oral liquid: 1?mg/mL.	**Atypical antipsychotic.** *Children:* Start 0.25?mg bid; increase per response to 3?mg bid. *Adolescents and adults:* Start 1?mg bid; increase to 3?mg bid or response.	*Caution:* May cause QT prolongation sudden cardiac death; monitor ECG a use with other drugs that prolong QT *Adverse events:* Dizziness, drowsines headache, tachycardia, constipation, hypotension, weight gain.
Riboflavin Generic. Tablet: 25, 50, 100?mg.	**Vitamin used in supplementation and deficiency states.** Deficiency: *Children:* 2.5–10?mg/24?hr PO, q8–12h. *Adults:* 5–30?mg/24?hr PO, q8–12h.	*Adverse effects:* Extremely rare. *Drug interaction:* Probenecid.
Rocuronium Zemuron. Injection: 10?mg/mL.	**Anesthetic/skeletal muscle relaxant, nondepolarizing neuromuscular blocking agent.** *Children and adults:* 0.6–1.2?mg/kg/initial dose: subsequent doses administered as needed 0.2?mg/kg q 20–30?min. Continuous IV infusion 10–12?µg/kg/min.	*Cautions:* Ventilation must be suppor neuromuscular blockade. Dose adjus dysfunction. *Adverse effects:* Tachycardia, hypote muscle weakness, bronchospasm. *Drug interactions:* Possible augmente with aminoglycosides, anesthetics, cc

Salmeterol Serevent. Aerosol canister.	**Long-acting ß$_2$ -adrenergic agonist (~8–12+ hr), bronchodilator used in the treatment of reversible airways disease. Excellent in patients with nocturnal asthma.** *Children and adults:* 1 (21?µg)–2 puffs, aerosol q12h; titrate to desired effect.	*Caution:* Not for use in acute asthma *Adverse effects:* Tachycardia, palpita nervousness, muscle tremor, cough,
Sargramostim Leukine, Prokine. Injection: 250, 500?µg	**Granulocyte-macrophage (GM-CSF) colony-stimulating factor for acceleration of myeloid recovery from chemotherapy/marrow insult.**	*Caution:* Monitor blood cell count to d therapy *Adverse effects:* Tachycardia, hypote retention, fever, malaise, bone pain, r dyspnea.
Scopolamine Transderm Scop, generic. Transdermal patch.	**Anticholinergic agent used for control of secretions, postoperative antiemetic and motion sickness.** **Postoperative emesis** *Children:* 6?µg/kg/dose IM, IV, SC q6–8h. *Adults:* 0.3–0.65?mg/dose IM, IV, SC q6–8h. **Motion sickness** *Children and adults:* One patch behind the ear at least 4?hr before movement.	*Caution:* Narrow-angle glaucoma, ileu cautiously in children younger than ag *Adverse effects:* Tachycardia, disorie psychosis, dry mouth, constipation, u blurred vision. *Drug interactions:* Other anticholinerg interfere with gastrointestinal absorpti
Senna Senokot, X-Prep, generic. Syrup: 218?mg/5?mL. Tablet: 187?mg, 217?mg, 600?mg. Granules: 326?mg/teaspoon.	**Stimulant cathartic for short-term treatment of constipation, bowel preparation before radiology.** *Children:* 10–20?mg/kg/dose PO, q12–24h.	*Caution:* Avoid prolonged use (>1 wk *Adverse effects:* Abdominal cramping electrolyte imbalance.
Sertraline Zoloft. Tablets: 25, 50, 100?mg Oral solution (concentrate): 20?mg/mL.	**Antidepressant. Serotonin reuptake inhibitor. Treatment of depression, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, attention deficit disorder.** *Children 6–12 years:* Start 25?mg q24h; increase by 25?mg weekly to response, dose q24h (max: 200?mg/24?hr). *Children >12 years and adults:* Start 50?mg q24h, increase 25–50?mg weekly to response, dose q24h (max: 200?mg/24?hr).	*Caution:* Do not discontinue abruptly symptoms (SSRI discontinuation synd Taper maximum 50?mg/24?hr every *Adverse events:* Insomnia, somnolen mouth, nausea, diarrhea.
Simethicone Mylicon, gas-X, generic. Chewable tablet: 40, 80, 125?mg. Capsule: 125?mg. Drops: 40?mg/0.6?mL.	**Antiflatulent for symptomatic relief of colic, excessive gas.** *Children <2 yr:* 20?mg/dose PO q4–6h. *Children 2–12 yr:* 40?mg/dose q6h. *Children >12 yr and adults:* 40–120?mg PO q6h, dose titrated to effect.	*Comments:* Very safe drug with rare a may be titrated to desired effect by in frequent doses per day. Avoid gas-pr gastrointestinal irritant foods.
Sodium polystyrene sulfonate Kayexalate, generic. Powder for suspension.	**Ion-exchange resin that removes potassium for sodium for the treatment of hyperkalemia.** *Children:* 4?g/kg/24?hr PO, q4–8h; Rectal: 4–12?g/kg/24?hr PR q2–6h. *Adults:* 15?g/dose PO, q6–12h.	*Cautions:* Follow serum potassium cl potassium containing liquids (e.g., ora *Adverse effects:* Abdominal cramping hypokalemia.

Sodium thiosulfate Tinver, generic. Injection: 100?mg/mL, 250?mg/mL.	**Cyanide (nitroprusside) and cisplatin antidote. Provides an extra sulfur to rhodanese enzyme to enhance cyanide detoxification.** **Nitroprusside:** *Children and adults:* 1?g sodium thiosulfate for every 100?mg nitroprusside administered. May infuse in same IV. **Cisplatin:** *Adults:* 12?g IV infused over 6?hr before or concurrent with cisplatin infusion. Alternate: 9?g/m^2 IV bolus followed by 1.2?g/m^2 /hr for 6?hr before or during cisplatin infusion.	*Caution:* Rapid IV infusion may cause *Adverse effects:* Very unusual. Hypot at infusion site.
Sotalol Betapace. Tablet: 80, 120, 160?mg.	**Class III antiarrhythmic. Treat supraventricular and ventricular arrhythmias.** *Children:* 2–8?mg/kg/24?hr divided q8–12h. *Adults:* Start 80?mg q12hr and titrate q 3–4 days to response (max: 640?mg/24?hr).	*Cautions:* Proarrhythmic effects, wors failure or diabetes. Reduce dose for c (½ dose for CrCl < 60?mL/min, ? dos 30?mL/min. Extend interval to decrea
Spironolactone Aldactone, generic. Tablet: 25, 50, 100?mg.	**Competitive aldosterone antagonist used as a mild, potassium-sparing diuretic, antihypertensive, in chronic liver disease.** *Neonates:* 1–3?mg/kg/24?hr PO divided q12–24h. *Children:* 1.5–3.3?mg/kg/24?hr PO divided q8–24h. *Adults:* 25–200?mg per dose PO q12–24h.	*Caution:* Careful monitoring of serum intake. Suspension may be made witl water/glycerin. *Adverse effects:* Lethargy, hyperkaler nausea, rash.

Streptokinase Streptase. Injection.	**Thrombolytic agent used in the treatment of deep-vein thrombosis, stroke, catheter patency.** Thrombosis: 3,500–4,000 units infused IV over 30?min followed by 1,000–1,500 units IV continuous infusion. Clotted catheter: 10,000–25,000 units in normal saline the volume of the catheter instilled into catheter for ~1?hr then removed (aspirated).	*Caution:* Recent strep infection may r *Adverse effects:* Bleeding bronchospa *Drug interactions:* Anticoagulants, ant
Succimer Chemet. Capsule: 100?mg.	**Metal chelator that forms water-soluble salts with lead, mercury, and arsenic.** *Children/adults:* 10?mg/kg/dose PO q8h for 5 days then 10?mg/kg/dose PO q12h for 14 days.	*Caution:* Maintain adequate hydratior opened and beads sprinkled onto sof *Adverse effects:* Headache, dizziness cramping, flu-like symptoms.
Succinylcholine Anectine. Injection.	**Neuromuscular blocking agent.** *Children:* 1–2?mg IV initial dose; maintenance 0.3–0.6?mg/kg IV q 5–10?min dose titrated to level of skeletal muscle relaxation. *Adults:* 0.6?mg/kg up to 150?mg IV initial dose; maintenance dose: 0.04–0.07?mg/kg IV q 5–10?min titrated to effect.	*Caution:* In patients with hyperkalemi increased intraocular or intracranial p *Adverse effects:* Bradycardia, hypoter hyperthermia, hyperkalemia, broncho *Drug interactions:* Muscle depressant
Sucralfate Carafate. Tablet: 1?g. Suspension: 1?g/10?mL.	**Aluminum salt of sulfated sucrose in the presence of acid forms a paste-like substance that adheres to damaged mucosa.** *Children:* 40–80?mg/kg/24?hr PO divided q6–8h. Stomatitis 5–10?mL swish/spit or swallow q6h. *Adults:* 1?g per dose PO q4–6h.	*Caution:* May use topically for stomat *Adverse effects:* Headache, constipat cramping, rash. *Drug interactions:* Decreases absorpt tetracycline, ketoconazole, theophyllir

Sufentanil Sufenta. Injection.	**Opioid analgesic used in anesthesia and for pain management.** *Children:* 10–25?µg/kg IV initial dose titrated to desired effect with 25–50?µg/kg. *Adults:* 0.5–8?µg/kg initial dose with maintenance 10–50?µg/kg	*Caution:* In patients with head trauma monoamine oxidase inhibitors advers opiates are potentiated. *Adverse effects:* Bradycardia, vasodil vomiting, blurred vision, respiratory d potential. *Drug interactions:* CNS/respiratory de
Sulfasalazine Azulfidine, generic. Tablet: 500?mg.	**Anti-inflammatory 5-aminosalicylic acid derivative combined with sulfonamide used in the treatment of inflammatory bowel disease.** *Children:* Initial 40–75?mg/kg/24?hr PO divided q4–6h not to exceed 6?g/24?hr; maintenance 30–50?mg/kg/24?hr PO divided q6–8h. *Adults:* 1?g per dose PO q6–8h (max dose: 6?g/24?hr).	*Caution:* Hypersensitivity to sulfa drug *Adverse effects:* Rash, dizziness, hea marrow suppression. *Drug interactions:* Decreases folate a
Tacrolimus Prograf. Injection. Capsule: 1?mg, 5?mg. Extemporaneous preparation.	**Prevent graft versus host disease in organ transplant (immunosuppressant).** *Children:* PO: 0.15?mg/kg every 12?hr; IV continuous infusion: 0.05–0.1?mg/kg/24?hr. *Adults:* PO: 0.075–0.15?mg/kg q12h; IV continuous infusion: 0.05–0.1?mg/kg/24?hr.	*Adverse events:* Hypertension, heada abdominal and back pain, fever, asth hypo/hyperkalemia, hypomagnesemi nausea, vomiting, diarrhea, anemia, l damage, nephrotoxicity, dyspnea, ple peripheral edema. *Monitoring:* Tacrolimus trough concer 9.8–19.4?ng/mL using whole-blood E 0.5–1.5?ng/mL using serum high-pre chromatography.
Teniposide, VM-26 Vumon. Injection: 10?mg/mL.	**Treatment of acute lymphocytic leukemia (ALL) and lung cancer (inhibits cells from entering mitosis).** *Children:* IV: Start 130?mg/m^2 /wk, increase at 3 wk to 150?mg/m^2 , and at 6 wk to 180?mg/m^2 . *Adults:* ALL 250?mg/m^2 wk for 4–8 wk.	*Caution:* Increases intracellular accur methotrexate and thus toxicity. *Adverse events:* Nausea, vomiting, di myelosuppression, alopecia, rash, fev peripheral neuropathy. *Comment:* Down syndrome patients s half the usual dose.
Terbutaline sulfate Brethine, generic. Injection. Tablet: 2.5, 5?mg. Metered-dose inhaler (MDI).	**Bronchodilator (ß$_2$ -receptor agonist).** *Children <12 yr:* PO: 0.05?mg/kg/dose (max: 5?mg) q8h. SC: 0.005–0.01?mg/kg/dose (max: 0.4?mg); may repeat in 15–20?min. *Children =12 yr and adults:* PO: 2.5–5?mg/dose q6–8h. SC: 0.25?mg/dose; may repeat in 15?min. *Children and adults:* MDI 1–2 puffs q6–8h as needed.	*Adverse events:* Tachycardia, arrhyth headache, nervousness, tremor, hypo cramps, paradoxical bronchospasm.
Terfenadine Seldane. Tablet: 60?mg.	**Treatment of allergic symptoms (antihistamine).** *Children:* *3–6 yr:* 15?mg bid. *6–12 yr:* 30?mg bid. *>12 yr and adults:* 60?mg twice/24?hr.	*Caution:* QT interval prolongation anc may occur if combined with drugs tha *Adverse events:* Drowsiness, fatigue. *Drug interactions:* Azole antifungals, r may prolong QT interval and produce
Testosterone Generic. Injection.	**Androgen replacement in male hypogonadism and delayed puberty (replacement therapy).** *Children:* IM **Male hypogonadism:** Initiation of prepubertal growth and delayed puberty: 40–50?mg/m^2 /dose monthly; terminal growth phase: 100?mg/m^2 /dose twice monthly. *Adults:* Hypogonadism: IM 50–400?mg q 2–4 wk.	*Caution:* May accelerate bone matura compensating gain in linear growth. *Adverse events:* Acne, bladder irritab behavior, depression, sleeplessness, hepatic dysfunction.

Tetanus antitoxin Injection.	Prevention or treatment of tetanus when tetanus immune globulin unavailable. *Children and adults:* SC, IM. Prophylaxis: <30?kg 1,500 units; >30?kg 3,000–5,000 units. Treatment: Inject 10,000–40,000 units into wound and 40,000–100,000 units IV.	*Adverse events:* Serum sickness, urti allergic reactions.
Tetanus immune globulin Hyper-Tet. Injection.	**Prophylaxis and treatment of tetanus.** Prophylaxis: *Children:* 4 units/kg. *Adults:* 250 units IM. Treatment: *Children:* 500–3,000 units. *Adults:* 3,000–6,000 units (infiltrate some of dose around wound).	*Adverse events:* Allergic reactions.
Theophylline Generic. Syrup, solution, elixir, capsule, tablet (sustained-release forms also). (See under *Aminophylline* for intravenous dosing.)	**Treatment of apnea of prematurity, symptoms of reversible airway disease (affects intracellular transport of calcium, phosphodiesterase inhibitor, weak anti-inflammatory agent).** *Neonates:* Apnea, bronchodilation: loading dose 6–10?mg/kg; maintenance dose: 2–4?mg/kg/dose q12h. *Infants and children:* *6 wk–6 mo:* 10?mg/kg/24?hr. *6 mo–1 yr:* 12–18?mg/kg/24?hr. *1–9 yr:* 20–24?mg/kg/24?hr. *9–12 yr:* 16?mg/kg/24?hr. *12–16 yr:* 13?mg/kg/24?hr. *Adults:* 10?mg/kg/24?hr. (Dosing may be increased for smokers and enzyme-inducing drugs; decrease dose if enzyme inhibitors, liver disease, heart failure, or hypothyroid.)	*Cautions:* May cause or worsen arrhy gastroesophageal reflux. Theophyllin modified by numerous disease states dosing adjustments guided by serum concentrations. Clearance is reduced fever >102℉ for >24?hr, cor pulmona inhibit P450 enzymes (cimetidine, ver quinolones); reduce dose by 50%. *Adverse events:* Tachycardia, nervou difficulty concentrating, irritability, agi nausea, vomiting, abdominal pain, fe frequent urination, seizures and arrhy *Monitoring:* Theophylline concentratio neonatal apnea: 6–15?µg/mL; prever promote extubation: 10–20?µg/mL; b 5–20?µg/mL; toxic >20?µg/mL.
Thiamine Generic. Injection. Tablet: 50, 100, 250, 500?mg.	**Nutritional supplement, treatment of beriberi and Wernicke encephalopathy (essential coenzyme in carbohydrate metabolism).** Beriberi: *Children:* IM, IV: 10–25?mg/24?hr; or PO: 10–50?mg/24?hr for 2 wk, then 5–10?mg/24?hr for 1 mo. *Adults:* IM, IV: 5–30?mg tid for 2 wk, then oral 5–30?mg/24?hr for 1 mo. Wernicke: IM, IV: 100?mg/24?hr until consuming a balanced diet.	*Adverse events:* Cardiovascular colla doses, angioedema, rash, tingling.
Thioguanine 6-TG. Tablet: 40?mg.	**Treatment of leukemias (purine analog inhibits synthesis and utilization of purine nucleotides).** *Children <3 yr:* Acute nonlymphocytic leukemia: PO: 3.3?mg/kg/24?hr in 2 doses for 4 days. *Children >3 yr and adults:* PO: 2–3?mg/kg once daily (rounded to nearest 20?mg) until remission.	*Adverse events:* Myelosuppression (c nadir, 14 days; recovery, 21 days), na diarrhea, anorexia, stomatitis, hyperu

Thiopental Pentothal Sodium. Injection.	**Anesthesia induction and maintenance, intractable seizures, increased intracranial pressure (ultra-short-acting barbiturate).** *Neonates:* Anesthesia: 3–4?mg/kg; seizures: 2–3?mg/kg IV; repeat doses 1?mg/kg as needed. *Infants and children:* IV anesthesia: 5–8?mg/kg; seizures: 2–3?mg/kg; increased intracranial pressure: 1.5–5?mg/kg; repeated as needed. *Adults:* IV: 25–250?mg as needed for effect. Sedation: Rectal. *Children:* 5–10?mg/kg/dose. *Adults:* 3–4?g/dose.	*Adverse events:* Cramping, diarrhea, hypotension, myocardial depression, somnolence and recovery, emergenc depression, coughing, bronchospasm hiccups, sneezing. *Monitoring:* Thiopental concentrations hypnosis: 1–5?µg/mL; anesthesia: 7– 30–100?µg/mL.
Thioridazine Mellaril, generic. Oral concentrate: 30, 100?mg/mL. Oral suspension: 25?mg/5?mL, 100?mg/5?mL. Tablet: 10, 15, 25, 50, 100, 150, 200?mg.	**Treatment of psychosis, neurosis, and severe behavior problems in children (phenothiazine, block dopamine receptors in the brain).** *Children >2 yr:* 0.5–3?mg/kg/24?hr in 2–3 doses. *Children >12 yr and adults:* 25–800?mg/24?hr in 2–4 doses.	*Adverse events:* Pseudoparkinsonism akathisia, dystonias, dizziness, neuro syndrome, impaired temperature regu hypotension, pigmentary retinopathy, leukopenia, agranulocytosis, urinary r dry mouth, gastrointestinal upset, hyp photosensitivity.
Thiotepa Thioplex. Injection.	**Cancer chemotherapy (alkylating agent, inhibit DNA, RNA, and protein synthesis).** *Children:* IV (depends on protocol): regular dose: 25–65?mg/m^2 q 3–4 wk; high dose: 300?mg/m^2 /24?hr for 3 doses. *Adults:* IV continuous infusion 15–35?mg/m^2 over 48?hr.	*Adverse events:* Myelosuppression (c nadir, 14 days; recovery, 28 days), di headache, anorexia, nausea, vomitin pruritus, hyperuricemia, hematuria, h stomatitis.
Thiothixene Navane, generic. Injection. Capsule: 1, 2, 5, 10, 20?mg. Oral concentrate: 5?mg/mL.	**Management of psychosis (phenothiazine, block CNS dopamine receptors).** *Children <12 yr:* 0.25?mg/kg/24?hr in divided doses. *Children >12 yr and adults:* PO: 6–60?mg/24?hr in 3 doses; IM: 4?mg 2–4 times/24?hr (max: 30?mg/24?hr).	*Adverse events:* Orthostatic hypotens pseudoparkinsonism, tardive dyskine dystonias, constipation, urinary retent stomach pain, nasal congestion, pigm agranulocytosis, leukopenia, neurolep syndrome, impaired temperature regu cholestatic jaundice.
Thrombin, topical Thrombinar, Thrombogen, Thrombostat. Powder.	**Hemostasis for minor bleeding from capillaries and venules (catalyze the conversion of fibrinogen to fibrin).** *Children and adults:* Apply topically as solution 1,000–2,000 units/mL directly to site.	*Adverse events:* Allergy.
Tiagabine Gabitril Tablet: 2, 4, 12, 16, 20?mg.	**Treatment of partial seizures. Used as adjunctive, add-on therapy. ?-Aminobutyric acid reuptake inhibitor.** *Infants and children:* 1.5?mg/kg/24?hr in 2–4 divided doses. *Adolescents and adults:* Start at 4?mg once daily; increase by 4–8?mg q wk until response (max: 56?mg/24?hr).	*Cautions:* CNS problems including di ataxia, tremor, and muscle weakness nonconvulsive status epilepticus.
Timolol Timoptic. Ophthalmic solution, ophthalmic gel, tablet.	**Treat elevated intraocular pressure (block ß$_1$ - and ß$_2$ -receptors, and decrease aqueous humor production).** *Children:* (Only ophthalmic use) instill 0.25% solution 1 drop twice daily, may increase to 0.5% solution if response inadequate, may decrease to once daily if controlled. *Adults:* Same ophthalmic dose as children.	*Adverse events:* Bronchospasm, brac visual disturbance, conjunctivitis, kera

Tissue plasminogen activator, TPA Alteplase, Retavase. Injection.	**Thrombolytic therapy (enhance conversion of plasminogen to plasmin).** *Neonates:* 0.1–0.5?mg/kg/hr for 3–10?hr. *Children:* 0.1–0.6?mg/kg/hr for 6?hr. *Adults:* 100?mg infused as 60?mg in first?hr, 20?mg in 2nd?hr, 20?mg in 3rd?hr.	*Caution:* Initiate heparin concurrently and thrombotic emboli. *Adverse events:* Bleeding, arrhythmia myocardial infarction reperfusion). *Monitoring:* D-Dimer, fibrinogen, bleed
Tolazoline Priscoline. Injection: 25?mg/mL.	**Treatment of persistent pulmonary hypertension (a-adrenergic blocker and histamine release).** *Neonates:* IV: 1–2?mg/kg load, then 1–2?mg/kg/hr continuous infusion.	*Adverse events:* Hypotension, flushin increases secretions from respiratory tract, gastrointestinal bleeding and pe pulmonary hemorrhage, thrombocyto *Monitoring:* Preductal and postductal arterial blood gases.
Tolmetin sodium Tolectin, generic. Tablet: 200, 600?mg. Capsule: 400?mg.	**Treatment of rheumatoid arthritis including JRA (NSAID, prostaglandin inhibition).** *Children >2 yr:* 15–30?mg/kg/24?hr in 3–4 doses. Analgesia: 5–7?mg/kg/dose. *Adults:* 400–600?mg 3 times/24?hr (max dose: 2?g/24?hr).	*Adverse events:* Gastrointestinal ups disease, hypertension, edema, dizzin renal failure, tinnitus.

Topiramate Topamax. Capsule: 15, 25?mg Tablet: 25, 100, 200?mg.	**Treatment of seizure disorders. Broad spectrum of seizure types covered and multiple mechanisms proposed.** *Children 2–16 years:* Start 1–3?mg/kg/24?hr PO qhs for 1 wk; titrate dose increases every 1–2 wk by 1–3?mg/kg/24?hr dosed bid; typical dose 5–10?mg/kg/24?hr divided q12h. Capsules may be sprinkled on food to administer. *Adults:* Start 25–50?mg PO q24h; increase by 25–50?mg/24?hr q wk (max dose: 1,600?mg/24?hr). Reduce dose by 50% if CrCl <60?mL/min.	*Cautions:* If used with other carbonic additive effects may predispose to re
Tranexamic acid Cyklokapron. Injection: 100?mg/mL. Tablet: 500?mg.	**Use in hemophilia patients during and after tooth extractions to reduce or prevent hemorrhage (competitively inhibits activation of plasminogen).** *Children and adults:* IV: 10?mg/kg immediately before surgery then oral 25?mg/kg/dose 3–4 times/24?hr for 2–8 days.	*Adverse events:* Hypotension, thromb complications (including CNS), throm vomiting, diarrhea. *Comment:* Decrease dose in renal im 50–80?mL/min give 50% of dose; Cr 25% of dose; CrCl <10?mL/min give
Trazodone Desyrel, generic. Tablet: 50, 100, 150, 300?mg.	**Antidepressant (inhibit serotonin reuptake, a-adrenergic blockade).** *Children 6–18 yr:* Start 1.5–2?mg/kg/24?hr in 3 doses; may increase q 3–4 days (max: 6?mg/kg/24?hr). *Adolescents:* Start 25–50?mg/24?hr; may increase gradually (max: 150?mg) in 2–3 doses. *Adults:* Start 50?mg tid; may increase by 50?mg q 3 days to effect (max: 600?mg/24?hr).	*Adverse events:* Headache, confusio mouth, nausea, bad taste in mouth, c vision, muscle tremors, hypotension, *Drug interactions:* Fluoxetine may inc *Monitoring:* Trazodone concentration with clinical effectiveness): therapeut toxic >4?µg/mL.

Tretinoin Retin-A. Cream: 0.025%, 0.05%, 0.1%. Topical gel: 0.01%, 0.025%. Topical liquid: 0.05%.	**Treatment of acne vulgaris, photo-damaged skin, and some skin cancers (inhibits microcomedone formation and eliminates lesions).** *Children >12 yr:* Apply weaker formulation once daily at bedtime. Increase as needed.	*Adverse events:* Excessive skin dryne and local stinging and burning; photo: block), initial acne flare-up.
Triamcinolone Generic. Injection (Amcort). Oral (Aristocort). Topical (Aristocort). Metered-dose inhaler (MDI) (Azmacort). Nasal spray (Nasacort).	**Treatment of inflammatory and allergic conditions (corticosteroid).** *Children 6–12 yr:* IM: 0.03–0.2?mg/kg q 1–7 days. MDI: 2 puffs 2–4 times/24?hr). Intranasal: 1 spray in each nostril 1–2 times/24?hr. Injection: Intra-articular, intrabursal, or tendon sheath 2.5–15?mg (repeat as needed). *Children >12 yr and adults:* MDI: 2–4 puffs 2–4 times/24?hr; intranasal: 2 sprays in each nostril once daily (max: 4 sprays/24?hr). Intra-articular, intrasynovial; 2.5–40?mg; PO: 40–100?mg/24?hr in 1–4 doses. Topical: Apply thin film bid–tid.	*Adverse events:* Atrophy of tissue at l fatigue, cataracts, osteoporosis, oral poor growth. *Comment:* See comparison of cortico *Hydrocortisone.*
Triamterene Dyrenium. Capsule: 50, 100?mg (combination drugs, e.g., with hydrochlorothiazide).	**Diuretic to treat edema or hypertension (competes with aldosterone for receptor sites in distal renal tubules).** *Children:* PO: 2–4?mg/kg/24?hr in 1–2 doses (max: 6?mg/kg/24?hr). *Adults:* 100–300?mg/24?hr in 1–2 doses.	*Caution:* Do not use in patients with r concurrent potassium supplements tc *Adverse events:* Constipation, nause hyperkalemia, hyponatremia, hyperch acidosis.

Trientine Syprine. Capsule: 250?mg.	**Treatment of Wilson disease in patients intolerant to penicillamine (chelating agent).** *Children <12 yr:* 500–1,500?mg/24?hr in 2–4 doses. *Children >2 yr and adults:* 750–2,000?mg/24?hr in 2–4 doses.	*Comment:* Take 1?hr before or 2?hr a break capsule in any way and take wi If capsule breaks, wash area of skin v thoroughly with water. *Adverse events:* Iron-deficiency anem pain, thickening and fissuring of skin, systemic lupus erythematosus.
Trifluoperazine Stelazine. Oral concentrate: 10?mg/mL. Tablet: 1, 2, 5, 10?mg. Injection.	**Treatment of psychosis (phenothiazine, block dopamine in the CNS).** *Children 6–12 yr:* PO: 1?mg 1–2 times/24?hr, gradually increase to effect (max: 15?mg/24?hr); IM: 1?mg twice daily. *>12 yr and adults:* PO: 1–2?mg bid; IM: 1–2?mg q4–6h as needed (max: 10?mg/24?hr).	*Adverse events:* Hypotension, tachyc pseudoparkinsonism, tardive dyskine dystonias, constipation, nasal conges malignant hypertension.
Trimethaphan camsylate Arfonad. Injection.	**Treatment of hypertensive emergencies (adrenergic and cholinergic blocker).** *Children:* 50–150?µ?g/kg/min *Adults:* 0.5–2?mg/min.	*Adverse events:* Anorexia, nausea, dı retention, cycloplegia, itching, urticari hypotension.
Trimethobenzamide Tigan, generic. Capsule: 100, 250?mg. Rectal suppository: 100, 200?mg. Injection: 100?mg/mL.	**Control of nausea and vomiting (inhibits CNS stimulation of chemoreceptor trigger zone).** *Children:* PO, rectal: 15–20?mg/kg/24?hr in 3–4 doses. *Adults:* PO: 250?mg tid–qid. IM, rectal: 200?mg tid–qid.	*Adverse events:* Drowsiness, dizzines diarrhea, muscle cramps.

Tromethamine THAM. Injection: 0.3?M (1?mEq THAM = 3.3?mL).	**Correction of metabolic acidosis (combines with hydrogen ions to form bicarbonate and buffer).** *Neonates, infants, children, and adults:* *Dose (mL of 0.3?M solution)* = Weight (kg) × base deficit; or 1–2?mEq/kg/dose.	*Adverse events:* Apnea, hypoglycemi tissue irritation, or necrosis if direct co
Tropicamide Mydriacyl. Ophthalmic solution 0.5%, 1%.	**Short-acting mydriatic agent (blocks sphincter muscle of iris and ciliary body from responding to cholinergic stimulation).** *Children and adults:* Cycloplegia: Instill 1–2 drops of 1% solution; may repeat in 5?min. Mydriasis: Instill 1–2 drops of 0.5% solution 15–20?min before examination.	*Adverse events:* Tachycardia, drowsi mouth, blurred vision, photophobia.
Tubocurarine Injection.	**Neuromuscular blocker used in anesthesia (block acetylcholine receptors).** *Neonates:* Start 0.3?mg/kg; maintenance: 0.1?mg/kg/dose. *Children:* Start 0.2–0.5?mg/kg, then 0.04–0.1?mg/kg/dose maintenance. *Adults:* Start 6–9?mg, then 3–4.5?mg maintenance.	*Adverse events:* Hypotension, prolon depression.
Urokinase Abbokinase. Injection.	**Thrombolytic agent for treatment of recent onset thrombosis (activates plasminogen conversion to plasmin).** *Neonates, infants, children, and adults:* IV load 4,400 units/kg, maintenance dose 4,000– 10,000 units/kg/hr. Occluded IV catheter: fill entire volume of catheter with urokinase 5,000 units/mL and leave in lumen for 1–4?hr.	*Adverse events:* Bleeding, hematoma bronchospasm. *Monitoring:* D-Dimer, fibrin degradatio coagulation time.

Ursodiol, ursodeoxycholic acid Actigall. Capsule: 300?mg. Extemporaneous formulations.	**Gallbladder stone dissolution, reversal of TPN- induced cholestasis in neonates (decrease cholesterol content of bile).** *Neonates:* 10–18?mg/kg/24?hr PO divided into 1–3 doses per day. *Infants:* 30?mg/kg/24?hr 0.8–12h. *Adults:* 300?mg at bedtime for 6–12 mo.	*Adverse events:* Diarrhea, dyspepsia, pruritus, headache.
Valproic acid and derivatives Depakene, generic, Depakote. Depakote delayed-release tablet, capsule sprinkle: 125, 250, 500?mg. Depakene capsule: 250?mg. Syrup: 250?mg/5?mL. Injection.	**Treatment of simple and complex generalized and partial seizures (block sodium and slow T channels).** *Neonates:* Refractory seizures: load 20?mg/kg orally, then 10?mg/kg/dose q12h. *Children and adults:* Seizures: 10–15?mg/kg/24?hr in 2–3 doses; then increase weekly by 5–10?mg/kg/24?hr to effect; may need up to 100?mg/kg/day in 3–4 divided doses, especially if used with concurrent enzyme inducers (e.g., phenytoin, carbamazepine).	*Caution:* Hepatic failure with fatalities especially if patient is younger than a other anticonvulsants. If used in neon ammonia. *Adverse events:* Drowsiness, irritabili headache, tremor, sensorineural hea hyperammonemia, hepatotoxicity, na diarrhea, pancreatitis, thrombocytope appetite, weight gain. *Monitoring:* Valproate concentrations: 50–100?µ?g/ml toxic >150?µ?g/ml

Vasopressin Pitressin. Injection: 20 pressor units/mL.	**Treatment of diabetes insipidus; prevention and treatment of postoperative abdominal distention; treatment of acute gastrointestinal hemorrhage (antidiuretic hormone analog).** *Children:* Diabetes insipidus: IM, SC: 2.5–10 units/dose 2–4 times/24?hr. Gastrointestinal hemorrhage: IV continuous infusion 0.002–0.01 units/kg/min. *Adults:* Diabetes insipidus: IM, SC: 5–10 units/dose 2–4 times/24?hr. Gastrointestinal hemorrhage: IV continuous infusion 0.2–0.4 units/min.	*Adverse events:* Increased blood pres arrhythmias, fever, flatulence, abdom vomiting, tremor, sweating, circumora intoxication.
Vecuronium Norcuron. Injection.	**Adjunct to anesthesia, neuromuscular blocker (blocks acetylcholine from binding to motor end-plates).** *Neonates:* 0.03–0.15?mg/kg/dose q1–2h as needed. *Infants >7 wk–12 mo:* 0.05–0.1?mg/kg qh as needed. *Children 1 yr–adults:* 0.05–0.1?mg/kg qh as needed.	*Adverse events:* Tachycardia, hypote bradycardia, circulatory collapse, hyp

Venlafaxine Effexor. Tablet: 25, 37.5, 50, 75, 100?mg.	**Treatment of depression, obsessive-compulsive disorder, attention deficit disorder (serotonin and norepinephrine reuptake inhibitor).** *Children:* 25–200?mg/24?hr; start low and titrate up every 4–7 days. *Adults:* Start 75?mg/24?hr; titrate q 4–7 days to effect or maximum of 375?mg/24?hr.	*Caution:* Taper slowly (max: 25?mg/2 stopping drug to avoid withdrawal syr *Adverse events:* Headache, somnoler insomnia, nervousness, nausea, dry r blurred vision.
Verapamil Calan, Isoptin, generic. Sustained-release capsule: 120, 180, 240, 360?mg. Sustained-release tablet: 120, 180, 240?mg. Tablet: 40, 80, 120?mg. Injection.	**Calcium-channel antagonist used in the treatment of hypertension and supraventricular dysrhythmias.** Doses in infants and young children not well established: *Infants:* 0.1–0.2?mg/kg and children 0.1–0.3?mg/kg per dose IV repeated to desired effect. *Children:* 4–8?mg/kg/24?hr PO q6–8h; usual dose 5?mg/kg/24?hr. *Adults:* 240–480?mg/24?hr PO divided q6–8?hr; q12h with extended-release products. May sprinkle contents of capsule onto soft food without affecting absorption.	*Caution:* Adjust dose in renal disease neonates/young infants, or those with *Adverse effects:* Hypotension, bradyc dizziness, seizure, abdominal discom newborns due to several reports of fa block. *Drug interactions:* May increase conc digoxin, carbamazepine, cyclosporine concentrations with rifampin, phenoba
Vigabatrin Sabril (not available in USA, available in Canada, Mexico, Europe, and other countries). Tablet: 500?mg. Dry powder sachet.	**Effective against infantile spasms, partial seizures, and other seizure types. Mechanism is ?-aminobutyric acid transaminase inhibitor.** *Children:* 40–150?mg/kg/24?hr in 1–2 doses.	*Caution:* May cause bilateral visual fi baseline eye examination and then e depression, psychiatric reactions, beh gastrointestinal intolerance may occu

Vinblastine sulfate Alkaban-AQ; Velban; generic. Injection.	**Treatment of several cancers (bind to mitotic spindle to inhibit metaphase).** *Children:* IV Hodgkin disease: 2.5–6?mg/m^2 /24?hr q 1–2 wk for 3–6 wk (max: 12.5?mg/m^2 /wk). *Adults:* 3.7–18.5?mg/m^2 /24?hr q 7–10 days.	*Adverse events:* Alopecia, nausea, vo cramps, constipation, diarrhea, stoma myelosuppression (onset, 4–7 days; r recovery, 17 days), tachycardia, ortho dermatitis, photosensitivity, muscle pa urinary retention, hyperuricemia, peri (loss of deep tendon reflexes, headac
Vincristine Oncovin, generic. Injection.	**Treatment of various cancers (bind to mitotic spindle to inhibit metaphase).** *Children: <10?kg or BSA <1?m^2 :* 0.05?mg/kg once/wk. *>10?kg or BSA >1?m^2 :* 1–2?mg/m^2 once/wk. *Adults:* 0.4–1.4?mg/m^2 once/wk.	*Adverse events:* Constipation, paraly confusion, insomnia, headache, jaw p blindness, loss of deep tendon reflexe tingling, pain, stocking-and-glove par wristdrop, syndrome of inappropriate antidiuretic hormone, photophobia, hy stomatitis, phlebitis, myelosuppressio nadir, 10 days; recovery, 21 days).
Vitamin A Aquasol A, generic. Injection. Oral drops. Capsule.	**Treatment or prevention of deficiency; supplementation in patients with measles (co-factor for many biochemical processes) and improve growth in children with HIV or malaria. Prevention of bronchopulmonary dysplasia in neonates.** *Neonates:* 4,000?IU IM 3 times/wk, or 2,000?IU IM every other day. *Children:* Vitamin A deficiency with xerophthalmia: *1–8 yr:* PO: 5,000 units/24?hr for 5 days; IM: 5000– 15,000 units/24?hr for 10 days. *>8 yr and adults:* PO: 500,000 units/24?hr for 3 days, then 50,000 units/24?hr for 14 days, then 20,000 units/24?hr for 2 months. Vitamin A deficiency without corneal changes: *Children <1 yr:* IM: 100,000 units q 4–6 mo. *>1 yr:* IM: 200,000 units q 4–6 mo. *>8 yr and adults:* IM: 100,000 units/24?hr for 3 days, then 50,000 units/24?hr for 14 days. Prophylaxis of patients at risk and supplementation in measles: PO dose q 4–6 mo. *Children <1 yr:* 100,000 units. *>1 yr:* 200,000 units. Improve growth in children with HIV or malaria or diarrheal disease: *Infants <1 yr:* 100,000 units q24h for 2 doses, then 100,000 units (one dose) at 4 and 8 mo. *Children > 1 yr:* 200,000 units q24h for 2 doses, then 200,000 units (one dose) at 4 and 8 mo.	*Adverse events:* Irritability, vertigo, le headache, hypercalcemia.
Vitamin E Generic. Capsule, oral drops, tablet, cream, ointment.	**Nutritional supplement (antioxidant).** *Neonates, premature infants:* 25–50 units/24?hr. *Children:* 1 unit/kg/24?hr; sickle cell anemia: 450 units/24?hr; cystic fibrosis: 100–400 units/24?hr; ß-thalassemia:750 units/24?hr. *Adults:* 60–75 units/24?hr.	*Adverse events:* Rare.

Warfarin Coumadin, generic. Tablet: 1, 2, 2.5, 4, 5, 7.5, 10?mg.	**Anticoagulant that antagonizes hepatic vitamin K synthesis depleting vitamin K–dependent clotting factors II, VII, IX, and X.** *Children:* Initial dose 0.2?mg/kg once PO then usual dose approximates 0.1?mg/kg/24?hr PO. Dose titrated to desired prothrombin time and INR targets. Avoid large loading doses because complete anticoagulant effect depends on elimination half-lives of the target clotting factors. Full effects may not be observed until 2–3 days after a warfarin dose adjustment negating rapid dose changes. *Caution:* Younger infants require higher doses (typical mean dose 0.3?mg/kg/24?hr). Avoid foods with high vitamin K content (green leafy vegetables).	*Adverse effects:* Bleeding, skin necro *Drug interactions:* Aspirin, barbiturate cimetidine, omeprazole, phenytoin, ri ritonavir, delavirdine.
Xylometazoline Otrivin. Nasal solution: 0.05%, 0.1%.	**Symptomatic relief of nasal congestion (stimulates a-adrenergic receptors to produce vasoconstriction).** *Children 2–12 yr:* Instill 2–3 drops 0.05% solution in each nostril q8–10h. *Children >12 yr and adults:* Instill 2–3 drops 0.1% solution in each nostril every 8–10?hr.	*Caution:* Do not use for more than 4 exceed recommended dosage becau rebound congestion and chemical pn dependence. *Adverse events:* Palpitations, headac drowsiness, sweating, blurred vision.

Zafirlukast Accolate. Tablet: 20?mg.	**Leukotriene D_4 and E_4 antagonist inhibiting the effect of slow-reactive substance(s) of anaphylaxis (SRS-A) on bronchial smooth muscle. Not effective in reversing acute bronchoconstriction, although therapy can be continued in acute attacks.** *Children 7–11 yr:* 20?mg/24?hr PO divided q12h. *Adolescents and adults:* 40?mg/24?hr PO divided q12h. Administer doses 1?hr before or 2?hr after meals.	*Caution:* Based on mechanism of act effective for prophylaxis and does not bronchoconstriction. *Adverse effects:* Headache, nausea, liver function tests. *Drug interactions:* Blocks CYP 2C9 a isozymes; macrolides, theophylline, c terfenadine, astemizole.
Zileuton Zyflo. Tablet: 600?mg.	**5-Lipoxygenase inhibitor inhibiting the formation of leukotrienes LTB1, LTC1, LTD1, and LTE1. Not effective in reversing acute bronchoconstriction, although therapy can be continued in acute attacks.** *Adolescents and adults:* 2,400?mg/24?hr PO divided q6h.	*Caution:* Based on mechanism of act effective for prophylaxis and does not bronchoconstriction. *Adverse effects:* Chest pain, headach elevated liver function tests. *Drug interactions:* Macrolides, theoph warfarin, terfenadine, astemizole.
Zinc supplements Generic. Injection, liquid, tablets.	**Prevention and treatment of zinc deficiency (replacement therapy).** Zinc deficiency: Oral: *Infants and children:* 0.5–1?mg/kg/24?hr in 1–3 doses. *Adults:* 25–50?mg/dose tid. TPN supplement: *Preterm infants:* 400?µg/kg/24hr. *Infants <3 mo:* 250?µg/kg/24?hr. *Infants >3 mo:* 100??µg/kg/24?hr. *Children:* 50?µg/kg/24?hr.	*Adverse events:* Rare, but if excessiv cause copper deficiency.

Ziprasidone Geodon Capsule: 20, 40, 60, 80?mg.	**Atypical antipsychotic.** *Children:* Start 5?mg/24?hr; increase q48h to response. Dose bid. *Adults:* Start 20?mg bid; increase q48h to response (max: 80?mg bid).	*Caution:* May prolong QTc intervals a arrhythmia (especially torsades de pc concurrent use of drugs that may alsc *Adverse events:* Agitation, anxiety, di headache, insomnia, tachycardia, coı orthostatic hypotension, weight gain. *Drug interactions:* CYP3A4 inhibitors clearance and predispose to toxicity. increase clearance and may increase
Zonisamide Zonegran. Capsules (gelatin): 100?mg.	**Treat seizure disorders. Mechanism uncertain.** *Children*: Start 2–4?mg/kg/24?hr; then increase by 2–5?mg/kg/24?hr q2–4days to response, usually 4–20?mg/kg/24?hr. *Adults*: Start with 100?mg/24?hr; may increase by 100?mg/24?hr every 2 wk to maximum of 600?mg/24?hr.	*Cautions*: Children are predisposed tc hyperthermia with this drug. Most cor drowsiness, rash, and renal stones

TABLE 712-2 -- **Antibacterial Medications (Antibiotics)**

Drug (Trade Names, Formulations)	Indications (Mechanism of Action) and Dosing	Comments
Amikacin sulfate Amikin. Injection: 50?mg/mL, 250?mg/mL.	**Aminoglycoside antibiotic active against gram-negative bacilli, especially *Escherichia coli, Klebsiella, Proteus, Enterobacter, Serratia,* and *Pseudomonas.*** *Neonates:* Postnatal age =7 days: 1,200–2,000?g: 7.5?mg/kg q12–18h IV or IM; >2,000?g: 10?mg/kg q12h IV or IM; postnatal age >7 days: 1,200–2,000?g IV or IM: 7.5?mg/kg q8–12hr IV or IM; >2,000?g: 10?mg/kg q8h IV or IM. *Children:* 15–25?mg/kg/24?hr divided q8–12h IV or IM. *Adults:* 15?mg/kg/24?hr divided q8–12h IV or IM.	*Cautions:* Anaerobes, *Streptococcus* (including *S. pneumoniae*) are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30–60?min. *Drug interactions:* May potentiate other ototoxic and nephrotoxic drugs. *Target serum concentrations:* Peak 25–40?mg/L; trough <10?mg/L.
Amoxicillin Amoxil, Polymox. Capsule: 250, 500?mg. Tablet: chewable: 125, 250?mg. Suspension: 125?mg/5?mL, 250?mg/5?mL. Drops: 50?mg/mL.	**Penicillinase-susceptible ß-lactam: gram-positive pathogens except *Staphylococcus, Salmonella, Shigella, Neisseria, E. coli,* and *Proteus mirabilis.*** *Children:* 20–50?mg/kg/24?hr divided q8–12h PO. Higher dose of 80–90?mg/kg/24?hr PO for otitis media. *Adults:* 250–500?mg q8–12h PO. Uncomplicated gonorrhea: 3?g with 1?g probenecid PO.	*Cautions:* Rash, diarrhea, abdominal cramping. Drug eliminated renally. *Drug interaction:* Probenecid.
Amoxicillin-clavulanate Augmentin. Tablet: 250, 500, 875?mg. Tablet, chewable: 125, 200, 250, 400?mg. Suspension: 125?mg/5?mL, 200?mg/5?mL, 250?mg/5?mL, 400?mg/5?mL.	**ß-Lactam (amoxicillin) and ß-lactamase inhibitor (clavulanate) enhances amoxicillin activity against penicillinase-producing bacteria: *S. aureus* (not methicillin-resistant organism), *Streptococcus, Haemophilus influenzae, Moraxella catarrhalis, E. coli, Klebsiella, Bacteroides fragilis.*** *Neonates:* 30?mg/kg/24?hr divided q12h PO. *Children:* 20–45?mg/kg/24?hr divided q8–12h PO. Higher dose 80–90?mg/kg/24?hr PO for otitis media.	*Cautions:* Drug dosed on amoxicillin component. May cause diarrhea, rash. Drug eliminated renally. *Drug interaction:* Probenecid. *Comment:* Higher dose may be active against penicillin tolerant/resistant *S. pneumoniae*.

Ampicillin Polycillin, Omnipen. Capsule: 250, 500?mg. Suspension: 125?mg/5?mL, 250?mg/5?mL, 500?mg/5?mL. Injection.	**ß-Lactam with same spectrum of antibacterial activity as amoxicillin.** Neonates: Postnatal age =7 days =2,000?g: 50?mg/kg/24?hr IV or IM q12hr (meningitis: 100?mg/kg/24?hr divided q12h IV or IM); >2,000?g: 75?mg/kg/24?hr divided q8h IV or IM (meningitis: 150?mg/kg/24?hr divided q8h IV or IM). Postnatal age >7 days <1200?g: 50?mg/kg/24?hr IV or IM q12h (meningitis: 100?mg/kg/24?hr divided q12h IV or IM); 1,200–2,000?g:75?mg/kg/24?hr divided q8h IV or IM (meningitis: 150?mg/kg/24?hr divided q8h IV or I M); >2,000?g: 100?mg/kg/24?hr divided q6h IV or IM (meningitis: 200?mg/kg/24?hr divided q6h IV or IM). *Children:* 100–200?mg/kg/24?hr divided q6h IV or IM (meningitis: 200–400?mg/kg/24?hr divided q4–6h IV or IM). *Adults:* 250–500?mg q4–8h IV or IM.	*Cautions:* Less bioavailable than amoxicillin causing greater diarrhea. *Drug interaction:* Probenecid.
Ampicillin-sulbactam Unasyn. Injection.	**ß-Lactam (ampicillin) ß-lactamase inhibitor (sulbactam) enhances ampicillin activity against penicillinase-producing bacteria: *S. aureus, Streptococcus, H. influenzae, M. catarrhalis, E. coli, Klebsiella, B. fragilis.*** *Children:* 100–200?mg/kg/24?hr divided q4–8h IV or IM. *Adults:* 1–2?g q6–8h IV or IM (max daily dose: 8?g).	*Cautions:* Drug dosed on ampicillin component. May cause diarrhea, rash. Drug eliminated renally. *Note:* Higher dose may be active against penicillin-tolerant/resistant *S. pneumoniae*. *Drug interaction:* Probenecid.
Azithromycin Zithromax. Tablet: 250?mg. Suspension: 100?mg/5?mL, 200?mg/5?mL.	**Azalide antibiotic with activity against *S. aureus, Streptococcus, H. influenzae, Mycoplasma, Legionella, Chlamydia trachomatis.*** *Children:* 10?mg/kg PO on day 1 (max: 500?mg) followed by 5?mg/kg PO q24h for 4 days. Group A *Streptococcus* pharyngitis: 12?mg/kg/24?hr PO (max: 500?mg) for 5 days. *Adults:* 500?mg PO day 1 followed by 250?mg for 4 days. Uncomplicated *C. trachomatis* infection: single 1?g dose PO.	*Note:* Very long half-life permitting once-daily dosing. No metabolic-based drug interactions (unlike erythromycin and clarithromycin), limited gastrointestinal distress. Shorter-course regimens (e.g., 1–3 days) under investigation. Three-day therapy (10?mg/kg/24?hr × 3 days) and single-dose therapy (30?mg/kg): use with increasing frequency (not for streptococcus pharyngitis).
Aztreonam Azactam. Injection.	**ß-Lactam (monobactam) antibiotic with activity against gram-negative aerobic bacteria, Enterobacteriaceae, and *Pseudomonas aeruginosa.*** *Neonates:* Postnatal age =7 days =2,000?g: 60?mg/kg/24?hr divided q12h IV or IM; >2,000?g: 90?mg/kg/24?hr divided q8h IV or IM; postnatal age >7 days <1,200?g: 60?mg/kg/24?hr divided q12h IV or IM; 1,200–2,000?g: 90?mg/kg/24?hr divided q8h IV or IM; >2,000?g: 120?mg/kg/24?hr divided q6–8h IV or IM. *Children:* 90–120?mg/kg/24?hr divided q6–8h IV or IM. For cystic fibrosis up to 200?mg/kg/24?hr IV. *Adults:* 1–2?g IV or IM q8–12h (max 8?g/24?hr).	*Cautions:* Rash, thrombophlebitis, eosinophilia. Renally eliminated. *Drug interaction:* Probenecid.

Carbenicillin Geopen Injection. Geocillin oral tablet.	**Extended-spectrum penicillin (remains susceptible to penicillinase destruction) active against *Enterobacter,* indole-positive *Proteus,* and *Pseudomonas.*** Neonates: Postnatal age =7 days =2,000?g: 225?mg/kg/24?hr divided q8h IV or IM; >2000?g: 300?mg/kg/24?hr divided q6h IV or IM; >7 days: 300–400?mg/kg/24?hr divided q6h IV or IM. *Children:* 400–600?mg/kg/24?hr divided q4–6h IV or IM.	*Cautions:* Painful given intramuscularly; rash; each gram contains 5.3?mEq sodium. Interferes with platelet aggregation at high doses, increases in liver transaminase levels. Renally eliminated. Oral tablet for treatment of urinary tract infection only. *Drug interaction:* Probenecid.
Cefaclor Ceclor. Capsule: 250, 500?mg. Suspension: 125?mg/5?mL, 187?mg/5?mL, 250?mg/5?mL, 375?mg/5?mL.	**Second-generation cephalosporin active against *S. aureus, Streptococcus* including *S. pneumoniae, H. influenzae, E. coli, Klebsiella,* and *Proteus.*** *Children:* 20–40?mg/kg/24?hr divided q8–12h PO (max dose: 2?g). *Adults:* 250–500?mg q6–8h PO.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia) with high incidence of serum sickness reaction. Renally eliminated. *Drug interaction:* Probenecid.
Cefadroxil Duricef, Ultracef. Capsule: 500?mg. Tablet: 1,000?mg. Suspension: 125?mg/5?mL, 250?mg/5?mL, 500?mg/5?mL.	**First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella,* and *Proteus.*** *Children:* 30?mg/kg/24?hr divided q12h PO. (max dose: 2g). *Adults:* 250–500?mg q8–12h PO.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Long half-life permits q12–24h dosing. *Drug interaction:* Probenecid.
Cefazolin Ancef, Kefzol. Injection.	**First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella,* and *Proteus.*** *Neonates:* Postnatal age =7 days 40?mg/kg/24?hr divided q12h IV or IM; >7 days 40–60?mg/kg/24?hr divided q8h IV or IM. *Children:* 50–100?mg/kg/24?hr divided q8h IV or IM. *Adults:* 0.5–2?g q8h IV or IM (max dose: 12?g/24?hr).	*Caution:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS. *Drug interaction:* Probenecid.
Cefdinir Omnicef. Capsule: 300?mg. Oral suspension: 125?mg/5?mL.	**Extended-spectrum, semi-synthetic cephalosporin.** *Children 6 mo-12 yr:* 14?mg/kg/24?hr in 1 or 2 doses PO (max: 600?mg/24?hr). *Adults:* 600?mg q24h PO.	*Cautions:* Reduce dosage in renal insufficiency (creatinine clearance <60?mL/min). Avoid taking concurrently with iron-containing products and antacids because absorption is markedly decreased; take at least 2?hr apart. *Drug interaction:* Probenecid.
Cefepime Maxipime. Injection.	**Expanded-spectrum, fourth-generation cephalosporin active against many gram-positive and gram-negative pathogens, including many multi-drug-resistant pathogens.** Children: 100–150?mg/kg/24?hr q8–12h IV or IM. Adults: 2–4?g/24?hr q12h IV or IM.	*Adverse events:* Diarrhea, nausea, vaginal candidiasis *Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.

Cefixime Suprax. Tablet: 200, 400?mg. Suspension: 100?mg/5?mL.	**Third-generation cephalosporin active against *Streptococcus, H. influenzae, M. catarrhalis, N. gonorrhoeae, S. marcescens,* and *P. vulgaris.* No antistaphylococcal or antipseudomonal activity.** *Children:* 8?mg/kg/24?hr divided q12–24h PO. *Adults:* 400?mg/24?hr divided q12–24h PO.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS. *Drug interaction:* Probenecid.
Cefoperazone sodium Cefobid. Injection.	**Third-generation cephalosporin active against many gram-positive and gram-negative pathogens.** *Neonates:* 100?mg/kg/24?hr divided q12h IV or IM. *Children:* 100–150?mg/kg/24?hr divided q8–12h IV or IM. *Adults:* 2–4?g/24?hr divided q8–12h IV or IM (max dose: 12?g/24?hr).	*Cautions:* Highly protein bound cephalosporin with limited potency reflected by weak antipseudomonal activity. Variable gram-positive activity. Primarily hepatically eliminated in bile. *Drug interaction:* Disulfiram-like reaction with alcohol.
Cefotaxime sodium Claforan. Injection.	**Third-generation cephalosporin active against gram-positive and gram-negative pathogens. No antipseudomonal activity.** Neonates: =7 days: 100?mg/kg/24?hr divided q12h IV or IM; >7 days: <1,200?g 100?mg/kg/24?hr divided q12h IV or IM; >12,000?g: 150?mg/kg/24?hr divided q8h IV or IM. *Children:* 150?mg/kg/24?hr divided q6–8h IV or IM (meningitis: 200?mg/kg/24?hr divided q6–8h IV). *Adults:* 1–2?g q8–12h IV or IM (max: 12?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Each gram of drug contains 2.2?mEq sodium. Active metabolite. *Drug interaction:* Probenecid.
Cefotetan disodium Cefotan. Injection.	**Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, Klebsiella, Proteus,* and *Bacteroides.* Inactive against *Enterobacter.*** *Children:* 40–80?mg/kg/24?hr divided IV or IM q12h. *Adults:* 2–4?g/24?hr divided q12h IV or IM (max: 6?g/24?hr).	*Cautions:* Highly protein-bound cephalosporin, poor CNS penetration; ß-lactam safety profile (rash, eosinophilia), disulfiram-like reaction with alcohol. Renally eliminated (~20% in bile).
Cefoxitin sodium Mefoxin. Injection.	**Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, Klebsiella, Proteus, and Bacteroides.* Inactive against *Enterobacter.*** *Neonates:* 70–100?mg/kg/24?hr divided q8–12h IV or IM. *Children:* 80–160?mg/kg/24?hr divided q6–8h IV or IM. *Adults:* 1–2?g q6–8h IV or IM (max dose: 12?g/24?hr).	*Cautions:* Poor CNS penetration; ß-lactam safety profile (rash, eosinophilia). Renally eliminated. Painful given intramuscularly. *Drug interaction:* Probenecid.
Cefpodoxime proxetil Vantin. Tablet: 100?mg, 200?mg. Suspension: 50?mg/5?mL, 100?mg/5?mL.	**Third-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, M. catarrhalis, N. gonorrhoeae, E. coli, Klebsiella,* and *Proteus.* No antipseudomonal activity.** *Children:* 10?mg/kg/24?hr divided q12h PO. *Adults:* 200–800?mg/24?hr divided q12h PO (max dose: 800?mg/24?hr). Uncomplicated gonorrhea: 200?mg PO as single-dose therapy.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS. Increased bioavailability when taken with food. *Drug interaction:* Probenecid; antacids and H-2 receptor antagonists may decrease absorption.
Cefprozil Cefzil. Tablet: 250, 500?mg. Suspension: 125?mg/5?mL, 250?mg/5?mL.	**Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, M. catarrhalis, Klebsiella,* and *Proteus.*** *Children:* 30?mg/kg/24?hr divided q8–12h PO. *Adults:* 500–1,000?mg/24?hr divided q12h PO (max dose: 1.5?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Good bioavailability; food does not affect bioavailability. *Drug interaction:* Probenecid.

Ceftazidime Fortaz, Ceptaz, Tazicef, Tazidime. Injection.	**Third-generation cephalosporin active against gram-positive and gram-negative pathogens including *Pseudomonas aeruginosa.*** *Neonates:* Postnatal age =7 days: 100?mg/kg/24?hr divided q12h IV or IM; >7 days =1,200?g: 100?mg/kg/24?hr divided q12h IV or IM; >1,200?g: 150?mg/kg/24?hr divided q8h IV or IM. *Children:* 150?mg/kg/24?hr divided q8h IV or IM (meningitis: 150?mg/kg/24?hr IV divided q8h). *Adults:* 1–2?g q8–12h IV or IM (max: 8–12?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Increasing pathogen resistance developing with long-term, widespread use. *Drug interaction:* Probenecid.
Ceftizoxime Cefizox. Injection.	**Third-generation cephalosporin active against gram-positive and gram-negative pathogens. No antipseudomonal activity.** *Children:* 150?mg/kg/24?hr divided q6–8h IV or IM. *Adults:* 1–2?g q6–8h IV or IM (max dose: 12?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Ceftriaxone sodium Rocephin. Injection.	**Third-generation cephalosporin active against gram-positive and gram-negative pathogens. No antipseudomonal activity. Very potent and ß-lactamase stable.** *Neonates:* 50–75?mg/kg q24h IV or IM. *Children:* 50–75?mg/kg q24h IV or IM (meningitis: 75?mg/kg dose 1 then 80–100?mg/kg/24?hr divided q12–24h IV or IM). *Adults:* 1–2?g q24h IV or IM (max dose: 4?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Eliminated via kidney (33–65%) and bile; can cause sludging. Long half-life and dose-dependent protein binding favors q24h rather than q12h dosing. Can add 1% lidocaine for IM injection.
Cefuroxime (cefuroxime axetil for oral administration) Ceftin, Kefurox, Zinacef. Injection. Suspension: 125?mg/5?mL. Tablet: 125, 250, 500?mg.	**Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, M. catarrhalis, Klebsiella,* and *Proteus.*** *Neonates:* 40–100?mg/kg/24?hr divided q12h IV or IM. *Children:* 200–240?mg/kg/24?hr divided q8h IV or IM; PO administration: 20–30?mg/kg/24?hr divided q8h PO. *Adults:* 750–1,500?mg q8h IV or IM (max dose: 6?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. Food increases PO bioavailability. *Drug interaction:* Probenecid.
Cephalexin Keflex, Keftab. Capsule: 250, 500?mg. Tablet: 500?mg, 1?g. Suspension: 125?mg/5?mL, 250?mg/5?mL, 100?mg/mL drops.	**First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella,* and *Proteus.*** *Children:* 25–100?mg/kg/24?hr divided q6–8h PO. *Adults:* 250–500?mg q6h PO (max dose: 4?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Cephradine Velosef. Capsule: 250, 500?mg. Suspension: 125?mg/5?mL, 250?mg/5?mL.	**First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella,* and *Proteus.*** *Children:* 50–100?mg/kg/24?hr divided q6–12h PO. *Adults:* 250–500?mg q6–12h PO (max dose: 4?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.

Chloramphenicol Chloromycetin. Injection. Capsule: 250?mg. Ophthalmic, otic solutions. Ointment.	**Broad-spectrum protein synthesis inhibitor active against many gram-positive and gram-negative bacteria, *Salmonella,* vancomycin-resistant *Enterococcus faecium, Bacteroides,* other anaerobes, *Mycoplasma, Chlamydia,* and *Rickettsia; Pseudomonas* usually resistant.** *Neonates:* Initial loading dose 20?mg/kg followed 12?hr later by: postnatal age =7 days: 25?mg/kg/24?hr q24h IV; >7 days: =2,000?g: 25?mg/kg/24?hr q24h IV; >2,000?g: 50?mg/kg/24?hr divided q12h IV. *Children:* 50–75?mg/kg/24?hr divided q6–8h IV or PO (meningitis: 75–100?mg/kg/24?hr IV divided q6h). *Adults:* 50?mg/kg/24?hr divided q6h IV or PO (max dose: 4?g/24?hr).	*Cautions:* Gray-baby syndrome (from too-high dose in neonate), bone marrow suppression, aplastic anemia (monitor hematocrit, free serum iron). *Drug interactions:* Phenytoin, phenobarbital, rifampin may decrease levels. *Target serum concentrations:* Peak 20–30?mg/L; trough 5–10?mg/L.
Ciprofloxacin Cipro. Tablet: 100, 250, 500, 750?mg. Injection. Ophthalmic solution and ointment. Otic suspension. Oral suspension: 250 and 500?mg/5?mL.	**Quinolone antibiotic active against *P. aeruginosa, Serratia, Enterobacter, Shigella, Salmonella, Campylobacter, Neisseria gonorrhoeae, H. influenzae, M. catarrhalis,* some *S. aureus,* and *Streptococcus.*** *Neonates:* 10?mg/kg q12h PO or IV. *Children:* 15–30?mg/kg/24?hr divided q12h PO or IV; cystic fibrosis: 20–40?mg/kg/24?hr divided q8–12h PO or IV. *Adults:* 250–750?mg q12h; 200–400?mg IV q12h PO (max dose: 1.5?g/24?hr).	*Cautions:* Concerns of joint destruction in juvenile animals not seen in humans; tendonitis, superinfection, dizziness, confusion, crystalluria, some photosensitivity *Drug interactions:* Theophylline, magnesium-, aluminum-, or calcium-containing antacids, sucralfate, probenecid, warfarin, cyclosporine.
Clarithromycin Biaxin. Tablet: 250, 500?mg. Suspension: 125?mg/5?mL, 250?mg/5?mL.	**Macrolide antibiotic with activity against *S. aureus, Streptococcus, H. influenzae, Legionella, Mycoplasma,* and *C. trachomatis.*** *Children:* 15?mg/kg/24?hr divided q12h PO. *Adults:* 250–500?mg q12h PO (max dose: 1?g/24?hr).	*Cautions:* Adverse events less than erythromycin; gastrointestinal upset, dyspepsia, nausea, cramping. *Drug interactions:* Same as erythromycin: astemizole carbamazepine, terfenadine cyclosporine, theophylline, digoxin, tacrolimus.
Clindamycin Cleocin. Capsule: 75, 150, 300?mg. Suspension: 75?mg/5?mL. Injection. Topical solution, lotion, and gel. Vaginal cream.	**Protein synthesis inhibitor active against most gram-positive aerobic and anaerobic cocci except *Enterococcus.*** *Neonates:* Postnatal age =7 days <200?g; 10?mg/kg/24?hr divided q12h IV or IM; >2000?g: 15?mg/kg/24?hr divided q8h IV or IM; >7 days <1,200?g: 10?mg/kg/24?hr IV or IM divided q12h; 1,200–2,000?g: 15?mg/kg/24?hr divided q8h IV or IM; >2,000?g: 20?mg/kg/24?hr divided q8h IV or IM. *Children:* 10–40?mg/kg/24?hr divided q6–8h IV, IM, or PO. *Adults:* 150–600?mg q6–8h IV, IM, or PO (max dose: 5?g/24?hr IV or IM or 2?g/24?hr PO).	*Cautions:* Diarrhea, nausea, *C. difficile*–associated colitis, rash. Administer slow IV over 30–60?min. Topically active as an acne treatment.
Cloxacillin sodium Tegopen. Capsule: 250, 500?mg. Suspension: 125?mg/5?mL.	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci except *Enterococcus* and coagulase-negative staphylococci.** *Children:* 50–100?mg/kg/24?hr divided q6h PO. *Adults:* 250–500?mg q6h PO (max dose: 4?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Primarily hepatically eliminated; requires dose reduction in renal disease. Food decreases bioavailability. *Drug interaction:* Probenecid.

Co-trimoxazole (trimethoprim-sulfamethoxazole; TMP-SMZ) Bactrim, Cotrim, Septra, Sulfatrim. Tablet: SMZ 400?mg and TMP 80?mg. Tablet DS: SMZ 800?mg and TMP 160?mg. Suspension: SMZ 200?mg and TMP 40?mg/5?mL. Injection.	**Antibiotic combination with sequential antagonism of bacterial folate synthesis with broad antibacterial activity: *Shigella, Legionella, Nocardia, Chlamydia, Pneumocystis carinii.* Dosage based on TMP component.** *Children:* 6–20?mg TMP/kg/24?hr or IV divided q12h PO. *P. carinii* pneumonia: 15–20?mg TMP/kg/24?hr divided q12h PO or IV. *P. carinii* prophylaxis: 5?mg TMP/kg/24?hr or 3 times/wk PO. *Adults:* 160?mg TMP q12h PO.	*Cautions:* Drug dosed on TMP (trimethoprim) component. Sulfonamide skin reactions: rash, erythema multiforme, Stevens-Johnson syndrome, nausea, leukopenia. Renal and hepatic elimination; reduce dose in renal failure. *Drug interactions:* Protein displacement with warfarin, possibly phenytoin, cyclosporine.
Demeclocycline Declomycin. Tablet: 150, 300?mg. Capsule: 150?mg.	**Tetracycline active against most gram-positive cocci except *Enterococcus* , many gram-negative bacilli, anaerobes, *Borrelia burgdorferi* (Lyme disease), *Mycoplasma,* and *Chlamydia.*** *Children:* 8–12?mg/kg/24?hr divided q6–12h PO. *Adults:* 150?mg PO q6–8h. Syndrome of inappropriate antidiuretic hormone secretion: 900–1,200?mg/24?hr or 13–15?mg/kg/24?hr divided q6–8h PO with dose reduction based on response to 600–900?mg/24?hr.	*Cautions:* Teeth staining, possibly permanent (if administered <8 yr of age) with prolonged use; photosensitivity, diabetes insipidus, nausea, vomiting, diarrhea, superinfections. *Drug interactions:* Aluminum-, calcium-, magnesium-, zinc- and iron-containing food, milk, dairy products may decrease absorption.
Dicloxacillin Dynapen, Pathocil. Capsule: 125, 250, 500?mg. Suspension: 62.5?mg/5?mL.	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci except *Enterococcus* and coagulase-negative staphylococci.** *Children:* 12.5–100?mg/kg/24?hr divided q6h PO. *Adults:* 125–500?mg q6h PO.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Primarily renally (65%) and bile (30%) elimination. Food may decrease bioavailability. *Drug interaction:* Probenecid.
Doxycycline Vibramycin, Doxy. Injection. Capsule: 50, 100?mg. Tablet: 50, 100?mg. Suspension: 25?mg/5?mL. Syrup: 50?mg/5?mL.	**Tetracycline antibiotic active against most gram-positive cocci except *Enterococcus*, many gram-negative bacilli, anaerobes, *Borrelia burgdorferi* (Lyme disease), *Mycoplasma*, and *Chlamydia.*** *Children:* 2–5?mg/kg/24?hr divided q12–24h PO or IV (max dose: 200?mg/24?hr). *Adults:* 100–200?mg/24?hr divided q12–24h PO or IV.	*Cautions:* Teeth staining, possibly permanent (<8 yr of age) with prolonged use; photosensitivity, nausea, vomiting, diarrhea, superinfections. *Drug interactions:* Aluminum-, calcium-, magnesium-, zinc-, iron-, kaolin-, and pectin-containing products, food, milk, dairy products may decrease absorption. Carbamazepine, rifampin, barbiturates may decrease half-life.
Erythromycin E-Mycin, Ery-Tab, Ery-C, Ilosone. Estolate 125, 500?mg. Tablet EES: 200?mg. Tablet base: 250, 333, 500?mg. Suspension: estolate 125?mg/5?mL, 250?mg/5?mL, EES 200?mg/5?mL, 400?mg/5?mL. Estolate drops: 100?mg/mL. EES drops: 100?mg/2.5?mL. Available in combination with sulfisoxazole (Pediazole), dosed on erythromycin content.	**Bacteriostatic macrolide antibiotic most active against gram-positive organisms, *Corynebacterium diphtheriae*, and *Mycoplasma pneumoniae*. May also be used to promote gastrointestinal motility and improve feeding intolerance in preterm infants.** *Neonates:* Postnatal age =7 days: 20?mg/kg/24?hr divided q12h PO; >7 days <1,200?g: 20?mg/kg/24?hr divided q12h PO; >1,200?g: 30?mg/kg/24?hr divided q8h PO (give as 5?mg/kg/dose q6h to improve feeding intolerance). *Children:* Usual max dose 2?g/24?hr. Base: 30–50?mg/kg/24?hr divided q6–8h PO. Estolate: 30–50?mg/kg/24?hr divided q8–12h PO. Stearate: 20–40?mg/kg/24?hr divided q6h PO. Lactobionate: 20–40?mg/kg/24?hr divided q6–8h IV. Gluceptate: 20–50?mg/kg/24?hr divided q6h IV: usual max dose 4?g/24?hr IV. *Adults:* Base: 333?mg PO q8h; estolate/stearate/base: 250–500?mg q6h PO.	*Cautions:* Motilin agonist leading to marked abdominal cramping, nausea, vomiting, diarrhea. Associated with hypertrophic pyloric stenosis in young infants. Many different salts with questionable tempering of gastrointestinal adverse events. Rare cardiac toxicity with IV use. Dose of salts differ. Topical formulation for treatment of acne. *Drug interactions:* Antagonizes hepatic CYP 450 3A4 activity: astemizole, carbamazepine, terfenadine, cyclosporine, theophylline, digoxin, tacrolimus, carbamazepine.

	Gluceptate: 20–50?mg/kg/24?hr divided q6h IV: usual max dose 4?g/24?hr IV. *Adults:* Base: 333?mg PO q8h; estolate/stearate/base: 250–500?mg q6h PO.	
Gentamicin Garamycin. Injection. Ophthalmic solution, ointment, topical cream.	**Aminoglycoside antibiotic active against gram-negative bacilli, especially *E. coli, Klebsiella, Proteus, Enterobacter, Serratia*, and *Pseudomonas.*** *Neonates:* Postnatal age =7 days 1,200–2,000?g: 2.5?mg/kg q12–18h IV or IM; >2,000?g: 2.5?mg/kg q12h IV or IM; postnatal age >7 days 1,200–2,000?g: 2.5?mg/kg q8–12h IV or IM; >2,000?g: 2.5?mg/kg q8h IV or IM. *Children:* 2.5?mg/kg/24?hr divided q8–12h IV or IM. Alternatively may administer 5–7.5?mg/kg/24?hr IV once daily. *Intrathecal:* Preservative-free preparation for intraventricular or intrathecal use: neonate: 1?mg/24?hr; children: 1–2?mg/24?hr IT; adults: 4–8?mg/24?hr. Adults: 3–6?mg/kg/24?hr divided q8h IV or IM.	*Cautions:* Anaerobes, *S. pneumoniae*, other *Streptococcus* are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30–60?min. *Drug interactions:* May potentiate other ototoxic and nephrotoxic drugs. *Target serum concentrations:* Peak 6–12?mg/L; trough <2?mg/L with intermittant daily dose regimens only.
Imipenem-cilastatin Primaxin. Injection.	**Carbapenem antibiotic active against broad-spectrum gram-positive cocci and gram-negative bacilli including *P. aeruginosa* and anerobes. No activity against *Stenotrophomonas maltophilia.*** *Neonates:* Postnatal age =7 days <1,200?g: 20?mg/kg q18–24h IV or IM; >1,200?g: 40?mg/kg divided q12h IV or IM; postnatal age > 7 days 1,200–2,000?g: 40?mg/kg q12h IV or IM; >2,000?g: 60?mg/kg q8h IV or IM. *Children:* 60–100?mg/kg/24?hr divided q6–8h IV or IM. *Adults:* 2–4?g/24?hr divided q6–8h IV or IM (max dose: 4?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia), nausea, seizures. Cilastatin possesses no antibacterial activity; reduces renal imipenem metabolism. Primarily renally eliminated. *Drug interaction:* Possibly ganciclovir.
Linezolid Zyvox. Tablet: 400, 600?mg. Oral suspension: 100?mg/5?mL. Injection: 100?mg/5mL.	**Oxazolidinone antibiotic active against gram-positive cocci (especially drug-resistant organisms), including *Staphylococcus, Streptococcus, Enterococcus faecium,* and *E. fecalis*. Interferes with protein synthesis by binding to 50S ribosome subunit.** *Children:* 10?mg/kg q12h IV or PO. *Adults:* Pneumonia: 600?mg q12h IV or PO; skin infections: 400?mg q12h IV or PO.	*Adverse events:* Myelosuppression, pseudomembranous colitis, nausea, diarrhea, headache. *Drug interaction:* Probenecid.
Loracarbef Lorabid. Capsule: 200?mg. Suspension: 100?mg/5?mL, 200?mg/5?mL.	**Carbacephem very closely related to cefaclor (second-generation cephalosporin) active against *S. aureus, Streptococcus, H. influenzae, M. catarrhalis, E. coli, Klebsiella*, and *Proteus*.** *Children:* 30?mg/kg/24?hr divided q12h PO (max dose: 2?g). *Adults:* 200–400?mg q12h PO (max dose: 800?mg/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Meropenem Merrem. Injection.	**Carbapenem antibiotic active against broad-spectrum gram-positive cocci and gram-negative bacilli including *P. aeruginosa* and anerobes. No activity against *Stenotrophomonas maltophilia.*** *Children:* 60?mg/kg/24?hr divided q8h IV meningitis: 120?mg/kg/24?hr [max 6?g/24?hr] q8h IV. *Adults:* 1.5–3?g q8h IV.	*Cautions:* ß-Lactam safety profile; appears to possess less CNS excitation than imipenem. 80% renal elimination. *Drug interaction:* Probenecid.

Metronidazole Flagyl, Metro-IV, generic. Topical gel, vaginal gel. Injection. Tablet: 250, 500?mg.	**Highly effective in the treatment of infections due to anaerobes.** *Neonates:* <1,200?g: 7.5?mg/kg q 48?hr PO or IV; postnatal age =7 days 1,200–2,000?g: 7.5?mg/kg/24?hr q 24?hr PO or IV; 2,000?g: 15?mg/kg/24?hr divided q12h PO or IV; postnatal age >7 days 1,200–2,000?g: 15?mg/kg/24?hr divided q12h PO or IV; >2,000?g: 30?mg/kg/24?hr divided q12h PO or IV. *Children:* 30?mg/kg/24?hr divided q6–8h PO or IV. *Adults:* 30?mg/kg/24?hr divided q6h PO or IV (max dose: 4?g/24?hr).	*Cautions:* Dizziness, seizures, metallic taste, nausea, disulfiram-like reaction with alcohol. Administer IV slow over 30–60?min. Adjust dose with hepatic impairment. *Drug interactions:* Carbamazepine, rifampin, phenobarbital may enhance metabolism; may increase levels of warfarin, phenytoin, lithium.
Mezlocillin sodium Mezlin. Injection.	**Extended-spectrum penicillin active against *E. coli, Enterobacter, Serratia*, and *Bacteroides;* limited antipseudomonal activity.** *Neonates:* Postnatal age =7 days: 150?mg/kg/24?hr divided q12h IV; >7 days: 225?mg/kg divided q8h IV. *Children:* 200–300?mg/kg/24?hr divided q4–6h IV; cystic fibrosis 300–450?mg/kg/24?hr IV. *Adults:* 2–4?g/dose q4–6h IV (max dose: 12?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 1.8?mEq sodium. Interferes with platelet aggregation with high doses; increases noted in liver function test results. Renally eliminated. Inactivated by ß-lactamase enzyme. *Drug interaction:* Probenecid.
Mupirocin Bactroban. Ointment.	**Topical antibiotic active against *Staphylococcus* and *Streptococcus.*** Topical application: Nasal (eliminate nasal carriage) and to the skin 2–4 times per day.	*Caution:* Minimal systemic absorption as drug metabolized within the skin.
Nafcillin sodium Nafcil, Unipen. Injection. Capsule: 250?mg. Tablet: 500?mg.	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci except *Enterococcus* and coagulase-negative staphylococci.** *Neonates:* Postnatal age = 7 days 1,200–2,000?g: 50?mg/kg/24?hr divided q12h IV or IM; >2,000?g: 75?mg/kg/24?hr divided q8h IV or IM; postnatal age >7 days 1,200–2,000?g: 75?mg/kg/q8h; >2,000?g: 100?mg/kg divided q6–8h IV (meningitis: 200?mg/kg/24?hr divided q6h IV). *Children:* 100–200?mg/kg/24?hr divided q 4–6?hr IV. *Adults:* 4–12?g/24?hr divided q4–6h IV (max dose: 12?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia), phlebitis; painful given intramuscularly; oral absorption highly variable and erratic (not recommended). *Adverse effect:* Neutropenia.
Nalidixic acid NegGram. Tablet: 250, 500, 1,000?mg. Suspension: 250?mg/5?mL.	**First-generation quinolone effective for short-term treatment of lower urinary tract infections caused by *E. coli, Enterobacter, Klebsiella* , and *Proteus.*** *Children:* 50–55?mg/kg/24?hr divided q6h PO; suppressive therapy 25–33?mg/kg/24?hr divided q6–8h PO. *Adults:* 1?g q6h PO; suppressive therapy: 500?mg q6h PO.	*Cautions:* Vertigo, dizziness, rash. Not for use in systemic infections. *Drug interactions:* Liquid antacids.
Neomycin sulfate Mycifradin, generic. Tablet: 500?mg. Topical cream, ointment. Solution: 125?mg/5?mL.	**Aminoglycoside antibiotic used for topical application or orally before surgery to decrease gastrointestinal flora (nonabsorbable) and hyperammonemia.** *Infants:* 50?mg/kg/24?hr divided q6h PO. *Children:* 50–100?mg/kg/24?hr divided q6–8h PO. *Adults:* 500–2,000?mg/dose q6–8h PO.	*Cautions:* In patients with renal dysfunction because small amount absorbed may accumulate. *Adverse events:* Primarily related to topical application, abdominal cramps, diarrhea, rash. Aminoglycoside ototoxicity and nephrotoxicity if absorbed.

Nitrofurantoin Furadantin, Furan, Macrodantin. Capsule: 50, 100?mg. Extended-release capsule: 100?mg. Macrocrystal: 50, 100?mg. Suspension: 25?mg/5?mL.	**Effective in the treatment of lower urinary tract infections caused by gram-positive and gram-negative pathogens.** *Children:* 5–7?mg/kg/24?hr divided q6h PO (max dose: 400?mg/24?hr); suppressive therapy 1–2.5?mg/kg/24?hr divided q12–24h PO (max dose: 100?mg/24?hr). Adults: 50–100?mg/24?hr divided q6h PO.	*Cautions:* Vertigo, dizziness, rash, jaundice, interstitial pneumonitis. Do not use with moderate to severe renal dysfunction. *Drug interactions:* Liquid antacids.
Ofloxacin Ocuflox 0.3% ophthalmic solution: 1, 5, 10?mL. Floxin 0.3% otic solution: 5, 10?mL.	**Quinolone antibiotic for treatment of conjunctivitis or corneal ulcers (ophthalmic solution); and otitis externa and chronic suppurative otitis media (otic solution) caused by susceptible gram-positive, gramnegative, anaerobic bacteria, or *Chlamydia trachomatis.*** *Child >1–12 yr:* Conjunctivitis: 1–2 drops in affected eye(s) q2–4h for 2 days, then 1–2 drops qid for 5 days. Corneal ulcers: 1–2 drops q 30?min while awake and at 4 hours at night for 2 days, then 1–2 drops hourly for 5 days while awake, then 1–2 drops q6h for 2 days. Otitis externa (otic solution): 5 drops into affected ear bid for 10 days. Chronic suppurative otitis media: treat for 14 days. *Child >12 yr and adults: Ophthalmic solution doses same as for younger children*. Otitis externa (otic solution): Use 10 drops bid for 10 or 14 days as for younger children.	*Adverse events:* Burning, stinging, eye redness (ophthalmic solution), dizziness with otic solution if not warmed.
Oxacillin sodium Prostaphlin. Injection. Capsule: 250, 500?mg. Suspension: 250?mg/5?mL.	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci except *Enterococcus* and coagulase-negative staphylococci.** *Neonates:* Postnatal age = 7 days 1,200–2,000?g: 50?mg/kg/24?hr divided q12h IV; >2,000?g: 75?mg/kg/24?hr IV divided q8h IV; postnatal age >7 days <1,200?g: 50?mg/kg/24?hr IV divided q12h IV; 1,200–2,000?g: 75?mg/kg/24?hr divided q8h IV; >2,000?g: 100?mg/kg/24?hr IV divided q6h IV. *Infants:* 100–200?mg/kg/24?hr divided q4–6h IV. *Children:* PO 50–100?mg/kg/24?hr divided q4–6h IV. *Adults:* 2–12?g/24?hr divided q4–6h IV (max dose: 12?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia). Moderate oral bioavailability (35–65%). Primarily renally eliminated. *Drug interaction:* Probenecid. *Adverse effect:* Neutropenia.

Penicillin G Injection. Tablets.	**Penicillin active against most gram-positive cocci; *S. pneumoniae* (resistance is increasing), group A *Streptococcus,* and some gram-negative bacteria (e.g., *N. gonorrhoeae, N. meningitidis*).** *Neonates:* Postnatal age =7 days 1,200–2,000?g: 50,000 units/kg/24?hr divided q12h IV or IM (meningitis: 100,000 units/kg/24?hr divided q12h IV or IM); >2,000?g: 75,000 units/kg/24?hr divided q8h IV or IM (meningitis: 150,000 units/kg/24?hr divided q8h IV or IM); postnatal age >7 days =1,200?g: 50,000 units/kg/24?hr divided q12h IV (meningitis: 100,000 units/kg/24?hr divided q12h IV); 1,200–2,000?g: 75,000 units/kg/24?hr q8h IV (meningitis: 225,000 units/kg/24?hr divided q8h IV); >2,000?g: 100,000 units/kg/24?hr divided q6h IV (meningitis: 200,000 units/kg/24?hr divided q6h IV). *Children:* 100,000–250,000 units/kg/24?hr divided q4–6h IV or IM (max: 400,000 units/kg/24?hr). *Adults:* 2–24 million units/24?hr divided q4–6h IV or IM.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia), allergy, seizures with excessive doses particularly in patients with marked renal disease. Substantial pathogen resistance. Primarily renally eliminated. *Drug interaction:* Probenecid.
Penicillin G, benzathine Bicillin. Injection.	**Long-acting repository form of penicillin effective in the treatment of infections responsive to persistent, low penicillin concentrations (1–4 wk), e.g., group A *Streptococcus* pharyngitis, rheumatic fever prophylaxis.** *Neonates >1,200?g:* 50,000 units/kg IM once. *Children:* 300,000–1.2 million units/kg q 3–4 wk IM (max: 1.2–2.4 million units/dose). *Adults:* 1.2 million units IM q 3–4 wk.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia), allergy. Administer by IM injection only. Substantial pathogen resistance. Primarily renally eliminated. *Drug interaction:* Probenecid.
Penicillin G, procaine Crysticillin. Injection.	**Repository form of penicillin providing low penicillin concentrations for ~12?hr.** *Neonates >1,200?g:* 50,000 units/kg/24?hr IM. *Children:* 25,000–50,000 units/kg/24?hr IM for 10 days (max: 4.8 million units/dose). Gonorrhea: 100,000 units/kg (max: 4.8 million units/24?hr) IM once with probenecid 25?mg/kg (max dose: 1?g). *Adults:* 0.6–4.8 million units q12–24h IM.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia), allergy. Administer by IM injection only. Substantial pathogen resistance. Primarily renally eliminated. *Drug interaction:* Probenecid.
Penicillin V Pen VK, V-Cillin K. Tablet: 125, 250, 500?mg. Suspension: 125?mg/5?mL, 250?mg/5?mL.	**Preferred oral dosing form of penicillin, active against most gram-positive cocci; *S. pneumoniae* (resistance is increasing), other *Streptococcus*, and some gram-negative bacteria (e.g., *N. gonorrhoeae, N. meningitidis*).** *Children:* 25–50?mg/kg/24?hr divided q4–8h PO. *Adults:* 125?mg–500?mg q6–8h PO (max dose: 3?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia), allergy, seizures with excessive doses particularly in patients with renal disease. Substantial pathogen resistance. Primarily renally eliminated. Inactivated by penicillinase. *Drug interaction:* Probenecid.
Pentamidine isethionate Pentam. Injection. Aerosol.	**Antiprotozoal agent effective in the prevention and treatment of *P. carinii* infections.** *Children: P. carinii* treatment 4?mg/kg/24?hr q24h IV or IM (preferred) for 14 days. Prophylaxis: 4?mg/kg IV or IM q 2–4 wk; aerosol adjusted to minute ventilation (4–8?mg/kg/dose) up to 300?mg/dose. Visceral leishmaniasis: 4?mg/kg/24?hr IV or IM for 14 days. *Adults: P. carinii* treatment 4?mg/kg/24?hr IV or IM (preferred) for 14 days. Prophylaxis: 300?mg/dose q 3–4 wk.	*Cautions:* Hypotension, hypoglycemia, cardiac arrhythmias, pain at injection site, nephrotoxicity; cough/bronchospasm with aerosol; 33–66% renally eliminated. *Drug interactions:* Other nephrotoxins (e.g., aminoglycosides, amphotericin B, cyclosporine).

Piperacillin Pipracil. Injection.	**Extended-spectrum penicillin active against *E. coli, Enterobacter, Serratia, P. aeruginosa*, and *Bacteroides.*** *Neonates:* Postnatal age =7 days 150?mg/kg/24?hr divided q8–12h IV; >7 days; 200?mg/kg divided q6–8r IV. *Children:* 200–300?mg/kg/24?hr divided q4–6h IV; cystic fibrosis: 350–500?mg/kg/24?hr IV. *Adults:* 2–4?g/dose q4–6h (max dose: 24?g/24?hr) IV.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 1.9?mEq sodium. Interferes with platelet aggregation/serum sickness-like reaction with high doses; increases in liver function tests. Renally eliminated. Inactivated by penicillinase. *Drug interaction:* Probenecid.
Piperacillin-tazobactam Zosyn. Injection.	**Extended-spectrum penicillin (piperacillin) combined with a ß-lactamase inhibitor (tazobactam) active against *S. aureus, H. influenzae, E. coli, Enterobacter, Serratia, Acinetobacter, P. aeruginosa*, and *Bacteroides.*** *Children:* 300–400?mg/kg/24?hr divided q6–8?h IV or IM. *Adults:* 3.375?g q6–8h IV or IM.	*Cautions:* ß-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 1.9?mEq sodium. Interferes with platelet aggregation, serum sickness–like reaction with high doses, increases in liver function test results. Renally eliminated. *Drug interaction:* Probenecid.
Quinupristin/dalfopristin Synercid. IV injection: powder for reconstitution, 10?mL contains 150?mg quinupristin, 350?mg dalfopristin.	**Streptogramin antibiotic (quinupristin) active against vancomycin-resistant *E. faecium* (VRE) and methicillin-resistant *S. aureus*. Not active against *E. faecalis.*** *Children and adults:* VRE: 7.5?mg/kg q8h IV for VRE; skin infections: 7.5?mg/kg q12h IV.	*Adverse events:* Pain, edema, or phlebitis at injection site, nausea, diarrhea. *Drug interactions:* Synercid is a potent inhibitor of CYP3A4.

Sulfadiazine Tablet: 500?mg.	**Sulfonamide antibiotic primarily indicated for the treatment of lower urinary tract infections due to *E. coli, P. mirabilis*, and *Klebsiella.*** Toxoplasmosis: *Neonates:* 100?mg/kg/24?hr divided q12h PO with pyrimethamine 1?mg/kg/24?hr PO (with folinic acid). *Children:* 120–200?mg/kg/24?hr divided q6h PO with pyrimethamine 2?mg/kg/24?hr divided q12h PO =3 days then 1?mg/kg/24?hr (max dose: 25?mg/24?hr) with folinic acid. Rheumatic fever prophylaxis: =30?kg: 500?mg/24?hr q24h PO; >30?kg: 1?g/24?hr q24h PO.	*Cautions:* Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life ~10?hr. *Drug interactions:* Protein displacement with warfarin, ?phenytoin, methotrexate.
Sulfamethoxazole Gantanol. Tablet: 500?mg. Suspension: 500?mg/5?mL.	**Sulfonamide antibiotic used for the treatment of otitis media, chronic bronchitis, and lower urinary tract infections due to susceptible bacteria.** *Children:* 50–60?mg/kg/24?hr divided q12h PO. *Adults:* 1?g/dose q12h PO (max dose: 3?g/24?hr).	*Cautions:* Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life ~ 12?hr. Initial dose often a loading dose (doubled). *Drug interactions:* Protein displacement with warfarin, ?phenytoin, methotrexate.
Sulfisoxazole Gantrisin. Tablet: 500?mg. Suspension: 500?mg/5?mL. Ophthalmic solution, ointment.	**Sulfonamide antibiotic used for the treatment of otitis media, chronic bronchitis, and lower urinary tract infections due to susceptible bacteria.** *Children:* 120–150?mg/kg/24?hr divided q4–6h PO (max dose: 6?g/24?hr). *Adults:* 4–8?g/24?hr q divided q4–6h PO.	*Cautions:* Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life ~ 7–12?hr. Initial dose often a loading dose (doubled). Drug interactions: Protein displacement with warfarin, ?phenytoin, methotrexate.

Ticarcillin Ticar. Injection.	**Extended-spectrum penicillin active against *E. coli, Enterobacter, Serratia, P. aeruginosa*, and *Bacteroides.*** *Neonates:* Postnatal age =7days <2,000?g: 150?mg/kg/24?hr divided q8–12h IV; >7 days: <2,000?g: 225?mg/kg/24?hr divided q8h IV; >7 days <1,200?g: 150?mg/kg/24?hr divided q12h IV; 1,200–2,000?g: 225?mg/kg/24?hr divided q8h IV; >2,000?g: 300?mg/kg/24?hr divided q6–8h IV. *Children:* 200–400?mg/kg/24?hr divided q4–6h IV; cystic fibrosis: 400–600?mg/kg/24?hr IV. *Adults:* 2–4?g/dose q4–6h IV (max dose: 24?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 5–6?mEq sodium. Interferes with platelet aggregation; increases in liver function tests. Renally eliminated. Inactivated by penicillinase. *Drug interaction:* Probenecid.
Ticarcillin-clavulanate Timentin. Injection.	**Extended-spectrum penicillin (ticarcillin) combined with a ß-lactamase inhibitor (clavulanate) active against *S. aureus, H. influenzae, Enterobacter, E. coli, Serratia, P. aeruginosa, Acinetobacter*, and *Bacteroides.*** *Children:* 280–400?mg/kg/24?hr q4–8h IV or IM. *Adults:* 3.1?g q4–8h IV or IM (max dose: 18–24?g/24?hr).	*Cautions:* ß-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 5–6?mEq sodium. Interferes with platelet aggregation; increases in liver function tests. Renally eliminated. *Drug interaction:* Probenecid.

Tobramycin Nebcin, Tobrex. Injection. Ophthalmic solution, ointment.	**Aminoglycoside antibiotic active against gram-negative bacilli, especially *E. coli, Klebsiella, Enterobacter, Serratia, Proteus,* and *Pseudomonas.*** *Neonates:* Postnatal age =7 days, 1,200–2,000?g: 2.5?mg/kg q12–18h IV or IM; >2,000?g: 2.5?mg/kg q12h IV or IM; postnatal age >7 days, 1,200–2,000?g: 2.5?mg/kg q8–12h IV or IM;>2,000?g: 2.5?mg/kg q8h IV or IM. *Children:* 2.5?mg/kg/24?hr divided q8–12h IV or IM. Alternatively may administer 5–7.5?mg/kg/24?hr IV. Preservative-free preparation for intraventricular or intrathecal use: neonate: 1?mg/24?hr; children: 1–2?mg/24?hr; adults: 4–8?mg/24?hr. *Adults:* 3–6?mg/kg/24?hr divided q8h IV or IM.	*Cautions: S. pneumoniae*, other *Streptococcus*, and anaerobes are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30–60?min. *Drug interactions:* May potentiate other ototoxic and nephrotoxic drugs. *Target serum concentrations:* Peak 6–12?mg/L; trough <2?mg/L.
Trimethoprim Proloprim, Trimpex. Tablet: 100, 200?mg.	**Folic acid antagonist effective in the prophylaxis and treatment of *E. coli, Klebsiella, Proteus mirabilis*, and *Enterobacter* urinary tract infections; *P. carinii* pneumonia.** *Children:* For urinary tract infection: 4–6?mg/kg/24?hr divided q12h PO. *Children >12 yr and adults:* 100–200?mg q12h PO. *P. carinii* pneumonia (with dapsone): 15–20?mg/kg/24?hr divided q6h for 21 days PO.	*Cautions:* Megaloblastic anemia, bone marrow suppression, nausea, epigastric distress, rash. *Drug interactions:* Possible interactions with phenytoin, cyclosporine, rifampin, warfarin.

Vancomycin Vancocin, Luphocin. Injection. Capsule: 125?mg, 250?mg. Suspension.	**Glycopeptide antibiotic active against most gram-positive pathogens including *Staphylococcus* (including methicillin- resistant *S. aureus* and coagulase-negative staphylococci), *S. pneumoniae* including penicillin-resistant strains, *Enterococcus* (resistance is increasing), and *Clostridium difficile*–associated colitis.** *Neonates:* Postnatal age =7 days, <1,200?g: 15?mg/kg/24?hr divided q24h IV; 1,200–2,000?g: 15?mg/kg/24?hr divided q12–18h IV; >2,000?g: 30?mg/kg/24?hr divided q12h IV; postnatal age >7 days, <1,200?g: 15?mg/kg/24?hr divided q24h IV; 1,200–2,000?g: 15?mg/kg/24?hr divided q8–12h IV; >2,000?g: 45?mg/kg/24?hr divided q8h IV. *Children:* 45–60?mg/kg/24?hr divided q8–12h IV; *Clostridium difficile–associated* colitis; 40–50?mg/kg/24?hr divided q6–8h PO. Adults: 0.5–1?g IV q12h IV.	*Cautions:* Ototoxicity and nephrotoxicity particularly when co-administered with other ototoxic and nephrotoxic drugs. Infuse IV over 45–60?min. Flushing (red-man syndrome) associated with rapid IV infusions, fever, chills, phlebitis (central line is preferred). Renally eliminated. *Target serum concentrations:* Peak (1?hr after 1?hr infusion) 30–40?mg/L; trough 5–10?mg/L.

TABLE 712-3 -- Antimycobacterial Medications

Drug (Trade Names, Formulations)	Indications (Mechanism of Action) and Dosing	Comments
Cycloserine Seromycin. Capsule: 250?mg.	**Adjunctive antituberculous agent less effective than isoniazid or streptomycin.** *Children:* 10–20?mg/kg/24?hr PO divided q12h. *Adults:* 250–500?mg per dose PO q12h (max daily dose: 1,000?mg).	*Cautions:* Headache, dizziness, confusion, psychosis, seizures, photosensitivity, folate/vitamin B_{12} deficiency. Primarily renally eliminated. *Drug interactions:* Phenytoin, additive CNS effects with isoniazid.
Ethambutol HCl Myambutol. Tablet: 100, 400?mg.	**For use in combination with other agents.** *Children:* 15?mg/kg/24?hr PO q24h. *Adults:* 15?mg/kg/24?hr PO q24h (max dose: 2.5?g/24?hr).	*Cautions:* Optic neuritis, decreased visual acuity, headache, dizziness, rash, peripheral neuropathy.
Ethionamide Trecator-SC. Tablet: 250?mg.	**For use in combination with other agents. Consider co-administration of vitamin B_6 .** *Children:* 15–20?mg/kg/24?hr PO divided q8–12h (max: 1,000?mg/24?hr). *Adults:* 500–1,000?mg PO q8–24h.	*Cautions:* Gastrointestinal upset, hepatotoxicity, vitamin B_6 deficiency, dizziness, headache, metallic taste, optic neuritis.
Isoniazid INH, Nydrazid. Tablet: 50, 100, 300?mg. Syrup: 50?mg/5?mL. Injection.	**For use in combination with other agents.** *Children:* 10–20?mg/kg/24?hr PO divided q12–24h (max: 300?mg/24?hr); prophylaxis dose 10?mg/kg/24?hr. *Adults:* 5?mg/kg/24?hr PO once daily; usual maximum dose: 300?mg/24?hr. Twice weekly therapy (after 3 mo daily therapy): *Children:* 20–40?mg/kg/dose (max: 900?mg) twice weekly. *Adults:* 15?mg/kg/dose (max: 900?mg) twice weekly.	*Cautions:* Dizziness, seizures, rash, pellagra, gastrointestinal upset, peripheral neuropathy (may give vitamin B_6 1–2?mg/kg/24?hr without effect on antituberculous activity), hepatotoxicity. *Drug interactions:* Increase serum concentrations of phenytoin, carbamazepine.
Kanamycin Injection.	**Aminoglycoside antibiotic used in combination with other agents.** *Children:* 15?mg/kg/24?hr IM or IV divided q12h. *Adults:* 1?g/24?hr IM or IV (max: dose 1?g/24?hr).	*Cautions:* Aminoglycoside adverse effect profile (ototoxicity, and nephrotoxicity).

Pyrazinamide Tablet: 500?mg.	**For use in combination with other agents.** *Children:* 15–40?mg/kg/24?hr PO divided q12–24h (max: 2?g/24?hr). *Adults:* 15–30?mg/kg/24?hr PO divided q6–24h (max: 2?g/24?hr).	*Cautions:* Photosensitivity, gastrointestinal upset, hyperuricemia, arthralgia, hepatotoxicity (especially doses >30?mg/kg/24?hr).
Rifabutin Mycobutin. Capsule: 150, 300?mg. Injection. Extemporaneous liquid formulation.	**Treatment (in combination with other antimycobacterial agents) and prevention of infections with *Mycobacterium avium* complex.** Inhibits DNA-dependent RNA polymerase. *Infants and children:* Treatment (preliminary guidelines): 5–7?mg/kg/24?hr PO once daily. Prophylaxis: 5?mg/kg/24?hr PO once daily. *Adults:* 300?mg PO once daily.	*Cautions:* Dosing information in pediatrics is evolving. Fever, headache, confusion, gastrointestinal upset, increased liver function tests, anemia, neutropenia may cause orange-red discoloration of secretions of urine, tears, sweat. *Drug interactions:* May enhance metabolism of many drugs: warfarin, corticosteroids, opiates, oral contraceptives.
Rifampin Rifadin, Rimactane. Capsule: 150, 300?mg. Injection. Extemporaneous liquid formulation.	**For use in combination with other agents.** *Children:* 10–20?mg/kg/24?hr PO or IV divided q12–24h. *Adults:* 10?mg/kg/24?hr PO or IV once daily (max: 600?mg/24?hr). Twice weekly therapy (after 3 mo daily therapy): *Children:* 10–20?mg/kg/dose (max: 600?mg) PO twice weekly. *Adults:* 10?mg/kg/dose (max: 600?mg) PO twice weekly.	*Cautions:* Hepatotoxicity, influenza-like syndrome, rash, pruritus, leukopenia, arthralgia; may cause orange-red discoloration of urine, tears, sweat. *Drug interactions:* Induces hepatic enzymes decreasing effect/concentrations of opiates, anticoagulants, barbiturates, carbamazepine, phenytoin, azole antifungals, cyclosporine, corticosteroids.
Rifapentine Priftin. Tablets: 150?mg.	**Treatment of pulmonary tuberculosis in combination with other drugs.** *Children >12 yr and adults:* 600?mg at intervals >72 hours for 2 mo; then 600?mg q wk for 4 mo.	*Cautions:* Red-orange discoloration of body fluids as with rifampin. Administer concomitant pyridoxine (vitamin B_6) to avoid neuropathy. *Drug Interactions:* Same as rifampin.
Streptomycin Generic. Injection.	**Aminoglycoside antibiotic used in combination with other agents.** *Neonates:* 10–20?mg/kg/24?hr IM q24h. *Children:* 20–40?mg/kg/24?hr IM divided q12h not to exceed 1?g/24?hr. *Adults:* 15?mg/kg/24?hr IM q24h, not to exceed 1?g/24?hr.	*Cautions:* Aminoglycoside adverse effect profile (ototoxicity and nephrotoxicity).

TABLE 712-4 -- **Antifungal Medications**

Drug (Trade Names, Formulations)	Indications (Mechanism of Action) and Dosing	Comments
Amphotericin B Lipid Complexes Abelcet (ABLC); Ambisome (liposome); Amphotec (ABCD). Injection.	**Polyene effective against a broad spectrum of fungi: *Candida, Aspergillus, Coccidioides, Histoplasma, Sporothrix, Blastomyces*.** Available as the traditional colloidal suspension and newer lipid-complex/liposomal formulations. Lipid formulations permit higher doses with increased patient tolerance. *Children and adults:* 2.5–5?mg/kg IV infused over 1–2?hr q24h; may use higher doses of 7.5–10?mg/kg/24?hr if indicated and if tolerated.	*Cautions:* Hypotension, fever, chills, flushing; pre-medicate with meperidine and acetaminophen. Drug augments potassium and magnesium excretion requiring aggressive monitoring and supplementation. Lipid formulations markedly attenuate renal toxicity. *Drug interactions:* Concurrent nephrotoxic drugs.
Caspofungin Cancidas. Powder for infusion: 50, 70?mg.	**Antifungal active against *Aspergillus*.** *Children:* 1–2?mg/kg/24?hr as single daily dose (dosing and use in pediatrics still investigational). *Adults:* Loading dose 70?mg day 1, then 50?mg q24h; infuse over 1?hr.	*Caution*: Reduce daily dose to 35?mg for moderate hepatic insufficiency

Clotrimazole Lotrimin, Gyne-Lotrimin. Troche, topical cream, vaginal tablets, and cream.	**Topical imidazole active against *Cryptococcus, Aspergillus, Candida*, and *Coccidioides* for the treatment of oropharyngeal, skin, vaginal infections.** *Children and adults:* 1 troche dissolved 5–6 times daily; vaginal cream/tablet: 100–200?mg qhs; topical cream: apply twice daily.	*Cautions:* Minimal adverse effects, nausea, skin irritation. Topical/troche ineffective for systemic infections.
Econazole nitrate Spectazole. Topical cream: 1%.	**Topical agent effective in the treatment of tinea corporis, cruris, pedis, and cutaneous candidiasis.** *Children and adults:* Apply over affected areas once daily.	*Cautions:* Minimal adverse effects—skin irritation.
Fluconazole Diflucan. Tablet: 50, 100, 150, 200?mg. Suspension: 10?mg/mL, 40?mg/mL. Injection.	**Imidazole effective against *Cryptococcus* and *Candida* infections of the oropharynx, vagina, meningitis.** *Neonates:* Thrush: 6?mg/kg IV or PO q24h for 1st day then 3?mg/kg/24?hr q24h for 14–21 days. Systemic infections: 6–12?mg/kg/24?hr IV or PO q72h for postnatal age <14 days or once daily for postnatal age >14 days. *Children:* 6–12?mg/kg/24?hr IV or PO q24h; cryptococcal meningitis: 12?mg/kg/24?hr 1st day then 6–12?mg/kg/24?hr IV or PO q24h.	*Cautions:* Dizziness, rash, nausea, abdominal pain, elevated liver function tests, superinfection with *C. krusei.* Reduce dose with reduced renal function. *Drug interactions:* Warfarin, oral antidiabetic agents, astemizole, cisapride, cyclosporine, phenytoin, rifampin, terfenadine, zidovudine.
Flucytosine Ancobon, 5FC. Capsule: 250, 500?mg.	**Used in combination with amphotericin B (resistance develops rapidly) against *Candida, Cryptococcus*, and *Aspergillus* infections.** *Neonates:* 50–100?mg/kg/24?hr PO divided q12–24hr. *Children and adults:* 100–150?mg/kg/24?hr PO divided q6–8h. Monitor blood levels.	*Cautions:* Confusion, rash, nausea, vomiting, bone marrow suppression with sustained serum concentrations >100?mg/L, elevation results of liver function tests. *Drug interactions:* Aluminum and magnesium salts delay absorption rate.
Griseofulvin Fulvicin, Grisactin. Microsize capsule: 125, 250?mg. Suspension: 125?mg/5?mL. Tablet: UF 250?mg, 500?mg. Ultra-microsize PG tablet: 125, 165, 250, 330?mg.	**Treatment of tinea infections of the hair, nails, and skin due to *Microsporum, Epidermophyton,* and *Trichophyton.*** Ultra-microsize formulation has almost complete absorption whereas absorption of microsize is variable (40–80%). *Children:* Microsize 10–20?mg/kg/24?hr PO divided q12–24h; ultra-microsize: 5–10?mg/kg/24?hr PO divided q12h. *Adults:* Microsize 500–1,000?mg/24?hr PO divided q12–24h; ultra-microsize: 330–375?mg/24?hr PO divided q12h.	*Cautions:* Headache, nausea, diarrhea, rash, photosensitivity. Administration with a fatty meal increases oral absorption. *Drug interactions:* Warfarin, phenobarbital, oral contraceptives, ?phenytoin.
Itraconazole Sporanox. Capsule: 100?mg.	**Synthetic triazole active against *Candida, Aspergillus, Cryptococcus*, and *Histoplasma*.** Limited dosing data in pediatrics. *Children:* 3–5?mg/kg/24?hr PO once daily; doses as high as 5–10?mg/kg/24?hr have been used. *Adults:* 200–400?mg/24?hr PO divided q12h; serious infections: 600?mg/24?hr q8h for 3–4 days then 200–400?mg/24?hr.	*Cautions:* Hypertension, nausea, headache, dizziness, rash, hepatitis. Food increases bioavailability. *Drug interactions:* Carbamazepine, isoniazid, rifampin, phenytoin, phenobarbital, cyclosporin. Antacids/H2 antagonists decrease bioavailability.
Miconazole Micatin, Monistat. Topical cream, vaginal tablet, lotion, powder. Injection.	**Imidazole active against *Cryptococcus, Candida, Coccidioides*, and *Pseudallescheria boydii* for topical or IV use in superficial infections.** *Neonates:* 5–15?mg/kg/24?hr IV divided q8–24h. *Children:* 20–40?mg/kg/24?hr IV divided q8h; vaginal cream/tablet 100–200?mg qhs; topical cream: apply twice daily. *Adults:* 200?mg stat then 1.2–3.6?g/24?hr IV divided q8h. *Bladder irrigation:* 200?mg in 25?mL saline.	*Cautions:* Dizziness, nausea, hyperlipidemia, tremors, rash, hives. Mostly used for the treatment of topical infections.

Natamycin Natacyn. Ophthalmic suspension: 5%.	**Fungal eye infections, e.g., blepharitis, conjunctivitis, keratitis caused by susceptible organisms (e.g., *Candida*, *Aspergillus*, *Cephalosporium*, *Fusarium*, and *Penicillium*).** Fungicidal by altering membrane permeability. *Children and adults:* Keratitis: Instill 1 drop into conjunctival sac every 1–2?hr for 3–4 days, then may reduce to 6–8 doses/24?hr. Blepharitis and conjunctivitis: instill 1 drop 4–6 times daily.	
Nystatin Mycostatin, Nilstat.	**Polyene effective against many yeasts and molds.** Oral candidiasis: *Neonates*: 100,000 units qid. *Infants:* 200,000 units qid. *Children and adults:* 400,000–600,000 units qid. Topical: Apply bid–qid.	*Cautions:* Minimal adverse effects with topical application, nausea, skin irritation. Tablet ineffective for systemic infections.
Terbinafine Lamisil. Tablet: 250?mg.	**Onychomycosis and tinea pedis.** *Children <20?kg:* 62.5?mg PO q24h (fingernails for 6 wk, toenails for 12 wk, tinea for 2 wk) *Children 20–40?kg:* 125?mg PO q24h (fingernails for 6 wk, toenails for 12 wk, tinea for 2 wk). *Children >40?kg and adults:* 250?mg PO q24h (fingernails for 6 wk, toenails for 12 wk, tinea for 2 wk).	*Cautions:* Administer with food for slightly increased bioavailibility (~20%) *Drug Interactions:* May interfere with CYP2D6 (tricyclic antidepressants, selective serotonin reuptake inhibitors, select ß-blockers. Metabolism increased by enzyme inducers.

TABLE 712-5 -- **Antiviral Medications**

Drug (Trade Names, Formulations)	Indications (Mechanism of Action) and Dosing	Comments
Acyclovir Zovirax. Capsule: 200?mg. Tablet: 400, 800?mg. Suspension: 200?mg/5?mL. Injection. Ointment.	**Herpes simplex (HSV) encephalitis, mucosal, cutaneous, genital infections; herpes zoster, varicella-zoster, cytomegalovirus (CMV) prophylaxis.** *Neonates:* HSV encephalitis: 60?mg/kg/24?hr IV divided q8h. *Children and adults:* 15?mg/kg/24?hr IV divided q8–12h. HSV infection in immunocompromised host: *Children and adults:* 15–30?mg/kg/24?hr IV divided q8h. HSV encephalitis/varicella infection/CMV prophylaxis in immunocompromised host: *Children and adults:* 30?mg/kg/24?hr IV divided q8h. Oral dosing for HSV/zoster infection: *Children and adults:* 1,200?mg/24?hr divided q4–8h (max pediatric dose: 80?mg/kg/24?hr).	*Cautions:* Headache, dizziness, rash, bone marrow suppression. Poor oral bioavailability—best given in frequent daily doses (e.g., q4h). Primarily renally eliminated. 4.2?mEq Na/g of acyclovir. *Drug interaction:* Probenecid, zidovudine.
Amantadine Symmetrel. Capsule: 100?mg. Syrup: 50?mg/5?mL.	**Prophylaxis and treatment (all ages) of influenza A infections.** Prophylaxis or treatment: *Children 1–9 yr or <40?kg:* 5?mg/kg/24?hr PO divided q12h (max: 150?mg/24?hr). *Children >9 yr and >40?kg and adults:* 200?mg/24?hr PO divided q12h.	*Cautions:* Anticholinergic effects, and may potentiate other anticholinergic medications. Drowsiness, dizziness, confusion, hypotension, urinary retention. Renally eliminated; reduce dose with renal impairment. No dosage reduction necessary for hepatic impairment. Not removed by hemodialysis.
Famciclovir Famvir. Tablet: 500?mg.	**Oral prodrug formulation of penciclovir used in the treatment of acute herpes zoster. Limited data in pediatrics.** *Adults:* 500?mg PO q8h for 7 days.	*Cautions:* Headache, dizziness, nausea, adjust dose in renal insufficiency (e.g., penciclovir). Rate of absorption, not overall bioavailability, reduced if taken with food.

Foscarnet Foscavir. Injection.	**Treatment of CMV infections, retinitis, and acyclovir-resistant HSV mucocutaneous infection, and herpes zoster.** CMV retinitis: IV infusion rate 60?mg/kg/hr. *Children and adults:* Induction therapy: 180?mg/kg/24?hr IV divided q8h; maintenance therapy: 90–120?mg/kg/24?hr IV once daily. Acyclovir-resistant HSV infection: *Children and adults:* 120?mg/kg/24?hr divided q8–12h.	*Cautions:* Hypertension, dizziness, seizures, decreased electrolytes (Ca, Mg, K), genitourinary complications, bronchospasm, nephrotoxicity. Adjust dose with renal dysfunction. IV infusion dilution for peripheral venous administration 12?mg/mL; central venous administration 24?mg/mL.
Ganciclovir Cytovene. Injection. Capsule: 250?mg.	**Treatment of CMV infections including retinitis.** CMV retinitis: *Children and adults:* Induction therapy: 10?mg/kg/24?hr IV (over 1–2?h) divided q12h for 14–21 days; maintenance therapy: 5–6?mg/kg/24?hr IV once daily. CMV disease and prophylaxis (solid organ transplant): Induction: 10?mg/kg/24?hr IV divided q12h for 7–14 days then 5–6?mg/kg/24?hr IV once daily.	*Cautions:* Headache, seizures, hypertension, nausea, marrow suppression, renal/liver toxicity, rash, photophobia. Primarily renally eliminated. *Drug interactions:* Probenecid, immunosuppressants. *Comment:* Oral dose form very poor bioavailability (5–6%).
Idoxuridine (IDU) Herplex. Ophthalmic solution: 1%.	**Topical therapy for herpes simplex keratitis.** *Children and adults:* Apply ointment 5 times daily and ophthalmic solution (1 drop) to affected eye(s) 7–10 times daily and at bedtime.	*Cautions:* Local irritation, pruritus, ocular edema.
Interferon alfa-2b Intron A. Powder for injection, lyophilized 3, 5, 10, 18, 25, and 50 million IU per vial. Solution for injection: 3, 5, 10, 18, and 25 million IU per vial.	**Chronic hepatitis B and chronic hepatitis C, and some neoplastic diseases.** *Adults:* Chronic hepatitis B dose: 5 million IU daily or 10 million IU 3 times/wk for total dose 30–35 million IU/wk SC or IM for 16 wk. Chronic hepatitis C dose: 3 million IU SC or IM 3 times weekly for 6 mo. *Children:* Safety and efficacy in children <18 yr not established.	*Cautions:* Flu-like symptoms and photosensitivity are common. Alanine aminotransferase often increases > 2 times baseline at 8–12 wk, especially in responders, and therapy should be continued if this occurs.
Interferon beta-1a/Interferon beta-1b Avonex/Betaseron. Powder for injection, lyophilized: 33?µg(6.6?mIU)/ 0.3?mg (9.6?mIU).	**Unlabeled use as antiviral agent for herpes of the lips or genitals, and acute non-A/non-B hepatitis. Labeled use is for relapsing-remitting multiple sclerosis.** *Adults:* 30?µg IM once weekly or 0.25?mg SC every other day. *Children:* Safety and efficacy in children <18 yr of age has not been established.	*Cautions:* Flu-like symptoms occur in up to 75% of patients. Photosensitivity is common.
Oseltamivir Tamiflu. Capsule: 75?mg. Suspension: 12?mg/mL.	**Use for prophylaxis or treatment of influenza A and B infections.** Acts by inhibiting influenza virus neuraminidase. Children: >1 yr: 30?mg q12h PO up to 15?kg; 45?mg q12h PO 16–23?kg; 60?mg q12h PO >23–40?kg and 75?mg PO q12h PO >40?kg. *Adults:* Treatment with 150?mg/24?hr divided q12h for 5 days (must be started within 2 days of onset of symptoms). Prophylaxis with 75?mg once daily for up to 6 wk if high risk of exposure.	*Cautions:* Most common adverse reactions include nausea, vomiting, and diarrhea.

Ribavirin Virazole. Powder for aerosol.	**Aerosol therapy for RSV infections, particularly for patients with underlying conditions, including bronchopulmonary dysplasia and/or congenital heart diseases.** *Children and adults:* Use SPAG-2 small particle generator at 20?mg/mL concentration for continuous aerosolization 12–18?hr per day. High-dose/short-duration aerosol administration under investigation.	*Cautions:* Rash, irritation, hypotension; drug may precipitate in ventilation tubing; use in well-ventilated areas, minimize staff contact. Best results when initiated early in clinical course.
Rimantadine Flumadine. Tablet: 100?mg. Syrup: 50?mg/5?mL.	**Prophylaxis (all ages) and treatment (>13 yr) of influenza A infections.** Prophylaxis only: *Children 1–9 yr or <40?kg:* 5?mg/kg/24?hr PO divided q12h (max: 150?mg/24?hr). *Children 10–13 yr:* 100?mg PO divided q12h. Prophylaxis or treatment: *Adolescents >13 yr and adults:* 200?mg/24?hr PO divided q12h.	*Cautions:* Anticholinergic effects, and may potentiate other anticholinergic medications. Drowsiness, dizziness, confusion, hypotension, urinary retention. Hepatically metabolized; reduce dosage to one-half usual dose for persons with severe liver disease or CrCl =10?mL/min.
Trifluridine Viroptic. Ophthalmic solution: 1%.	**Treatment of herpes simplex keratitis.** *Children and adults:* Instill 1 drop into affected eye(s) q2h while awake and at bedtime for up to 21 days.	*Cautions:* Local irritation, pruritus, ocular edema.
Vidarabine (Ara-A) Vira-A. Injection. Ophthalmic ointment.	**Herpes simplex and varicella zoster infections.** HSV infections: *Neonates:* 15–30?mg/kg/24?hr IV infusion over 18–24?hr. *Children and adults:* 15?mg/kg/24?hr IV once daily over 12?hr. Herpes zoster/varicella zoster infections: *Children and adults:* 10?mg/kg/24?hr IV once daily over 12?hr.	*Cautions:* Bone marrow suppression, disorientation, ataxia, seizures, syndrome of inappropriate secretion of antidiuretic hormone. Metabolites primarily renally eliminated. *Drug interactions:* Marrow suppressants.
Zanamivir Relenza. Blisters of powder for inhalation: 5?mg.	**Treatment of influenza infections type A and B via selective inhibition of influenza virus neuraminidase.** *Children and adolescents = 7 yr:* 2 inhalations (10?mg) q12h for 5 days. Day 1 administer 2 doses provided dosing interval is >2?hr.	*Cautions:* Administer with caution to patients with hyperreactive airway disease because bronchospasm may occur from the powder. If the patient uses a bronchodilator, pretreatment before the zanamivir dose is advised. May cause nausea, diarrhea, nasal symptoms, and sinusitis in a small proportion of patients. Best results if therapy is started within 2 days of onset of symptoms.

TABLE 712-6 -- Antiretroviral-HIV Medications

Drug (Trade Names, Formulations)	Indications (Mechanism of Action) and Dosing	Comments
Abacavir Ziagen. Tablet: 300?mg. Oral solution: 20?mg/mL.	**Nucleoside reverse transcriptase inhibitor for treatment of HIV-1 infection.** *Children > 3 mo and < 50?kg:* 8?mg/kg q12h (using oral solution). *Children >50?kg:* 20?mg/kg q12h or 15?mg/kg q8h (use capsules). *Adults:* 300?mg q12h.	*Cautions:* Nausea and vomiting 5–15%, diarrhea 5–10%; hypersensitivity reactions within first 6 wk of therapy.

Amprenavir Agenerase. Capsules: 50, 150?mg. Oral solution: 15?mg/mL.	**Protease inhibitor for treatment of HIV-1 infection.** *Children 4–12 yr or <50?kg:* 20?mg/kg bid or 15?mg/kg tid (max daily dose: 2,400?mg) as capsules; or 22.5?mg/kg bid or 17?mg/kg tid as oral solution. *Adolescents 13–16 yr and > 50?kg:* 1,200?mg bid. *Adults:* 1,200?mg bid. Reduce dose with moderate or severe liver impairment.	*Cautions:* May exacerbate diabetes mellitus or cause new- onset diabetes. Nausea, vomiting, diarrhea, rash, and taste disorders are also seen in > 3% of patients. Product provides relatively high doses of vitamin E. *Drug interactions:* Inhibits CYP3A4 liver enzymes and may cause toxic levels of warfarin, anticonvulsants, antiarrhythmics, calcium channel blockers, etc. Amprenavir is highly metabolized by cytochrome P450, and elimination may be altered by enzyme inhibitors or enzyme inducers.
Didanosine Videx, DDI. Chewable buffered tablet: 25, 50, 100, 150?mg. Buffered powder packet: 100, 167, 250?mg. Capule, delayed release: 125, 200, 250, 400?mg.	**Purine analog—intracellular metabolite inhibits viral RNA-directed DNA polymerase.** *Infants <90 days:* 100?mg/m^2 /24?hr PO divided q12h. *Children:* 180–300?mg/m^2 /24?hr PO divided q12h. *Adolescents (>13 yr) and adults <60?kg:* 125?mg PO q12h (buffered oral solution 167?mg PO q12h. *>60?kg:* 200?mg PO q12h (buffered oral solution 250?mg PO q12h). Administer on an empty stomach 1?hr before or 2?hr after a meal to decrease food effect.	*Cautions:* Headache (~30%), diarrhea, pancreatitis, peripheral neuropathy, optic neuritis, liver dysfunction. Renally eliminated. Food decreases bioavailability up to 50%. Tablets dissolved in water stable for 1?hr (4?hr in buffered solution). *Drug interactions:* Antacids/gastric acid antagonists may increase bioavailability; possible decreased absorption of ciprofloxacin, ganciclovir, ketoconazole, itraconazole.
Efavirenz Sustiva. Capsule: 50, 100, 200?mg.	**Non-nucleoside reverse transcriptase inhibitor used in combination with other antiretroviral agents to treat HIV-1 infection.** *Adolescents and adults:* 600?mg/24?hr, at bedtime. *Children = 3 yr:* 10–<15?kg = 200?mg; 15–<20?kg = 250?mg; 20–<25?kg = 300?mg; 25–<32.5?kg = 350?mg; 32.5–<40?kg = 400?mg; = 40?kg = 600?mg (give all doses once daily). Do not administer with fatty foods because absorption is increased 50%, but may administer with regular meals or without food.	*Cautions:* Combining with nelfinavir causes rash in 40% of pediatric patients. Severe CNS and psychiatric symptoms, including depression, may occur, especially if psychiatric or drug abuse history. False-positive screening tests for cannabinoid have been observed, but confirmatory tests are accurate. *Drug interactions:* Efavirenz induces CYP3A4 liver enzymes and may increase clearance of drugs metabolized by this pathway (e.g., warfarin, ethinyl estradiol) and several other HIV drugs. Drugs that induce CYP3A4 (e.g., phenobarbital, rifampin, rifabutin) will increase clearance of efavirenz. Drug also inhibits CYPs 2C9 and 2C19.
Indinavir Crixivan. Capsule: 100, 200, 333, 400?mg.	**Protease inhibitor for combination use with nucleoside analogs and other protease inhibitors. Evolving experience with neonatal and pediatric dosing.** *Children:* 1,500?mg/m^2 /24?hr PO divided q8h (max single dose: 800?mg). *Adults:* 2,400?mg/24?hr PO divided q8h. Chemoprophylaxis after high-risk exposure given in combination with zidovudine and lamivudine. Administer on an empty stomach 1?hr before or 2?hr after a meal to decrease food effect.	*Cautions:* Nephrolithiasis, nausea, hyperbilirubinemia, headache, diabetes. Reduce dose by ~25% with mild to moderate liver dysfunction. *Drug interactions:* Didanosine decreases absorption; rifampin reduces levels; ketoconazole, ritonavir, and other protease inhibitors decrease indinavir metabolism. Do not co-administer astemizole, cisapride, terfenadine.

Lamivudine Epivir, 3TC. Tablet: 150?mg. Solution: 5?mg/mL, 10?mg/mL.	**Reverse transcriptase inhibitor used in combination with zidovudine and/or other anti-HIV drugs. Evolving experience with neonatal and pediatric dosing.** *Infants, children and adolescents:* 8?mg/kg/24?hr PO divided q12h (max dose: 300?mg). *Adults:* 300?mg/24?hr PO divided q12h. Suggested chemoprophylaxis regimen for occupational exposure: lamivudine, 150?mg PO q12h, with zidovudine, 200?mg PO q8h, and indinavir, 800?mg PO q8h.	*Cautions:* Headache, psychomotor disorders, nausea, feeding problems, abdominal pain, pancreatitis, neutropenia, musculoskeletal pain. Adjust dose in patients with creatinine clearance <30?mL/min. Medication may be administered with or without food. *Drug interactions:* Trimethoprim/sulfamethoxazole may increase 3TC levels.
Nelfinavir Viracept. Tablet: 250?mg. Suspension: 250?mg/5?g powder.	**Protease inhibitor as monotherapy or preferably in combination with nucleoside analogs and other protease inhibitors. Evolving experience with neonatal and pediatric dosing.** *Neonates:* 30?mg/kg/24?hr PO divided q8h under study. *Children and adolescents:* 60–135?mg/kg/24?hr PO divided q8h. *Adults:* 750?mg/dose PO q8h or 1250?mg PO q12h. Administer with a meal to optimize absorption; avoid acidic food or drink (e.g., orange juice). Tablet can be dissolved in water to administer as a solution.	*Cautions:* Many adverse effects including hypertension, headaches, dizziness, diarrhea, anemia, leukopenia, hepatitis, iritis, dyspnea, sweating. *Drug interactions:* Rifampin, phenobarbital, carbamazepine reduce levels; ketoconazole, ritonavir, indinavir, and other protease inhibitors decrease nelfinavir metabolism. Nelfinavir inhibits CYP3A4 activity. Do not co-administer astemizole, cisapride, terfenadine. May interfere with oral contraceptives.
Nevirapine Viramune. Tablet: 200?mg. Suspension: 50?mg/5?mL.	**Non-nucleosides reverse transcriptase inhibitor specific for HIV-1 transcriptase (not HIV-2) or human polymerase. Evolving experience with neonatal and pediatric dosing.** *Neonates:* 5?mg/kg/24?hr PO for 14 days, then 240?mg/m^2 /24?hr PO divided q12h for 14 days, then 400?mg/m^2 /24?hr PO divided q12h. *Children:* 240?mg/m^2 /24?hr PO divided q12h for 14 days; if tolerated, increase dose to maximum dose 400?mg/m^2 /24?hr PO divided q12h, or 400?mg/24?hr. *Adolescents and adults:* 200?mg PO q24h for 14 days; if tolerated, 200?mg/dose q12h.	*Cautions:* Severe rash, Stevens-Johnson syndrome, headache, nausea, diarrhea, increased liver function tests. May give with or without food. *Drug interactions:* Nevirapine induces hepatic CYP450 3A activity and decreases indinavir, saquinavir concentrations; rifampin decreases nevirapine serum levels; cimetidine, macrolides block metabolism.
Ritonavir Norvir. Capsule: 100?mg. Solution: 80?mg/mL.	**Protease inhibitor often effective against saquinavir and zidovudine-resistant virus; ritonavir-resistant strains often cross-resistant with other agents.** *Children:* 400?mg/m^2 /24?hr PO divided q12h; titrate upward in 50?mg/m^2 per dose increments to 800?mg/m^2 /24?hr PO q12h. *Adolescents and adults:* 400–600?mg per dose PO q12h. Administer dose with food to enhance. bioavailability	*Cautions:* Headache, nausea, taste aversion, pancreatitis, elevated serum lipids, elevated liver function tests, hypoglycemia, rash. *Drug interactions:* Ritonavir is a substrate and has affinity for many hepatic CYP450 enzymes that may lead to many important drug interactions (e.g., protease inhibitors, antiarrhythmics, antidepressants, cisapride). Ritonavir metabolism is influenced by enzyme inducers and inhibitors

Saquinavir Invirase, hard gelatin capsule. Mesylate capsule: 200?mg. Gelatin liquid-filled (Fortovase) capsule: 200?mg.	**Protease inhibitor. Dosing information in neonates, infants, and children is evolving.** = *16 yr:* Liquid filled (Fortovase base): 1200?mg q8h PO, hard gelatin capsule (Inverase-mesylate salt): 600?mg q8h PO) Administration with a high-fat meal enhances bioavailability. Concurrent grapefruit juice may increase bioavailability.	*Cautions:* Photosensitivity, changes in blood pressure, confusion, ataxia, nausea, elevated liver function tests, rash, marrow suppression, bleeding. *Drug interactions:* Rifampin, phenobarbital, carbamazepine decreases serum levels; saquinavir may decrease metabolism of calcium channel antagonists; azoles (e.g., ketoconazole), macrolides, indinavir, ritonavir may increase levels.
Stavudine Zerit; d4T. Capsule: 15, 20, 30, 40?mg. Powder for oral suspension.	**Nucleoside analog reverse transcriptase inhibitor. Dosing information in neonates and infants is evolving.** *Children <30?kg*: 2?mg/kg/24?hr PO divided q12h. *Adolescents and adults:* 30–60?kg 30?mg per dose PO q12h; >60?kg 40?mg per dose PO q12h.	*Cautions:* Peripheral neuropathy, headache, nausea, pancreatitis, elevated liver function tests, rash. Primary renal elimination. *Drug interactions:* Other drugs associated with peripheral neuropathy (e.g., cisplatin, gold, isoniazid).
Zalcitabine Hivid; ddc. Tablet: 0.375, 0.75?mg.	**Nucleoside analog reverse transcriptase inhibitor. Dosing information in neonates, infants, and children is evolving.** *Children:* 0.01?mg/kg PO q8h. *Adolescents and adults:* 0.75?mg PO q8h. Doses best taken 1?hr before or 2?hr after a meal.	*Cautions:* Cumulative dose-related peripheral neuropathy, pancreatitis. Cardiac dysfunction, lactic acidosis, marrow suppression, hepatitis, jaundice, rash. Primary renal elimination. *Drug interactions:* Magnesium and aluminum antacids, metoclopramide may decrease absorption; other drugs associated with peripheral neuropathy (e.g., cisplatin, gold, isoniazid).
Zidovudine Retrovir, AZT, ZDV. Capsule: 100?mg. Tablet: 300?mg. Syrup: 50?mg/5?mL. Injection.	**Nucleoside analog reverse transcriptase inhibitor. Dosing information in premature neonates is evolving.** *Neonates:* 8?mg/kg/24?hr PO divided q6h; 6?mg/kg/24?hr IV divided q6h. *Children 6 wk–12 yr:* 480?mg/m^2 /24?hr PO divided 8h; 360?mg/m^2 /24?hr IV divided q6h; continuous infusion 20?mg/m^2 /hr. *Children >12 yr and adults:* 200?mg per dose PO q8h or 300?mg per dose PO q12h; 1–2?mg/kg per dose IV q4h.	*Cautions:* Headache, seizure, lactic acidosis, diarrhea, bone marrow suppression, cholestatic hepatitis, rash. Primarily renal elimination. Infuse IV over 1?hr at a final concentration of 4?mg/mL. *Drug interactions:* Rifampin may increase metabolism; cimetidine, fluconazole, valproic acid may decrease metabolism.

TABLE 712-7 -- **Antiparasitic Medications**

Drug (Trade Names, Formulations)	Indications (Mechanism of Action) and Dosing	Comments
Atovaquone Mepron. Suspension: 750?mg/5?mL.	**Alternative therapy for mild to moderate *Pneumocystis carinii* pneumonia in patients intolerant of trimethoprim/sulfamethoxazole. Very limited experience with the drug in children.** Treatment of *P. carinii* pneumonia: *Children <13 y:* limited data, 40?mg/kg/24?hr PO q12h. *Adolescents and adults:* 750?mg PO q12h. Prophylaxis of *P. carinii: Children <13 yr,* limited data, 40?mg/kg/24?hr PO q12h. *Adolescents and adults:* 1500mg PO qd. Toxoplasmosis prophylaxis: *Adolescents and adults:* 1500?mg PO qd. Administer doses with food.	*Cautions:* Dizziness, fever, rash, elevations in liver enzymes, neutropenia. Drug absorption increased when co-administered with food. *Drug interaction:* Rifampin may decrease levels.

Chloroquine phosphate Aralen, generic. Tablet: 250?mg (contains 150?mg base) and 500?mg (contains 300?mg base). Injection.	**Effective in the suppression and treatment of malaria and extraintestinal amebiasis. Dose drug on base equivalent.** Malaria prophylaxis: *Children:*5?mg/kg/wk PO (max: 300?mg/dose). *Adults:*300?mg/wk PO. Acute malaria treatment: *Children:*10?mg/kg PO initial dose (max dose: 600?mg); 5?mg/kg 6?hr later then 5?mg/kg PO once daily for 2 days. IM 5?mg/kg initial dose, 5?mg/kg 6?hr later (max IM dose: 10?mg/kg/24?hr). *Adults:*600?mg PO initially, 300?mg 6?hr later then 300?mg PO once daily for 2 days. Extraintestinal amebiasis: *Children:*10?mg/kg PO daily for 2–3 wk (max daily dose: 300?mg). *Adults:*600?mg PO once daily for 2 days then 300?mg once daily for 2–3 wk.	*Cautions:*Hypotension, headache, confusion, psychotic episodes, rash, peripheral neuropathy, blood dyscrasias, retinopathy, tinnitus. Administer with meals to decrease gastrointestinal upset. Liquid may be prepared from tablets using strong flavoring agent (cherry or chocolate) to mask bitter taste.
Furazolidone Furoxone. Tablet: 100?mg. Suspension: 50?mg/15?mL.	**Effective in the treatment of protozoal diarrhea, enteritis.** *Infants >1 mo and children:*5–9?mg/kg/24?hr PO divided q6h (max daily dose: 400?mg). *Adults:*100?mg/dose PO q6h.	*Cautions:*May cause hemolytic anemia in infants <1 mo of age; caution in glucose-6-phosphate dehydrogenase deficiency, hypotension, nausea, vomiting, hypoglycemia, hypersensitivity reactions, pulmonary infiltration. *Drug interactions:*Monoamine oxidase inhibitors; disulfiram-like alcohol reaction.
Lindane Kwell, Scabene. Lotion: 1%. Shampoo: 1%.	**Topical treatment for scabies, head lice*(Pediculus capitis),* crab lice *(Pediculus pubis)*.** *Scabies:*Apply thin layer to affected area, remove (by showering) in 6–8?hr in children and after 18–24?hr in adults. *Pediculosis:*Shampoo with adequate amount (15–30?mL) and lather for 5?min then rinse thoroughly and comb.	*Cautions:*Dermal absorption may cause seizures, dizziness, hepatitis, blood dyscrasias. Do not apply to denuded/inflamed skin; avoid contact to eyes/mucous membranes.
Mebendazole Vermox, generic. Chewable tablet: 100?mg.	**Treatment of ascariasis (roundworm), hookworm, enterobiasis (pinworm), trichuriasis (whipworm).** *Children and adults:* Pinworm: 100?mg PO once; may repeat in 2 wk. Hookworm/roundworm/whipworm: 100?mg PO q12h for 3 consecutive days; 2nd course, if needed, in 3–4 wk. Capillariasis: 200?mg PO q12h for 3 wk.	*Cautions:*Very well tolerated; dizziness, nausea, rash, leukopenia, transient elevation in liver function tests. Enhanced absorption when administered with food. Tablets may be chewed or swallowed whole.
Metronidazole Flagyl, Metro-IV, generic. Topical gel, vaginal gel. Tablet: 250, 500?mg. Injection.	**Effective in the treatment of anaerobic and protozoal infections particularly, amebiasis, giardiasis, trichomoniasis.** Amebiasis: *Children:*35–50?mg/kg/24?hr PO divided q8h. *Adults:*500–750?mg per dose PO q8h. Other parasitic infections *Children:*15–30?mg/kg/24?hr PO divided q8h. *Adults:*250?mg per dose PO q8h; alternate dose 2?g single-dose therapy.	*Cautions:*Dizziness, seizures, metallic taste, nausea, disulfiram-like reaction with alcohol. Administer IV slowly over 30–60?min. *Drug interactions:*Carbamazepine, rifampin, phenobarbital may enhance metabolism; may increase levels of warfarin, phenytoin, lithium.
Niclosamide Niclocide. Chewable tablet: 500?mg.	**Effective in the treatment of tapeworm infections (beef, fish, dog/cat, and dwarf tapeworms). Drug active against intestinal cestodes only.** Beef and fish tapeworm: *Children:*40?mg/kg PO once (max dose: 2?g). *Adults:*2?g PO once. May repeat in 7 days. Dwarf tapeworm: *Children:*40?mg/kg q24h PO for 7 days (max daily dose: 2?g). *Adults:*2?g q24h PO for 7 days.	*Cautions:*Dizziness, headache, rash, alopecia, abdominal pain, nausea. Patients should chew tablets completely. *Drug interactions:*Hepatic enzyme inducers may enhance metabolism (e.g., carbamazepine, rifampin, phenobarbital).

Pentamidine isethionate Pentam, Nebupent. Inhalation, injection.	**For the treatment and prevention of *Pneumocystis carinii* pneumonia usually in patients intolerant of trimethoprim/sulfamethoxazole.** *Pneumocystis carinii*pneumonia treatment: *Infants (> 4 mo) children, and adults:*4?mg/kg/24?hr IM or IV for 14–21 days. *Pneumocystis carinii*prophylaxis: *Children and adults:*4?mg/kg/dose IM, IV q 2–4 wk. Aerosol once/mo using Respigard II nebulizer: *Infants:*Use dose formula (2.27?mg/kg pentamidine) ×[nebulizer output (L/min)] × patient body weight (kg) divided by alveolar ventilation (L/min). *Children >5 yr:*300?mg per dose q 4 wk. *Adults:*300?mg q 4 wk.	*Cautions:*Hypotension, tachycardia, dizziness, hypoglycemia, nausea, marrow suppression, pain at injection site, nephrotoxicity, irritation of airway, cough, bronchospasm with aerosol. Adjust dose with renal dysfunction. IV route preferred. *Drug interactions:*Other nephrotoxins (aminoglycosides, vancomycin, amphotericin B, cyclosporine).
Permethrin Elimite, Nix. Cream: 5%. Creme rinse: 1%.	**Topical treatment for scabies, head lice*(Pediculus capitis),* crab lice*(Pediculus pubis)*.** Head lice: *Children and adults:*wash areas, rinse, apply creme rinse liberally, leave on hair for 10?min, rinse and comb. May repeat treatment in 7 days. Scabies: *Children and adults:*Apply and leave on for 8–16?hr before removing with water.	*Cautions:*Dermal absorption unlikely. Do not apply to denuded/inflamed skin; avoid contact to eyes/mucous membranes. May cause rash.
Piperazine citrate Vermizine, generic. Tablet: 250?mg.	**Alternative therapy for pinworm and roundworm.** Pinworm: *Children and adults:*65?mg/kg/24?hr PO once daily for 7 days; may repeat course in 7 days. Roundworm: *Children and adults:*75?mg/kg/24?hr PO once daily for 2 days (max dose: 3.5?g/24?hr); may repeat course in 7 days.	*Cautions:*Neurotoxicity, dizziness, seizures, tremor, visual disturbances, allergic reactions.
Praziquantel Biltricide. Tablet: 600?mg.	**Effective in all stages of schistosomiasis and many intestinal tapeworm and trematode infestations.** Schistosomiasis: *Children and adults:*20?mg/kg/dose PO q8h for 1 day. May be effective at lower dose (20?mg/kg PO q12h for 1 day). Other trematodes: *Children and Adults:*75?mg/kg/24?hr PO divided q8h for 1–2 days. Tapeworm: *Children and adults:*5–10?mg/kg as a single dose.	*Cautions:*Central nervous system depression, dizziness, fever, rash, abdominal pain, eosinophilia. *Drug interaction:*Alcohol may increase CNS depression.
Primaquine phosphate Tablet: 26?mg (15?mg base).	**Effective in the prevention and treatment of malaria. Dose drug on base equivalent.** *Children:*0.3?mg base/kg/24?hr PO once daily for 14 days (max daily dose: 15?mg). *Adults:*15?mg PO once daily for 14 days.	*Cautions:*Pruritus, abdominal complaints, anemia, methemoglobinemia. Caution in patients with G6PD or NADH methemoglobin reductase deficiency.
Pyrantel pamoate Antiminth; Pin-Rid. Capsule: 180?mg. Liquid: 50, 144?mg/mL. Suspension: 50?mg/mL.	**Treatment of ascariasis (roundworm) hookworm, enterobiasis (pinworm), and trichostrongyliasis infections.** *Children and adults:* Pinworm, roundworm, trichostrongyliasis: 100?mg PO once; may repeat in 2 wk. Hookworms, roundworms, or whipworms: 11?mg/kg PO single dose (max dose: 1?g); may repeat in 2 wk for pinworm infestation. Hookworms: 11?mg/kg PO once daily for 3 consecutive days (max dose: 1?g/24?hr).	*Cautions:*Rash, elevation in liver function tests, abdominal cramps, dizziness, headache. *Drug interaction:*Possible antagonism of piperazine activity.

Pyrimethamine Daraprim. Tablet: 25?mg.	**Prophylaxis and in combination with other drugs for the treatment of malaria in combination with sulfa in treatment of toxoplasmosis and in combination with dapsone for prophylaxis against *P. carinii* infection in HIV patients.** Malaria prophylaxis: Begin drug 2 wk before entering endemic areas. Use for malaria decreasing owing to increased resistance and adverse effects. *Children:* 0.5?mg/kg once wk (max dose: 25?mg). Chloroquine-resistant malaria (with quinine and sulfa). Toxoplasmosis (with sulfadiazine): *Children:* 2?mg/kg/24?hr PO divided q12h for 2–3 days then 1?mg/kg/24?hr PO q24?hr, with sulfadiazine for 6 mo then 1?mg/kg/24?hr PO q24hr, 3 times/wk (max daily dose: 25?mg/24?hr). *Adults:* 50–75?mg plus 1–4?g sulfadiazine PO 3 times/wk. *Toxoplasma gondii* prophylaxis: *Infants >1 mo:* 1?mg/kg/24?hr PO q24h plus dapsone. *Adolescents and adults:* 50?mg PO once weekly plus dapsone. *Pneumocystis carinii* prophylaxis: *Adolescents and adults:* 50–75?mg PO once wk plus dapsone.	*Cautions:* Administer folinic acid (5–10?mg/kg 3 times/wk) to prevent hematologic toxicity; seizures, headache, photosensitivity, rash, folic acid deficiency, marrow suppression, tremor. Tablets may be crushed to prepare an extemporaneous suspension formulation.
Quinine Quinamm, generic. Capsule: 65, 200, 300, 325?mg. Tablet: 162.5, 260?mg.	**Antimalarial agent with decreasing effectiveness as resistance increasingly develops.** Chloroquine-resistant malaria: *Children:* 30?mg/kg/24?hr PO divided q8h for 3–7 days with another antimalarial agent. *Adults:* 650?mg per dose PO q8h for 3–7 days with another antimalarial agent.	*Cautions:* Glucose-6-phosphate dehydrogenase hemolysis, flushing, tachycardia, fever, headache, rash, nausea, tinnitus, cinchonism. *Drug interactions:* Interferes with digoxin disposition; aluminum-containing antacids decrease absorption.

Chapter 713 - Herbal Medicines

2502

Kathi J. Kemper
Paula Gardiner

Herbs and other dietary supplements are the most commonly used complementary therapies for children and adolescents. Several billion dollars are spent on these products each year in the United States. In a survey conducted in the late 1990s by the Puget Sound Pediatric Research Network, approximately one third of parents reported having given their child products containing *Echinacea* to prevent or treat upper respiratory tract infections. In other surveys, 20–30% of children or adolescents report using herbs or other dietary supplements such as creatine, androstenedione, and protein powders. Rates are higher among children with chronic, incurable, or recurrent conditions such as cystic fibrosis, cancer, arthritis, inflammatory bowel disease, and recurrent otitis media. Because physicians have not routinely asked patients and families about their use of these products, only 40% of patients who use herbs have talked with their physician about their use.

Herbal products are widely perceived as being safe because they are natural. They are also frequently considered as having low therapeutic efficacy, owing to a paucity of publications about them in scientific journals. However, conventional wisdom about herbs may be mistaken, resulting in risks to patients and providers.

Although as a general rule most herbs are safer and less costly than most medications, herbal products can cause serious toxicity. Acute hepatic toxicity and death may result from ingestion of even small amounts of *Amanita* mushrooms; overdoses of other herbs, such as digitalis, ephedra, and pennyroyal can cause life-threatening complications. Despite its historical use for spiritual and medicinal purposes, chronic use of tobacco has become a leading cause of morbidity and mortality in the past century. Although they may not cause problems with one-time use, chronic use of other herbs, such as *Aristolochia*, coltsfoot, and comfrey can cause severe hepatic or renal damage and cancer. As with medications, even when an herb is safe when used correctly, it can cause mild or severe toxicity when used incorrectly. For example, tea tree oil is safe when applied to mild fungal infections of the skin but can cause stinging and irritation when applied to eczema; if taken orally, it can cause coma in small children and animals. Furthermore, some persons are more sensitive to adverse effects than others; although most persons note only bad breath or body odor when taking garlic supplements, others report severe gastrointestinal distress after eating even moderate amounts of garlic. Similarly, although peppermint is a commonly used and usually benign gastrointestinal spasmolytic (included in after-dinner mints and teas and increasingly used to ease discomfort during colonoscopy), it can exacerbate gastroesophageal reflux in other patients.

The potency of herbal products is far less consistent than pharmaceutical medications. Because of natural variability, herbal products may contain widely varying concentrations of active ingredients; variations of 10- to 1,000-fold have been reported for several popular herbs by independent consumer testing groups. Labels are not required to reflect accurate content or concentrations of ingredients. Herbal products may be unintentionally contaminated with pesticides, animal wastes, or the wrong herb that was misidentified during harvesting. Products from developing countries may contain toxic levels of mercury, cadmium, or lead, either from unintentional contamination during manufacturing or from intentional additions by producers who believe these metals have therapeutic value. Thirty to 40% of Asian patent medicines include potent pharmaceuticals such as analgesics, antibiotics, hypoglycemic agents, or corticosteroids; typically, the labels for these products are not written in English and do not note the inclusion of pharmaceutical agents.

Even when herbal products contain known amounts of standardized ingredients and are used correctly, they may cause serious interactions with other medications. For example, St. John's wort can enhance elimination of digoxin, protease inhibitors, and numerous antibiotics, leading to subtherapeutic serum levels of these important medications; it can also increase the risk of serotonin syndrome in patients taking antidepressant medications. Ginkgo increases the risk of bleeding in patients taking anticoagulants. Licorice may enhance the anti-inflammatory effects and adverse effects of glucocorticoid medications. Ma huang (ephedra) increases the cardiovascular and sympathetic nervous system effects of a number of medications such as decongestants.

In the United States, herbal products are not regulated like medications. The 1994 Dietary Supplement and Health Education (DSHEA) Act allows herbal products to be marketed without prior testing for efficacy or safety. Products may contain little or none of the herb on the label, and they may contain other herbs. Product labels may make “structure-function” claims but may not claim to prevent or treat specific medical conditions. For example, a label may claim that a product “promotes a healthy immune system” but it may not claim to cure the common cold. The U.S. Food and Drug Administration (FDA) can only begin the process of restricting sales of certain products after receiving reports of adverse effects. As with medications, adverse reactions to herbs should be reported to the FDA's MedWatch program (https://www.accessdata.fda.gov/scripts/medwatch/); failure to do so limits the FDA's ability to monitor and manage the clinical and public health risks of these products.

Some herbal products may be helpful adjunctive treatments for common childhood problems. For example, one study documented that 3–4?oz/day of an herbal tea (containing chamomile, fennel, vervain, licorice, and balm-mint) was significantly more effective than a placebo tea as a treatment for infant colic. Numerous studies have documented the wound healing properties of topical aloe vera. Other studies have proven that ginger is an effective antiemetic. Kava kava, gotu kola, hops, lemon

balm, lavender and passion flower, and valerian have mild anxiolytic and/or sedative effects. Herbal ear drops provide mild analgesia for mild to moderate otitis media.

As with medications, most herbs have undergone far more testing in adult than in pediatric populations. Typically, herbalists recommend that teenagers use adult doses, children 7–12 yr of age use half of the adult dose, children 3–6 yr of age use one fourth of the adult dose, and herbs be used only cautiously, if at all, in children 2 yr of age or younger. Herbs used for common conditions and the toxicity of selected herbs are described in Tables 713–1 through 713–4 and resources for information on herbal medicine are listed in Box 713–1 .

TABLE 713-1 -- **Herbs for Asthma**

Herb or Combination	RCTs?	Demonstrated Benefit?	Adverse Effects/Drug Interactions	Purported Mechanism
Coffee/tea	None recently in children	Epidemiologic data suggest fewer symptoms in coffee drinkers	Tachycardia, insomnia, jitteriness, decreased appetite; potential interaction with ß-agonist	Methylxanthines Increased intracellular cAMP Bronchodilator
Shinpi-To	None in children	Yes, in historical data	Unknown. Potential interaction with leukotriene blockers	Blocks 5-lipo-oxygenase and phospholipase A_2
Saiboku-To	Yes in adults	Yes, corticosteroid-sparing in adults	Unknown. Potential increase in corticosteroid adverse effects	Inhibits 11 ß-hydroxylase (blocks steroid breakdown) Blocks 5-lipo-oxygenase Inhibits platelet-activating factor
Ma huang (*Ephedra sinica*)	Yes	Yes	Cardiovascular and central nervous system toxicity, deaths reported, potential interaction with ß-agonists	ß-Agonist Bronchodilator
Licorice (*Glycyrrhiza glabra*)	No	Case series suggest corticosteroid-sparing effects	Pseudohyperaldosteronism, hypertension, peripheral edema, potential increase in corticosteroid adverse effects	Inhibits 11 ß-hydroxylase and cortisol breakdown
Coleus forskolii	No	Case series in adults	Unknown	Decreased cAMP metabolism Bronchodilator
Tylophora indica	Yes in adults	Yes	Unknown	Unknown
Ginkgo biloba	No	Yes in pilot study	Unknown	Platelet-activating factor antagonist Antioxidant
Onions (*Allium cepa*)	No	In vitro and animal data support use	Hypersensitivity is rare	Blocks leukotriene synthesis
Bee pollen	No	No	Anaphylaxis	Unknown

RCT = randomized controlled trials; cAMP = cyclic adenosine monophosphate.

From Kemper KJ, Lester MR: Alternative asthma therapies: An evidence-based review.Contemp Pediatr 1999;16:162–95.

TABLE 713-2 -- **Commonly Used Sedative Herbs**

Sedative Herbs	Scientific Studies	Potential Adverse Effects or Interactions	Adult Dose
German chamomile	In controlled trials, chamomile and its constituents have positive effects as a mild sedative.	*Adverse effects*: Allergic reactions *Pregnancy and lactation*: no known adverse effects in pregnancy, lactation, and childhood *Drug interactions*: none known	*Tea*: 150?mL of boiling water over 3?g fresh flower heads, steep for 5–10?min; 3 × day.
Hops (*Humulus lupulus)*	Historical and anecdotal use. Controlled trials have used hops/ valerian combinations; these show improvements in sleep with the combination.	*Adverse effects*: allergic reactions, skin irritation *Pregnancy and lactation*: no data available *Drug interactions*: sedative activity increases the sleeping time induced by pentobarbital	*Tea*: 0.5 to 1?g dried hops before bed, typically in combination with valerian

Kava kava (*Piper methysticum*)	Randomized controlled trials in adults demonstrate anxiolytic effects.	*Adverse effects*: drowsiness, lethargy; slowed reaction time; withdrawal syndrome; chronic use may lead to yellow, dry skin and red eyes *Pregnancy and lactation*: insufficient information available *Drug interactions*: may potentiate sedative and anxiolytic effects of other herbs and medications	60–120?mg kava lactones up to 300?mg of kava lactones daily to dried root/rhizome: 1.5–3.0?g/day in divided doses
Lavender (*Lavandula*)	Animal data and adult case series and controlled trials suggest anticonvulsant and sedative effects.	*Adverse effects*: allergies with topical use; toxic if large doses taken internally *Pregnancy and lactation*: historically contraindicated during pregnancy owing to possible emmenagogue effects; no documented adverse effects *Drug interactions*: may potentiate sedative and anticonvulsant effects of other drugs	*Massage aromatherapy*: 1–10?mL of the essential oil can be added to 25?mL of a carrier oil. *Bath soak*: add ¼ – ½ cup of dried lavender flowers to the hot bath water.
Lemon balm (*Melissa officinalis)*	Animal data suggest sedative hypnotic effects. All RCTs have examined lemon balm/valerian combinations; most show enhanced sleep quality.	*Adverse effects*: allergic reactions are possible *Pregnancy and lactation*: insufficient data; generally recognized as safe *Drug interactions*: none known	*Tea*: 2–3?g of dried herb, steeped in water; usually combined with valerian or lavender
Passionflower (*Passiflora alata*)	Case reports and historical use; most often combined with other herbs such as valerian. *Drug interactions*: none known.	*Adverse effects*: allergic reactions are possible *Pregnancy and lactation*: insufficient data;	*Tea*: 0.25–1?g (about 1 tsp. of crushed dried flowers per cup water) *Solid extract*: 150–300?mg (sold in capsules) daily
Valerian (*Valeriana officinalis*)	Randomized double-blind placebo controlled studies in adults show decreased sleep latency and improved sleep quality.	*Adverse effects*: headaches, insomnia *Pregnancy and lactation*: insufficient data *Drug interactions*: sedative activity increases the sleeping time induced by pentobarbital	*Tea:* 2–3?g of fresh or dried root per cup; 1–3 × day. *Capsules*: 400?mg before bed

From Gardiner P, Kemper KJ: Herbs for sleep problems. Contemp Pediatr 2002;19(2):69–87 and Gardiner P, Kemper KJ: Herbs in pediatric and adolescent medicine. Pediatr Rev 2000;21:44–57.

TABLE 713-3 -- Herbs for Skin Conditions

Action	Herb/Supplement for Topical Use
Soothing/emollient	Aloe, calendula
Anti-inflammatory	Aloe, chamomile, evening primrose oil (PO), lemon balm
Antiviral	Aloe vera, calendula, chamomile, lemon balm
Antibacterial	Aloe vera, calendula, chamomile, lavender, lemon balm, tea tree oil
Antifungal	Lavender, tea tree oil

From Gardiner P, Coles D, Kemper KJ: The skinny on herbal remedies for dermatologic disorders.Contemp Pediatr 2001;18:103–4, 107–10, 112–14.

TABLE 713-4 -- Potentially Toxic Herbs

Herb	Toxic Constituents	Typical Uses	Potential Acute Adverse Effects	How to Treat Overdose

Aconitum (monkshood, wolfsbane)	Di-ester alkaloids: hypaconitine and aconitine (aconitine increases permeability for sodium ions and slows down repolarization leading to paralysis of the nerve)	Facial neuralgia and sciatica Headache and migraines Rheumatic pain, arthritis, gout Pericarditis sicca	Nausea, vomiting, and hypersalivation CNS: paresthesias, muscular weakness dizziness, ataxia, seizures, and coma Cardiac: bradycardia, hypotension, rhythm disorders	Supportive ca Dioxin-specific antibodies, unless history excludes cardi glycosides Do not give ipecac Activated charcoal and gastric emptyi may help Avoid type 1 antiarrhythmic
Artemisia absinthium (wormwood)	Thujone and isothujone—neurotoxins	Anorexia Dyspeptic conditions Liver and gallbladder disorders	Mental status changes: restlessness, vertigo, tremors, agitation and seizures, headache Vomiting, stomach and intestinal cramps Rhabdomyolysis and renal failure	Supportive ca Benzodiazepi
Atropa belladonna (deadly nightshade)	Alkaloids: hyoscyamine (the L-isomer of atropine	Gastrointestinal complaints Cardiac insufficiency and arrhythmia Asthma	Anticholinergic reaction: tachycardia, hyperthermia, mydriasis, urinary and bowel retention, restlessness Nervous system and respiratory depression	Gastric lavage Physostigmine given in consultation w poison special External cooli if temperature >102°F Benzodiazepi Hydration
Digitalis purpurea (foxglove)	Cardioactive glycosides: purpurea glycoside, digitoxin gitoxin,	Ulcers, boils, headaches, abscesses, paralysis, cardiac insufficiency	Nausea and vomiting, headache, loss of appetite Cardiac rhythm disorders Central nervous system: stupor, confusion, visual disorders, depression, psychosis, hallucinations	Supportive ca Gastric lavage Activated charcoal Treat the symptoms
Ephedra sinica (ma huang) Common names: Miner's tea Mexican tea Desert herb	Alkaloids: ephedrine, pseudoephedrine (stimulates sympathomimetic receptors and the central nervous system)	Decongestant for upper respiratory infection Asthma Weight loss Stimulant	Cardiac: hypertension, cardiomyopathy, myocardial infarction, arrhythmias Central nervous system: dizziness, restlessness, headaches, anxiety, hallucinations, tremors, seizures, psychosis, strokes Nausea and vomiting Contraindicated if diabetic or has hypertension, angle-closure glaucoma, anxiety, prostate adenoma, thyroid disease, pheochromocytoma	Activated charcoal Benzodiazepi for seizures ar sedation Vasodilators fo hypertension Lidocaine and blockers for arrhythmias External cooli if temperature >102°F Hydration therapy
Lobelia inflata (lobelia)	Piperidine alkaloid: L-Lobeline (stimulates nicotinic receptors)	Expectorant Asthma Spasmolytic Emetic To induce mental clarity and a feeling of well-being	Gastrointestinal: nausea and vomiting, abdominal pain, diarrhea Central nervous system: anxiety and headache, dizziness, tremors, seizures, paresthesias, euphoria Cardiac: arrhythmias, bradycardia, transient increase in blood pressure, decreased respiratory rate In overdose, lobeline may cause hypotension Diaphoresis, muscle fasciculations and weakness, tremors, respiratory depression Dermatitis	Supportive ca Gastric empty Activated charcoal Benzodiazepi

			muscle fasciculations and weakness, tremors, respiratory depression Dermatitis	
Mentha pulegium (pennyroyal)	Pennyroyal oil has a hepatotoxic effect. Acute poisoning is not found with Proper administration of the designated therapeutic use of pennyroyal leaf. However, drug is not recommended owing to hepatotoxicity.	Insect repellent Respiratory illness Digestive disorders Emmenagogue Abortifacient Wound treatment Gout	Uterine contractions, Gastrointestinal: nausea, vomiting, abdominal pain, hepatitis Neurotoxin: delirium, dizziness, convulsions, seizures, paralysis, encephalopathy, and coma Renal failure and hypertension Shock and disseminated intravascular coagulation Contraindicated in pregnancy	Supportive ca[illegible] *N*-acetylcystei[illegible]
Pausinystalia yohimbe (yohimbe)	Indole alkaloids Yohimbe: a_2 -adrenoreceptor antagonist	Sexual disorders Exhaustion Improve muscle function	Adverse reactions: dizziness, headache, anxiety, hypertension, indigestion, rash, insomnia, tachycardia, tremor, vomiting, hallucinations, nervousness, paresthesias, hypothermia, salivation, mydriasis, diarrhea, palpations, and tachycardia Contraindicated in kidney and liver disease	Gastric empty[illegible] Activated charcoal Antiarrhythmic Hydration
Phytolacca americana (pokeweed, American nightshade)	Triterpene saponins (irritate mucous membranes) Lectins (toxic)	Anti-inflammatory Arthritis Cancer treatment Emetic and cathartic Rheumatism	Dizziness, somnolence, nausea, vomiting, diarrhea, tachycardia, hemorrhagic gastritis, hypotension, lymphocytosis, headache, respiratory depression, seizures	Hydration therapy, electrolyte correction gas emptying activated charcoal electrolyte replacement Emesis shoul[illegible] not be induce[illegible] patient is experiencing symptoms of overdose.
Stramonium folium (jimson weed)	Alkaloids: hyoscyamine (the L-isomer of atropine)	Asthma and cough Diseases of the autonomic nervous system	In high doses leads to restlessness, mania, hallucinations, delirium Overdose: tachycardia, mydriasis, flushing, dry mouth, decreased sweating, miction, constipation	Supportive ca[illegible] Gastric lavage Decreasing temperature Physostigmine Benzodiazepi[illegible]
Viscum album (mistletoe)	Alkaloids Viscotoxins (*Viscum album*) cause hypotension, bradycardia, and arterial vasoconstriction Lectins	Antineoplastic adjuvant Antihypertensive Nervous disorders—calmative agent Rheumatism Antispasmodic	Fever, headaches, nausea, vomiting, diarrhea, bradycardia, angina, change in blood pressure, seizures, confusion, hallucination, allergic reactions, miosis, mydriasis, chills, coma Two reported deaths in the past 35 yr; most ingestions lead to mild reactions	Supportive therapy Data inconclusive f[illegible] inducing emes[illegible] Activated charcoal

See also Table 12–2 .)

Figure 15-3 Skinfold thickness by age and sex, as measured by Harpenden skinfold calipers over triceps and under scapula. Scale is in millimeters on the left side and logarithmic transformation units on the right side. The lines shown are the 50th percentiles for British children. (From Tanner JM: *Fetus into Man: Physical Growth from Conception to Maturity.* Cambridge, MA, Harvard University Press, 1978.)

Figure 16-1 The Pediatric Symptom Checklist. (From Little M, Murphy JM, Jellinek MS, et al: Screening 4- and 5-year-old children for psychosocial dysfunction: A preliminary study with the pediatric symptom checklist. *J Dev Behav Pediatr* 1994;15:191.)

Figure 35-1 The spectrum of child maltreatment. Child maltreatment encompasses acts of commission, or abuse, and acts of omission, or neglect, by a caretaker that adversely affect children. The act can be physical or psychologic. The boundaries between these areas are indistinct and psychologic; physical abuse and neglect overlap and may exist at the same time or various times in the child's life. Sexual abuse may be considered a specific type of physical abuse that has strong emotional components. Physical abuse and neglect invariably have short- and long-term psychologic consequences. Psychologic consequences may persist long after the physical wounds heal.

Figure 35-2 A variety of instruments may be used to inflict injury on a child. Often the choice of an instrument is a matter of convenience. Marks tend to silhouette or outline the shape of the instrument. The possibility of intentional trauma should prompt a high degree of suspicion when injuries to a child are geometric, paired, mirrored, of various ages or types, or on relatively protected parts of the body. Early recognition of intentional trauma is important to provide therapy and prevent escalation to more serious injury.

Figure 35-3 Marks from heated objects cause burns in a pattern that duplicates that of the object. Familiarity with the common heated objects that are used to traumatize children facilitates recognition of possible intentional injuries. The location of the burn is important in determining its cause. Children tend to explore surfaces with the palmar surface of the hand and rarely touch a heated object repeatedly.

Figure 35.1-4 Normal hymen. This is the hymen of an 8 yr old. The hymen opening (O) has a delicate and almost transparent edge. There is a right (r) and left (l) wall, which may vary in size from 1 to 3?mm. The base of the hymen (H) may vary from 1 to 4?mm. The term *attenuation* is applied to the base when it is less than 1?mm wide. The fourchette (F) is the joining of the labia minora posteriorly. It may be injured from trauma. The vestibule, or space anterior to the hymen which is surrounded by the labia minora, may be penetrated without damage to the hymen.

Figure 35.1-5 Hymen with estrogen effects and wart. With the onset of puberty, the hymen becomes thickened, paler in color, and redundant. The resulting folds make it difficult to determine whether there are abnormalities of the edge of the hymen. The *arrow* points to a glistening bump on the left hymen wall. This is a venereal wart. The appearance of these warts varies with location. Other warts on the skin surface were dark in color with an irregular “cauliflower-like” appearance.

Figure 35.1-6 Hymen tear. The base (*arrow*) of the hymen has been torn to the floor of the vagina. The injury, from finger insertion according to the 8-year-old child, is bleeding. The fourchette (F) has escaped injury. Careful observation may reveal complete healing of the injury over time. The tear also may heal with a V-shaped notch, or remain separated.

Figure 41-1 Food guide pyramid for 2–6 yr old children. (From U.S. Department of Agriculture/ USDHHS.)

Figure 42-1 *A,* Kwashiorkor in a 2 yr old boy. Note the generalized edema, the typical skin lesions, and the state of prostration. *B,* Close-up of the same child showing the hair changes and psychic alterations (apathy and misery); the edema of the face and the skin lesions can be seen more clearly. (Photographs made available by the Institute of Nutrition of Central America and Panama, Guatemala, courtesy of Moises Behar, MD.)

Figure 42-1 *A,* Kwashiorkor in a 2 yr old boy. Note the generalized edema, the typical skin lesions, and the state of prostration. *B,* Close-up of the same child showing the hair changes and psychic alterations (apathy and misery); the edema of the face and the skin lesions can be seen more clearly. (Photographs made available by the Institute of Nutrition of Central America and Panama, Guatemala, courtesy of Moises Behar, MD.)

Figure 44-1 Recovery from xerophthalmia, showing permanent eye lesion. (From Bloch CE: Blindness and other diseases arising from deficient nutrition [lack of fat-soluble A factor]. *Am J Dis Child* 1924;27:139.)

Figure 44-2 Hyperostosis of the ulna and the tibia in an infant 21 mo of age, resulting from vitamin A poisoning. *A,* Long, wavy cortical hyperostosis of the ulna. *B,* Long, wavy cortical hyperostosis of the right tibia; striking absence of metaphyseal changes. (From Caffey J: *Pediatric X-ray Diagnosis,* 5th ed. Chicago, Year Book, 1967, p 994.)

Figure 44-3 Pellagra showing an early lesion on the neck (Casal necklace).

Figure 44-4 Scorbutic rosary and depression of sternum.

Figure 44-5 Radiographs of a leg. *A,* Early scurvy: “white line” is visible on the ends of the shafts of the tibia and fibula; rings are shown around the epiphyses of the femur and tibia. *B,* More advanced scorbutic changes; zones of destruction (ZD) are evident in the femur and tibia.

Figure 44-6 Line tests in rats (proximal end of the tibia) (calcified tissue stained with silver appears black). *A,* Active rickets. The light broad zone between the epiphysis and the shaft represents the rachitic metaphysis (R.M.) C = cartilage; O = osteoid. *B,* Healing rickets. The line of preparatory calcification (L.P.C.) between the zone of cartilage (C) and the osteoid (O). *C,* Healed rickets. Cartilaginous disc (C) between the epiphysis and the normal shaft.

Figure 44-7 Rachitic rosary in a young infant.

Figure 44-8 *A,* Active rickets; cupping and fraying of the distal ends of the radius and ulna; double contour along the lateral outline of the radius (periosteal osteoid). The two dense zones in the shaft of the ulna are calluses of greenstick fractures. *B,* Healing rickets after 12 days of treatment with vitamin D. Zones of preparatory calcification (ZPC); above them in the rachitic metaphyses there is beginning calcification. *C,* Healing rickets after 18 days of treatment. The zones of preparatory calcification are well defined, and the rachitic metaphyses appear well calcified. The epiphysis of the radius has become visible. *D,* Healing rickets after 29 days of treatment. Zones of preparatory calcification, rachitic metaphyses, and shafts have become united.

Figure 45.3-4 Mechanism of brain edema during correction of hypernatremia. A rapid decrease of the serum concentration during treatment of hypernatremia causes movement of water into brain cells, leading to cerebral edema. The presence of idiogenic osmoles in brain cells is responsible for the osmotic gradient.

Figure 45.8-5 Tubular sites involved in acid-base balance. The proximal tubule is the site where most filtered bicarbonate is reclaimed, even though other sites along the nephron, especially the thick ascending limb of the loop of Henle, reabsorb some of the filtered bicarbonate. The collecting duct is the principal location for the hydrogen ion secretion that acidifies the urine. The proximal tubule generates the ammonia that serves as a urinary buffer in he collecting duct.

Figure 45.8-6 Reabsorption of filtered bicarbonate in the proximal tubule. The Na+,K+-ATPase (1) excretes sodium across the basolateral cell membrane, maintaining a low intracellular sodium concentration. The low intracellular sodium concentration provides the energy for the Na+,H+ antiporter (2), which exchanges sodium from the tubular lumen for intracellular hydrogen ions. The hydrogen ions that are secreted into the tubular lumen then combine with filtered bicarbonate to generate carbonic acid. Carbon dioxide and water are produced from carbonic acid (H2CO3). This reaction is catalyzed by luminal carbonic anhydrase (3). Carbon dioxide diffuses into the cell and combines with OH^- ions to generate bicarbonate. This reaction is catalyzed by an intracellular carbonic anhydrase (4). The dissociation of water generates an OH^- ion and an H+ ion. The Na+,H+ (2) antiporter secretes the hydrogen ions. Bicarbonate ions cross the basolateral membrane and enter the blood via the 3HCO3 $^-$ /1Na+ co-transporter (5). The energy for the $3HCO3^-$ /1Na+ co-transporter comes from the negatively charged cell interior, which makes it electrically favorable to transport a net negative charge (i.e., three bicarbonates and only one sodium) out of the cell.

Figure 45.8-7 Secretion of hydrogen ions in the collecting duct. The dissociation of water generates an OH^- ion and an H^+ ion. The H^+ ATPase (1) secretes hydrogen ions into the tubular lumen. Bicarbonate is formed when OH^- ion combines with carbon dioxide in a reaction mediated by carbonic anhydrase (2). Bicarbonate ions cross the basolateral membrane and enter the blood via the $HCO3^-$ /Cl^- exchanger (3). The hydrogen ions in the tubular lumen are buffered by phosphate and ammonia. Ammonia (NH_3) can diffuse from the peritubular fluid into the tubular lumen, but ammonium ($NH4^+$) cannot pass through the cells of the collecting duct.

Figure 45.8-8 Three-step process for interpreting acid-base disturbances. In the first step, determine whether the pH is low (acidemia) or high (alkalemia). In the second step, establish an explanation for the acidemia or alkalemia. In the third step, calculate the expected compensation (see Table 45–3) and determine whether a mixed disturbance is present. Met. Alk. = Metabolic alkalosis; Met. Acid. = Metabolic acidosis; Resp. Alk. = Respiratory alkalosis; Resp. Acid. = Respiratory acidosis.

Figure 45.8-9 The anion gap. The anion gap is the difference between the sodium concentration and the combined concentrations of chloride and bicarbonate (*vertical line*). In both a gap and non-gap metabolic acidosis, there is a decrease in the bicarbonate concentration. There is an increase in unmeasured anions (UA) in patients with a gap metabolic acidosis. In a non-gap metabolic acidosis, there is an increase in the serum chloride concentration. UC = unmeasured cations.

Figure 49-1 Acute Illness Observational Scales for use in clinical evaluation of the well and sick child. (From McCarthy PL, Sharpe MR, Spiesel SZ, et al: Observation scales to identify serious illness in febrile children. *Pediatrics* 1982;70:802, with permission.)

Figure 50-1 Emergency department visit rates for leading first-listed causes of injury by age: United States, 1993–1994. (Data from Centers for Disease Control and Prevention, National Center for Health Statistics, and National Hospital Ambulatory Medical Case Survey.)

Figure 51-1 The EMS-C continuum of care: Seriously ill and injured children interface with a large number of health care personnel as they move through the EMS-C system. The system both begins and ends in the community.

Figure 55-1 Components and functional features of a thermodilution flow-directed balloon flotation pulmonary artery catheter (PAC). The flexible multilumen catheter with the balloon at the distal tip inflated is in the wedge position. The proximal ends of the five lumens are labeled. The distal port is connected to a pressure measurement system for catheter insertion and subsequent monitoring. When the distal tip is within the central venous circulation, the balloon is inflated to enhance flow-direction of the tip through the right atrium into the right ventricle and then to the pulmonary artery. Recorded pressures in the lower part of the figure correspond to these locations, confirming the course of the catheter. The last tracing on the right is that corresponding to the “wedge” position, commonly reflecting the pressure transmitted from the left atrium via the pulmonary veins and fiberoptic monitor available on adult-sized catheters. (Redrawn from Daily EK, Tilkian AG: Hemodynamic monitoring. In Tilkian AG, Daily EK [editors]: *Cardiovascular Procedures, Diagnostic Techniques and Therapeutic Procedures*. St. Louis, CV Mosby, 1986.

Figure 55-2 Sites for monitoring intracranial pressure. A variety of monitor types are shown. Intraventricular catheters are most often fluid-filled tubes connected by pressure tubing to a pressure transducer. CSF can be withdrawn through the catheter. Subarachnoid (also subdural) monitors are fluid-filled, hollow devices that can be bolted to the calvaria connected by pressure tubing to a pressure transducer. CSF cannot be withdrawn. Epidural monitors are waferlike devices of several types, placed in the epidural space. CSF cannot be withdrawn. Intraparenchymal pressure, without the ability to withdraw CSF, can also be monitored. (Redrawn from Lyons MK, Meyer FB: Cerebrospinal fluid physiology and the management of increased intracranial pressure. *Mayo Clin Proc* 1990; 65:684.)

Figure 68-3 The Southern blotting procedure for analyzing specific DNA sequences in a complex mix of different sequences, such as genomic DNA. In this example, sample 3 has a different restriction enzyme pattern for the DNA sequence detected by the probe. This variation might be due to a restriction fragment length polymorphism or to a deletion of DNA near the detected sequence. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

Figure 68-4 The polymerase chain reaction. By repeatedly synthesizing a region of DNA located between two DNA primers, this region of DNA is specifically and selectively amplified in an exponential fashion. Three successive rounds of amplification are shown, resulting in a total of eight copies of the targeted sequence. After 30 rounds of amplification, more than a billion copies of the sequence are created. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

Figure 69-1 Symbols commonly used in pedigree charts. Although there is no uniform system of pedigree notation, the symbols used here are according to recent recommendations made by the professionals in the field of genetic counseling. (From Bennett RL, Steinhaus KA, Uhrich SB, et al: Recommendations for standardized pedigree nomenclature. *J Genet Counsel* 1995;4:267–79.)

Figure 69-2 Pedigree showing typical inheritance of a form of progressive sensorineural deafness (DFNA1) inherited as an autosomal dominant trait. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

Figure 70-7 In pedigrees suggestive of paternal imprinting, phenotypic effects occur only when the gene is transmitted from the mother but not when transmitted from the father. There are equal numbers of males and females affected and nonaffected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; in other words, in paternal imprinting there are “skipped” female nonmanifesting individuals.

Figure 70-8 In pedigrees suggestive of maternal imprinting, phenotypic effects occur only when the gene is transmitted from the father but not when transmitted from the mother. There are equal numbers of males and females affected and nonaffected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; in other words, in maternal imprinting there are “skipped” male nonmanifesting individuals.

Figure 71-1 Life cycle and organization of wild type and recombinant retrovirus genomes. Retroviruses bind to specific cellular receptors on the target cell surface and are internalized by receptor-mediated endocytosis. Following entry, the retroviral RNA genome is removed from its capsid coat and is reverse transcribed by viral reverse transcriptase into DNA that is transported to the nucleus, where integration into the host genome occurs. In wild-type virus, the life cycle is completed by the synthesis of viral proteins and RNA by the host cell, packaging the retroviral particle that is released by budding from the cell surface. Recombinant viruses containing the therapeutic gene or cDNA are replication incompetent, the insert taking the place of the viral genes *GAG*, *POL*, and *ENV*. "Packaging" lines produce these retroviral gene products in vitro, allowing encapsulation of virus and production of the infectious virions. The "packaged" recombinant virus contains an RNA copy of the therapeutic gene insert that can be used to infect target cells.

Figure 73-1 Clinical approach to a newborn infant with a suspected metabolic disorder. This schema is a guide to the elucidation of some of the metabolic disorders in newborn infants. Although some exceptions to this schema exist, it is appropriate for most cases.

Figure 74.1-1 Pathways of phenylalanine and tyrosine metabolism. Inborn errors are depicted as bars crossing the reaction arrow(s). Pathways for synthesis of cofactor BH_4 are shown in purple. PKU* refers to defects of BH4 metabolism that affect the phenylalanine, tyrosine, and tryptophan hydroxylases. See Figures 74–2 and 74–4 . **Enzymes:** (1) phenylalanine hydroxylase; (2) carbinolamine dehydratase; (3) dihydropteridine reductase; (4) 6-pyruvoyltetrahydropterin synthase; (5) guanosine triphosphate (GTP) cyclohydrolase; (6) tyrosine aminotransferase; (7a) intramolecular rearrangement; (7 + 7a) 4-hydroxyphenylpyruvate dioxygenase; (8) Homogentisic acid dioxygenase; (9) maleylacetoacetate isomerase; (10) fumarylacetoacetate hydroxylase.

Figure 74.1-2 Other pathways involving tyrosine metabolism. PKU* indicates hyperphenylalaninemia due to tetrahydrobiopterin deficiency (see Fig. 74–1). **Enzymes:** (1) thyrosine hydroxylase; (2) aromatic L-amino acid decarboxylase (AADC); (3) dopamine hydroxylase; (4) phenylethanolamine-*N*-methyltransferase (PNMT).

Figure 74.3-3 Pathways in the metabolism of the sulfur-containing amino acids. **Enzymes:** (1) methionine adenosyltransferase; (2) adenosylhomocysteine hydrolase; (3) cystathionine synthase; (4) cystathionase; (5) sulfite oxidase; (6) betaine homocysteine methyltransferase; (7) methionine synthase; (8) methylene tetrahydrofolate reductase.

Figure 74.5-4 Pathways in the metabolism of tryptophan. PKU* indicates hyperphenylalaninemia due to tetrahydrobiopterin deficiency (see Fig. 74–1). **Enzymes:** (1) tryptophan hydroxylase; (2) aromatic L-amino acid decarboxylase (AADC); (3) monoamine oxidase (MAO).

Figure 74.6-5 Pathways in the metabolism of the branched-chain amino acids, biotin, and vitamin B_{12} (cobalamin). MMA = methylmalonic acidemia; HCU = homocystinuria; Cbl = cobalamin; OHCbl = hydroxycobalamin; cbl = defect in metabolism of cobalamin; TC = transcobalamin.

Figure 74.6-6 Clinical approach to infants with organic acidemia. Asterisks indicate disorders in which patients have a characteristic odor (see text and Table 73–1).

Figure 74.6-7 Formation (liver) and metabolism (peripheral tissues) of ketone bodies and cholesterol synthesis. **Enzymes:** (1) mitochondrial acetoacetyl-CoA thiolase; (2) HMG-CoA synthase; (3) HMG-CoA lyase; (4) cytosolic acetoacetyl-CoA-thiolase; (5) mevalonic kinase; (6) succinyl-CoA; 3-ketoacid CoA transferase (SCOT).

Figure 74.7-8 Pathways in metabolism of glycine and gloxylic acid. **Enzymes:** (1) glycine cleavage enzyme; (2) alanine:glyoxylate aminotransferase; (3) d-glyceric acid dehydrogenase; (4) glycerate kinase; (5) trimethylamine oxidase; (6) lactate dehydrogenase; (7) glycolate oxidase; (8) sarcosine dehydrogenase. NKH* = nonketotic hyperglycinemia; FH_4 = tetrahydrofolate.

Figure 74.10-11 The ?-glutamyl cycle. Defects of glutathione synthesis and degradation are noted. **Enzymes:** (1) ?-glutamyl transpeptidase; (2) ?-glutamyl cyclotransferase; (3) 5-oxoprolinase; (4) ?-glutamylcysteine synthetase; (5) glutathione synthetase; (6) glutamic acid decarboxylase; (7) GABA transaminase; (8) succinic semialdehyde dehydrogenase.

Figure 74.11-12 Urea cycle: pathways for ammonia disposal and ornithine metabolism. Reactions occurring in the mitochondria are depicted in purple. Reactions shown with interrupted arrows are the alternate pathways for the disposal of ammonia. **Enzymes:** (1) carbamylphosphate synthetase (CPS); (2) ornithine transcarbamylase (OCT); (3) argininosuccinic acid synthetase; (4) argininosuccinic acid lyase; (5) arginase; (6) ornithine 5-aminotransferase; (7) *N*-acetylglutamate synthetase. *HHH syndrome: hyperammonemia-hyperornithinemia-homocitrullinemia.

Figure 74.11-13 Clinical approach to a newborn infant with symptomatic hyperammonemia. *HHH syndrome = hyperammonemia-hyperornithinemia-homocitrullinemia.

Figure 74.13-14 Pathways in the metabolism of lysine. **Enzymes:** (1) lysine ketoglutarate reductase; (2) saccharopine dehydrogenase; (3) a-aminoadipic acid transferase; (4) a-ketoadipic acid dehydrogenase; (5) glutaryl CoA dehydrogenase; (6) a-aminoadipic semialdehyde oxidase.

Figure 74.14-15 Axial T-weighted MRI of a 2-yr-old patient with Canavan disease. Extensive thickening of the white matter is seen.

Figure 75.1-1 Mitochondrial fatty acid oxidation. Carnitine enters the cell through the action of the organic cation/carnitine transporter (OCTN2). Palmitate, a typical 16-carbon long-chain fatty acid, is transported across the plasma membrane and can be activated to form a long chain (LC) fatty acyl-CoA. It then enters into the carnitine cycle, where it is transesterified by carnitine palmitoyltransferase-I (CPT-I), translocated across the inner mitochondrial membrane by carnitine/acylcarnitine translocase (TRANS), and then reconverted into a long-chain fatty acyl CoA by carnitine palmitoyltransferase-II (CPT-II) to undergo ß-oxidation. Very long chain acyl-CoA dehydrogenase (VLCAD/LCAD) leads to the production of (C16-10) 2,3 enoyl-CoA. Trifunctional protein (TFP) contains the activities of enoyl-CoA hydratase (hydratase), 3-OH-hydroxyacyl CoA dehydrogenase (3-OH-ACD), and ß-ketothiolase (thiolase). Acetyl CoA, FADH, and NADH are produced. Medium- and short-chain fatty acids (C8-4) can enter the mitochondrial matrix independent of the carnitine cycle. Medium-chain acyl-CoA dehydrogenase (MCAD), short-chain acyl-CoA dehydrogenase (SCAD), and short-chain hydroxy acyl-CoA dehydrogenase (SCHAD) are required. Acetyl-CoA can then enter the Krebs (TCA) cycle. Electrons are transported from FADH to the respiratory chain via the electron-transfer flavoprotein (ETF) and the electron-transfer flavoprotein dehydrogenase (ETF-DH). NADH enters the electron transport chain through complex I. Acetyl-CoA can be converted into hydroxymethylglutaryl-CoA (HMG-CoA) by ß-hydroxy-ß-methylglutaryl-CoA synthase (HMG-CoA synthase) and then the ketone body acetoacetate by the action of ß-hydroxy-ß-methylglutaryl-CoA lyase (HMG-CoA lyase).

Figure 75.1-2 Pathway of mitochondrial oxidation of palmitate, a typical 16-carbon long-chain fatty acid. Enzyme steps include carnitine palmitoyltransferase (CPT) 1 and 2, carnitine/acylcarnitine translocase (TRANS), electron transfer flavoprotein (ETF), ETF-dehydrogenase (ETF-DH), acyl-CoA dehydrogenase (ACD), enoyl-CoA hydratase (hydratase), 3-hydroxy-acyl-CoA dehydrogenase (3-OH-ACD), ß-ketothiolase (thiolase), ß-hydroxy-B-methylglutaryl-CoA (HMG-CoA) synthase, and lyase.

Figure 75.2-3 Four patients with Zellweger cerebrohepatorenal syndrome. Note the high forehead, epicanthal folds, and hypoplasia of supraorbital ridges and midface. (Courtesy of Hans Zellweger, MD.)

Figure 75.2-3 Four patients with Zellweger cerebrohepatorenal syndrome. Note the high forehead, epicanthal folds, and hypoplasia of supraorbital ridges and midface. (Courtesy of Hans Zellweger, MD.)

Figure 75.2-4 *A*, A newborn infant with RCDP. Note the severe shortening of the proximal limbs, the depressed bridge of the nose, hypertelorism, and widespread scaling skin lesions. *B*, Note the marked shortening of the humerus and epiphyseal stippling at the shoulder and the elbow joints. (Courtesy of John P. Dorst, MD.)

Figure 75.3-5 *A*, Contrast-enhanced CT abnormalities in ALD with typical parieto-occipital location, showing symmetric bilateral hypodense inactive zones (Ho). The enhancing active periphery zone of hypodensity is demarcated by *arrows*. Compare the anterior zone of hypodensity *(arrowheads)* with that on the MRI in *B*. CC = corpus callosum. *B*, MRI of the same patient and area shown by CT. MRI T2-weighted image shows a high-intensity signal of the abnormally bright parieto-occipital white matter. Subcortical involvement is better identified on MRI. Separation of active zones may be better appreciated by CT, because both inactive and active zones are seen at high-signal areas on MRI. However, it is assumed that such major distinctions afforded by CT will also be demonstrable when IV enhancement (paramagnetic enhancement) becomes readily available. Note the hypodense involvement of CT (*arrowheads* and *arrows* in *A*) compared with the well-resolved lesions on MRI in *B*. (From Kumar AJ, Rosenbaum WE, Naidu S, et al: Adrenoleukodystrophy: Correlating MR imaging with CT. *Radiology* 1987;165:697.)

Figure 75.4-6 Pathway of chylomicron metabolism in human plasma. Fatty acids (FA) and cholesterol (C) are esterified in the intestinal mucosa to form triglycerides (TG) and cholesteryl esters (CE), respectively. They combine with apoA and apoB-48 to form chylomicrons, which are secreted into the circulation: TG *(shaded area)* and CE *(black area)*. Chylomicrons undergo lipolysis in the capillary endothelium near adipose tissue and muscle tissue, losing TG via lipoprotein lipase (LPL), gaining apoE from HDL, and losing apoA and apoC to HDL. The resultant chylomicron remnants are taken up by hepatic apoE receptors for degradation by lysosomes. (Adapted from Havel RJ: Approach to the patient with hyperlipidemia. *Med Clin North Am* 1982;66:319.)

Figure 75.4-7 Pathways of VLDL and LDL metabolism in human plasma. Triglycerides (TG) and cholesteryl esters (CE) are combined with apoB-100, apoC, and apoE in the liver and then secreted as VLDL, TG *(shaded area)*, and CE *(black area)*. VLDL undergo lipolysis in the capillary endothelium near adipose tissue and muscle tissue, losing TG via lipoprotein lipase (LPL). The resulting VLDL remnants are either converted to low-density lipoproteins (LDL) for transport to peripheral cells via LDL receptor-mediated uptake or are taken up by hepatic receptors. FFA = free fatty acids. (Adapted from Havel RJ: Approach to the patient with hyperlipidemia. *Med Clin North Am* 1982;66:319.)

Figure 75.5-9 Pathways in the metabolism of sphingolipids found in nervous tissues. The name of the enzyme catalyzing each reaction is given with the name of the substrate acted on. Inborn errors are depicted as bars crossing the reaction arrows, and the name of the associated defect or defects is given within the nearest box. The gangliosides are named according to the nomenclature of Svennerholm. Anomeric configurations are given only at the largest starting a compound. gal = galactose; glc = glucose; NAcgal = *N*-acetyl-galactosamine; NANA = *N*-acetyl-neuraminic acid; PC = phosphorylcholine.

Figure 75.5-10 Pathways in the degradation of sphingolipids found in visceral organs and red or white blood cells. See also the legend for Figure 75–9 . fuc = fucose; NAcglc = *N*-acetylglucosamine.

Figure 75.5-11 Cells from a spleen of a patient with Gaucher disease. A characteristic spleen cell is shown engorged with glucocerebroside.

Figure 75.5-12 A forearm of an 18-mo-old girl with Farber disease. Note the painful joint swelling and the nodule formation. The infant was suspected of having rheumatoid arthritis.

Figure 76.1-2 Growth and development in a patient with type IIIb glycogen storage disease. The patient has debrancher deficiency in liver but normal activity in muscle. As a child he had hepatomegaly, hypoglycemia, and growth retardation. After puberty, he no longer had hepatomegaly or hypoglycemia, and his final adult height is normal. He has no muscle weakness or atrophy; this is in contrast to type IIIa patients, in whom a progressive myopathy is seen in adulthood.

Figure 78-1 Early steps in the biosynthesis of the purine ring.

Figure 78-2 Pathways in purine metabolism and salvage.

Figure 80-1 Structure of heme.

Figure 80-2 The heme biosynthetic pathway. A = $-CH_2-COOH$; P = $-CH_2-CH_2-COOH$; M = $-CH_3$; V = $-CH=CH_2$; • = carbon atom derived from the a-carbon of glycine; * = location of the a-carbon atom from glycine in the pyrrole ring that undergoes reversion; [] = a presumed intermediate. (Modified from Hayashi N: The synthesis of heme and its regulation. *Protein Nucl Acid Enzyme (Tokyo)* 1987;32:797.)

Figure 80-3 Enzymatic defects in the porphyrias. The enzymatic defect in each porphyria is shown by a *broken line*. In patients, the substrate for the defective enzymatic step accumulates in the tissue and is excreted in large excess into urine and/or stool. Porphyrin precursors, for example, ALA and PBG, may also be increased in patients with acute hepatic porphyrias as a result of derepression of ALAS-N activity.

Figure 81-1 Schematic representation of the pancreatic cell with some important steps in insulin secretion. The membrane-spanning, adenosine triphosphate (ATP)-sensitive potassium (K^+) channel (K_{ATP}) consists of two subunits: the sulfonylurea receptor (SUR) and the inward rectifying K channel (K_{IR} 6.2). In the resting state, the ratio of ATP to adenosine diphosphate (ADP) maintains K_{ATP} in an open state, permitting efflux of intracellular K^+ . When blood glucose concentration rises, its entry into the ß cell is facilitated by the GLUT-2 glucose transporter, a process not regulated by insulin. Within the ß cell, glucose is converted to glucose-6-phosphate by the enzyme glucokinase and then undergoes metabolism to generate energy. The resultant increase in ATP relative to ADP closes K_{ATP} , preventing efflux of K^+ , and the rise of intracellular K^+ depolarizes the cell membrane and opens a calcium (Ca^{2+}) channel. The intracellular rise in Ca^{2+} triggers insulin secretion via exocytosis. Sulfonylureas trigger insulin secretion by reacting with their receptor (SUR) to close K_{ATP} ; diazoxide inhibits this process, whereas somatostatin, or its analogue octreotide, inhibits insulin secretion by interfering with calcium influx. Genetic mutations in SUR or K_{IR} 6.2 that prevent K_{ATP} from being open are responsible for autosomal recessive forms of persistent hyperinsulinemic hypoglycemia of infancy (PHHI). One form of autosomal dominant PHHI is due to an activating mutation in glucokinase. The amino acid leucine also triggers insulin secretion by closure of K_{ATP} . Metabolism of leucine is facilitated by the enzyme glutamate dehydrogenase (GDH), and overactivity of this enzyme in the pancreas leads to hyperinsulinemia with hypoglycemia, associated with hyperammonemia from overactivity of GDH in the liver. X = inhibition; 4 = stimulation.

Figure 82-1 Infant, neonatal, and postneonatal mortality, LBW and VLBW, and preterm delivery, United States, 1980–2000. IMR = infant deaths per 1,000 live births; NMR = neonatal deaths per 1,000 live births; PNMR = postneonatal deaths per 1,000 live births; LBW = percent low birthweight (<2500?g); VLBW = percent very low birthweight (<1500?g); PT = percent preterm (<37 weeks' gestation). (From Hoyert DL, Freedman MA, Strobino DM, Guyer B: Annual summary of vital statistics: 2000. *Pediatrics* 2001;108:1241.)

Figure 82-2 Neonatal mortality, by birthweight categories, for black (*filled circles*) and for white (*open circles*) infants in the United States. *Solid lines* denote data for 1989; *dashed lines* are for 1997. Data shown are for births of newborn infants weighing less than 2,250?g only. (From Demissie K, Rhoads GG, Ananth CV, et al: Trends in preterm birth and neonatal mortality among Blacks and Whites in the United States from 1989 to 1997. *Am J Epidemiol* 2001;154:307.)

Figure 82-3 Birthrates for teenagers by age: United States, 1950–2000. (From Ventura SJ, Mathews TJ, Hamilton BE: Births to teenagers in the United States, 1940–2000. *Natl Vital Stat Rep* 2001;49:1.)

Figure 82-4 Percent low birthweight by race and ethnicity, selected years: United States, 1950–1999. (From Guyer B, Freedman MA, StrobinoDM, et al: Annual summary of vital statistics: Trends in the health of Americans during the 20th century. *Pediatrics* 2000; 106:1307.)

Figure 82-5 Infant mortality rates by race and ethnicity, 1998. (From Mathews TJ, Curtin SC, MacDorman MF: Infant mortality statistics from the 1998 period linked birth/infant death data set. *Natl Vital Stat Rep* 2000; 48:1.)

Figure 83.2-1 Infant with intrauterine growth retardation as a result of placental insufficiency. Note the long, thin appearance with peeling, parchment-like dry skin, alert expression, meconium staining of the skin, and long nails. (From Clifford S: *Advances in Pediatrics*, Vol 9. Chicago, Year Book, 1962.)

Figure 83.2-2 Nomogram for mean blood pressure (BP) in neonates with gestational ages of 23–43 wk derived from continuous arterial BP measurements obtained from 103 infants admitted to the neonatal intensive care unit. The graph shows the predicted mean BP of neonates of different gestational age during the first 72 hours of life. Each line represents the lower limit of the 80% confidence interval (two-tail) of the mean BP for each gestational age group; 90% of infants for each gestational age group will be expected to have a mean BP value equal to or above the value indicated by the corresponding line, the lower limit of the confidence interval. (From Nuntnarumit P, Yang W, Bada-Ellzey SB: Blood pressure measurements in the newborn. *Clin Perinatol* 1999;26:981–96.)

Figure 84-1 Natural birth prevalence of Down syndrome according to maternal age. (From Wald NJ, Leck I: *Antenatal and Neonatal Screening*, 2nd ed. Oxford, Oxford University Press, 2000.)

Figure 84-2 Rates of detection of Down syndrome and false-positive rates for various screening tests. The triple test includes measurements of serum a-fetoprotein, unconjugated estriol, and human chorionic gonadotropin in the 2nd trimester. The quadruple test includes measurements of serum a-fetoprotein, unconjugated estriol, human chorionic gonadotropin, and inhibin A in the 2nd trimester. The combined test includes measurements of serum pregnancy-associated plasma protein A, free ß subunit of human gonadotropin, and nuchal translucency in the 1st trimester. The integrated test includes measurements of serum pregnancy-associated plasma protein A and nuchal translucency in the 1st trimester and measurements of serum a-fetoprotein, unconjugated estriol, human chorionic gonadotropin, and inhibin A in the 2nd trimester. (From Wald NJ, Watt HC, Hackshaw AK: Integrated screening for Down syndrome based on tests performed during the first and second trimester. *N Engl J Med* 1999; 341:461–7.)

Figure 85.2-1 *A*, Example of a “low-profile” growth retardation pattern in an uneventful pregnancy and labor. The baby cried at 1?min and hypoglycemia did not develop. Birthweight was below the 5th percentile for gestational age. *B*, Example of a “late flattening” growth retardation pattern. The mother had a typical history of preeclampsia, and the infant had intrapartum fetal distress, a low Apgar score, and postnatal hypoglycemia. Birthweight was below the 5th percentile for gestational age. (From Campbell S: *Clin Obstet Gynecol* 1974;1:41.)

Figure 85.2-2 Normal Doppler velocimetry in sequential studies of fetal umbilical artery flow velocity waveforms from one normal pregnancy. Note the systolic peak flow with lower, but constant flow during diastole. The systolic:diastolic ratio can be determined and, in normal pregnancies, is less than 3 after the 30th wk of gestation. The numbers indicate the week of gestation. (From Trudinger B: Doppler ultrasound assessment of blood flow. In Creasy RK, Resnik R [editors]: *Maternal-Fetal Medicine: Principles and Practice*, 3rd ed. Philadelphia, WB Saunders, 1994.)

Figure 85.2-3 Abnormal Doppler velocimetry. On an umbilical artery Doppler flow velocity waveform, the umbilical placental impedance is so high that the diastolic component shows flow in a reverse direction. This finding is an indication of severe intrauterine hypoxia and intrauterine growth restriction. (From Trudinger B: Doppler ultrasound assessment of blood flow. In Creasy RK, Resnik R [editors]: *Maternal-Fetal Medicine: Principles and Practice*, 3rd ed. Philadelphia, WB Saunders, 1994.)

Figure 85.3-4 Patterns of periodic fetal heart rate (FHR) deceleration. The tracing in *A* shows early deceleration occurring during the peak of uterine contractions as a result of pressure on the fetal head. *B*, Late deceleration caused by uteroplacental insufficiency. *C*, Variable deceleration as a result of umbilical cord compression. Arrows denote the time relationship between the onset of FHR changes and uterine contractions. (From Hon EH: *An Atlas of Fetal Heart Rate Patterns*. New Haven, CT, Harty Press, 1968.)

Figure 86-1 Estimated mortality risk by birthweight and gestational age based on singleton infants in NICHD Neonatal Research Network Centers between January 1, 1995, and December 31, 1996. (From Lemons JA, Bauers CR, OH W, et al: Very low birthweight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1995 through December 1996. *Pediatrics* 2001;107. (http://www.pediatrics.org.cgi/content/full/107/1/e1)

Figure 86.2-2 Physical criteria for maturity. The expanded New Ballard Score includes extremely premature infants and has been refined to improve accuracy in more mature infants. (From Ballard JL, Khoury JC, Wedig K, et al: New Ballard Score, expanded to include extremely premature infants. *J Pediatr* 1991;119:417.)

Figure 86.2-3 Neuromuscular criteria for maturity. The expanded New Ballard Score includes extremely premature infants and has been refined to improve accuracy in more mature infants. (From Ballard JL, Khoury JC, Wedig K, et al: New Ballard Score, expanded to include extremely premature infants. *J Pediatr* 1991;119:417.)

Figure 86.2-4 Maturity rating. The physical and neurologic scores are added to calculate gestational age. (From Ballard JL, Khoury JC, Wedig K, et al: New Ballard Score, expanded to include extremely premature infants. *J Pediatr* 1991;119:417.)

Figure 86.2-5 Average daily weight (grams) vs postnatal age (days) for infants with birthweight ranges of 501–750?g, 751–1,000?g, 1,001–1,250?g, and 1,251–1,500?g (*dotted lines*), plotted with the curves of Dancis and colleagues for infants with birthweights of 750?g, 1,000?g, 1,250?g, and 1,500?g (*solid lines*). (From Wright K, Dawson JP, Fallis D, et al: New postnatal growth grids for very low birth weight infants. *Pediatrics* 1993; 91:922.)

Figure 88.1-1 Cephalohematoma of the right parietal bone.

Figure 88.2-2 Schematic of possible associations linking prematurity, intraventricular hemorrhage (IVH), and white matter disorders (WMD). Antenatal factors may represent factors that both lead to prematurity and act as an independent marker of risk for IVH and WMD. Factors that occur as a result of or in association with prematurity may in turn modify the likelihood of having IVH or WMD. IVH in its own right may contribute to WMD. (From Kuban K, Sanocka U, Leviton A, et al: White matter disorders of prematurity: Association with intraventricular hemorrhage and ventriculomegaly. *J Pediatr* 1999;134:539.)

Figure 88.2-3 Grading the severity of germinal matrix intraventricular hemorrhage with parasagittal ultrasound scans. *A*, Grade I. Note the echogenic blood in the germinal matrix *(arrowheads)* just anterior to the anterior tip of the choroid plexus, which (normally) is also echogenic. *B*, Grade II. Note the echogenic blood *(arrowheads)* filling less than 50% of the ventricular area. *C*, Grade III. Note the large blood clot nearly completely filling and distending the entire lateral ventricle. (From Intracranial hemorrhage: Germinal matrix-intraventricular hemorrhage of the premature infant. In Volpe JJ [editor]: *Neurology of the Newborn*, 3rd ed. Philadelphia, WB Saunders, 1995.)

Figure 90.5-6 Fetal aspiration syndrome (aspiration pneumonia). Note the coarsely granular pattern with irregular aeration typical of fetal distress from the aspiration of material contained in amniotic fluid, such as vernix caseosa, epithelial cells, and meconium.

Figure 90.6-7 Pathophysiology of meconium passage and the meconium aspiration syndrome. (From Wiswell TE, Bent RC: Meconium staining and the meconium aspiration syndrome. *Pediatr Clin North Am* 1993;40:955.)

Figure 90.8-8 Pneumomediastinum in a newborn infant. The anteroposterior view demonstrates compression of the lungs, and the lateral view shows bulging of the sternum, each resulting from distention of the mediastinum by trapped air.

Figure 91.1-2 Meconium ileus. Impacted meconium with small amounts of air interspersed throughout it can be seen in loops of intestine on the right side of the abdomen. The intestinal loops above this impaction are greatly distended.

Figure 91.1-3 Meconium ileus. The colon, outlined by contrast material, is small because meconium has not reached it.

Figure 91.2-4 Necrotizing enterocolitis. A kidney-ureter-bladder film demonstrates abdominal distention, hepatic portal venous gas *(arrow),* and a bubbly appearance of pneumatosis intestinalis *(arrowhead; right lower quadrant).* The latter two signs are thought to be pathognomonic for neonatal necrotizing enterocolitis.

Figure 91.2-5 Intestinal perforation. A cross-table abdominal roentgenogram in a patient with neonatal necrotizing enterocolitis demonstrates marked distention and massive pneumoperitoneum as evidenced by the free air below the anterior abdominal wall.

Figure 91.3-6 The neonatal production rate of bilirubin is 6–8?mg/kg/24?hr (in contrast to 3–4?mg/kg/24?hr in adults). Water-insoluble bilirubin is bound to albumin. At the plasma-hepatocyte interface, a liver membrane carrier (bilitranslocase) transports bilirubin to a cytosolic binding protein (ligandin or Y protein, now known to be glutathione *S*-transferase), which prevents back-absorption to plasma. Bilirubin is converted to bilirubin monoglucuronide (BMG) or diglucuronide (BDG) by several classes of the enzyme bilirubin glucuronyl transferase. Neonates excrete more BMG than adults do. In the fetus, conjugated lipid-insoluble BMG and BDG must be deconjugated by tissue ß-glucuronidases to facilitate placental transfer of lipid-soluble unconjugated bilirubin across the placental lipid membranes. After birth, intestinal or milk-containing glucuronidases contribute to the enterohepatic recirculation of bilirubin and possibly to the development of hyperbilirubinemia.

Figure 91.3-7 Schematic approach to the diagnosis of neonatal jaundice. G6PD = glucose-6-phosphate dehydrogenase; PK = pyruvate kinase. (From Oski FA: Differential diagnosis of jaundice. In Taeusch HW, Ballard RA, Avery MA [editors]: *Schaffer and Avery's Diseases of the Newborn,* 6th ed. Philadelphia, WB Saunders, 1991.)

Figure 91.3-8 Risk designation of term and near-term well newborns based on their hour-specific serum bilirubin values. The high-risk zone is designated by the 95th percentile track. The intermediate-risk zone is subdivided into upper and lower risk zones by the 75th percentile track. The low-risk zone has been electively and statistically defined by the 40th percentile track. *(Dotted extensions* are based on less than 300 total serum bilirubin values/epoch.) (From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics* 1999;103:9.)

Figure 91.4-9 Distribution of maximal bilirubin levels during the 1st wk of life in breast-fed and formula-fed white infants over 2,500?g. (From Maisels J, Gifford K: Normal serum bilirubin levels in the newborn and the effect of breast-feeding. *Pediatrics* 1986;78:837.)

Figure 92.1-1 Range (mean and 95% confidence limits) of hemoglobin concentration from 16 to 40 wk of gestational age from normal (zone I) fetuses obtained by cordocentesis (percutaneous umbilical blood sample). *Solid circles* depict maternal red blood cell isoimmunization; *open circles* indicate hemoglobin levels in fetuses with ultrasonographic evidence of hydrops (zone III). (From Soothill P: Cordocentesis: Role in assessment of fetal condition. *Clin Perinatol* 1989;16:755.)

Figure 92.1-2 Diagnostic approach to anemia in newborn infants. MCV = mean corpuscular volume; G6PD = glucose-6-phosphate dehydrogenase. (From Blanchette V, Zipursky A: Assessment of anemia in newborn infants. *Clin Perinatol* 1984;11:489.)

Figure 96.1-1 Large, plump, plethoric infant of a gestational diabetic mother. The baby was born at 38 wk of gestation but weighed 9?lb, 11 oz (4,408?g). Mild respiratory distress was the only symptom other than appearance.

Figure 96.2-2 Incidence of hypoglycemia by birthweight, gestational age, and intrauterine growth. (From Lubchenco LO, Bard H: Incidence of hypoglycemia in newborn infants classified by birth weight and gestational age. *Pediatrics* 1971;47:832.)

In Stamatoyannopoulis G, Nienhuis A, Majerus P, Varmus H [editors]: *Molecular Basis of Blood Diseases*, 2nd ed. Philadelphia, WB Saunders, 1994.)

Figure 113-2 Antigen-independent human B-cell development. (From Haynes BF, Denning SM: Lymphopoiesis. In Stamatoyannopoulis G, Nienhuis A, Majerus P, Varmus H [editors]: *Molecular Basis of Blood Diseases*, 2nd ed. Philadelphia, WB Saunders, 1994.)

Figure 114-1 Location of mutations in the functional domains of the BTK protein. Deletion and point mutations in BTK identified to date in many boys with classic XLA are in the kinase domain, whereas CBA/N xid mice with a less severe B-cell defect have a point mutation causing an amino acid substitution at position 28 in the N-terminal domain. A male with a less severe B-cell defect than in classic XLA has had a point mutation at position 361 in the SH2 domain. However, more recently boys with classic XLA are also reported to have mutations at the xid mutation site and in the SH2 domain. (From Buckley RH: Breakthroughs in the understanding and therapy of primary immunodeficiency. *Pediatr Clin North Am* 1994;41:665–90.)

Figure 117-1 Major cytokine sources and actions. Cells of the bone marrow microenvironment such as macrophages (ma), endothelial cells (ec), and reticular fibroblastoid cells (fb) produce macrophage colony-stimulating factor (M-CSF), granulocytemacrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), interleukin (IL-6), and probably stem cell factor (SCF; cellular sources not yet precisely determined) after induction with endotoxin (ma) or IL-1/TNF (ec, fb). T cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages optimal development requires a combination of early- and late-acting factors. PSC = pluripotent stem cells; MSC = myeloid stem cells; TNF = tumor necrosis factor. (Modified from Sieff CA, Nathan DG, Clark SC: The anatomy and physiology of hematopoiesis. In Nathan DG and Orkin SH [editors]: *Hematology of Infancy and Childhood*, 5th ed. Philadelphia, WB Saunders, 1997.)

Figure 117-2 Various cytokines and chemokines that act at different levels of granulopoiesis and monocytopoiesis. Multiple cytokines regulate progenitor cells or mature effector cells at each stage of maturation/differentiation from the primitive pluripotent stem cell to nondividing terminally differentiated precursors (monocytes, neutrophils, eosinophils, and basophil/mast cells). The cytokines and chemokines also have varying degrees of specificity; some, such as M-CSF and IL-5, act predominantly on the monocytic and eosinophilic pathways, respectively, whereas others, such as CSF-GM, act on multiple granulocytic-monocytic (erythroid not shown) cell types. (Modified from Abboud CN, Liesveld JL: Granulopoiesis and monocytopoiesis. In Hoffman R, Benz EB, Shattil SJ, et al [editors]: *Hematology: Basic Principles and Practice*, 2nd ed. New York, Churchill Livingstone, 1995.)

Figure 117-3 The neutrophil-mediated inflammatory response. *A*, Unstimulated neutrophils (expressing L-selectin) entering a post capillary venule. *B*, Invasion of gram-negative bacteria with release of lipopolysaccharide stimulates tissue macrophages to secrete inflammatory monokines, IL-1 and TNF, which, in turn, activate endothelial cells to express E- and P-selectins. E- and P-selectins serve as counter receptors for neutrophils sialyl Lewis X and Lewis X to cause low-avidity neutrophil rolling. *C*, Activated endothelial cells express ICAM-1, which serves as a counter-receptor for neutrophil $ß_2$ integrin molecules, leading to high-avidity leukocyte spreading and the start of transendothelial migration. Transendothelial migration of activated neutrophils is stimulated by chemotactic factors such as endothelial cell-derived IL-8 and formylated bacterial factors. Chemoattractants promote neutrophil activation with release of L-selectin and an increase in $ß_2$ integrin affinity for ICAM-1 and for other counter-receptors promoting intravascular and neutrophil aggregation. *D*, Neutrophils invade through the vascular basement membrane with the release of proteases and reactive oxidative intermediates, causing local destruction of surrounding tissue at sites of high concentrations of chemotactic factors. (From Smolen JE, Boxer LA: Functions of neutrophils. In Williams WJ, Beutler E, Erslev AJ, et al [editors]: *Hematology*, 5th ed. New York, McGraw-Hill, 1994, with permission of The McGraw-Hill Companies.)

Figure 117-4 The mechanisms for the production, action, and detoxification of peroxides in neutrophils. Oxygen is reduced to superoxide (O^-_2) by an oxidase. NADPH is regenerated from NADPH by the hexose monophosphate shunt. Superoxide may spontaneously decompose to hydrogen peroxide in singlet oxygen ($^1O_2$). Hydrogen peroxide can react with superoxide to form hydroxyl radicals and generate bactericidal aldehydes (RCHO) by oxidizing bacterial constituents in the presence of halide ions and myeloperoxidase that were delivered to the phagosome by degranulation. Hydroxyl radicals (•OH) can peroxidize unsaturated fatty acids of the phagosomal membrane and thus yield the potentially bactericidal aldehydes. Hydrogen peroxide in the presence of myeloperoxidase and chloride ion can create hypochlorous acid (HOCl) in the phagosome. Superoxide leaking out of the phagosome may be converted rapidly to hydrogen peroxide by superoxide dismutase (SOD). Hydrogen peroxide in the cytosol is destroyed by catalase or reduced glutathione (GSH). Glutathione is regenerated by coupled reactions that stimulate the flow of glucose-6-phosphate (G-6-P) into the hexose monophosphate shunt. (Modified from Stossel TP, Boxer LA: Functions of neutrophils. In Williams WJ, Beutler E, Erslev AJ, Lichtman MA [editors]: *Hematology*, 3rd ed. New York, McGraw-Hill, 1972, p 751.)

Figure 117-5 This is a modification of a hypothetical model of NADPH oxidase activation. Current knowledge suggests that the oxidase in its dormant state *(left)* is composed of both membrane-bound and cytosolic components. The former includes the gp91^{phox} and p22^{phox} subunits of cytochrome-b (and possibly Rap-1A). The flavin and heme groups (Fe) that mediate the transfer of electrons from NADPH to molecular oxygen are localized in the cytochrome. The cytosolic components p47^{phox} and p67^{phox} may exist as a preformed complex of 260?kD, which includes a third protein, p40^{phox}. The small GTPase Rac2 is present in the cytosol in its inactive guanosine diphosphate-bound state (GDP). Following phagocyte activation, the cytosolic complex translocates to the membrane, which may be under the control of the active guanosine triphosphate (GTP)–bound form of Rac2 and further regulated by phosphorylation of p47^{phox}. By a mechanism that is not fully understood, binding of the cytosolic components activates the flavocytochrome to catalyze the transfer of electrons from NADPH to oxygen through the FAD and heme redox centers. (Modified from Curnutte J, Orkin S, Dinauer M: Genetic disorders of phagocyte function. In Stamatopyannopoulous G, Nienhuis AW, Majerus PW, Varmus H [editors]: *The Molecular Basis of Blood Diseases*, 2nd ed. Philadelphia, WB Saunders, 1994, p 522.)

Figure 120-1 Algorithm for the evaluation of the patient with recurrent infections suggesting disorders of phagocyte function. CBC = complete blood count; Ig = immunoglobulin; G-6-PD = glucose-6-phosphate dehydrogenase; LAD = leukocyte adhesion deficiency. (Modified from Curnutte JT, Boxer LA: Clinically significant phagocyte cell defects. In Remington JS, Swartz MN [editors]: *Current Clinical Topics in Infectious Diseases,* 6th ed. New York, McGraw-Hill, 1985, p 144.)

Figure 120-2 The pathogenesis of chronic granulomatous disease (CGD). The manner in which the metabolic deficiency of the CGD neutrophil predisposes the host to infection is shown schematically. Normal neutrophils stimulate hydrogen peroxide in the phagosome containing ingested *Escherichia coli*. Myeloperoxidase is delivered to the phagosome by degranulation, as indicated by the closed circles. In this setting, hydrogen peroxide acts as a substrate for myeloperoxidase to oxidize halide to hypochlorous acid and chloramines that kill the microbes. The quantity of hydrogen peroxide produced by the normal neutrophil is sufficient to exceed the capacity of catalase, a hydrogen peroxide–catabolizing enzyme of many aerobic microorganisms, including most gram-negative enteric bacteria, *Staphylococcus aureus, Candida albicans*, and *Aspergillus*. When organisms such as *E. coli* gain entry into CGD neutrophils, they are not exposed to hydrogen peroxide because the neutrophils do not produce it, and the hydrogen peroxide generated by microorganisms themselves is destroyed by their own catalase. When CGD neutrophils ingest streptococci, these organisms, which lack catalase, generate enough hydrogen peroxide to result in a microbicidal effect. As indicated (*middle*), catalase-positive microbes such as E. coli can survive within the phagosome of the CGD neutrophil. Modified from Boxer LA: Quantitative abnormalities of granulocytes. In Beutler E, Lichtman MA, Coller BS, Kipps TJ, Seligsohn V [editors]: *Williams Hematology,* 6th ed. New York, McGraw-Hill, 2001, p 845.)

Figure 121-1 Algorithm for the evaluation of a patient with leukopenia. ANC = absolute neutrophil count; NK = natural killer; WBC = white blood cell count. (Modified from Boxer LA: Approach to the patient with leukopenia. In Humes HD [editor]: *Kelley's Textbook of Internal Medicine*, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2000, p 1578.)

Figure 122-1 Cytokine control of the phagocyte production and activation by release of endotoxin during infection. Both endothelial cells and fibroblasts release substantial quantities of both granulocyte macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) in response to tumor necrosis factor (TNF) and interleukin-1 (IL-1). Both TNF and IL-1 are released from endotoxin-activated monocytes and antigen-activated T-lymphocytes. Stem cell factor (SCF), interleukin-3 (IL-3), GM-CSF, and interleukin-6 (IL-6) each influence the growth and differentiation of multilineage progenitor cells known as colony forming units (CFU)-granulocytes, eosinophils, monocytes, megakaryocytes (CFU_{GEMM})-to the committed colony forming unit macrophage (CFU_{M}), CFU eosinophil (CFU_{eo}), or CFU granulocyte (CFU_{G}). Platelet production can also be augmented by expansion of CFU megakaryocyte (CFU_{meg}). Factors that serve as growth and differentiation factors for a specific lineage also act as activation factors for the terminally differentiated forms of the same lineage. Macrophage-colony stimulating factor (M-CSF) enhances antibody-mediated cytotoxicity and phagocyte functions of monocytes. G-CSF promotes neutrophil bactericidal capacity, and interleukin-5 (IL-5) activates eosinophil function. Within hours of an infection, cytokine primed neutrophils move to the invasion site from the circulation under the influence of interleukin-8 (IL-8), which is released from endothelial cells and fibroblasts.

Figure 123-1 Sequence of activation of the components of the classical/MBL pathway of complement and interaction with the alternative pathway. Activation of C3 is the functionally essential target. (Ag = antigen [bacterium, virus, tumor cell, or erythrocyte]; Ab = antibody [IgG or IgM class only]; C-CRP = C carbohydrate-C-reactive protein; B,D,I,H = factors B, D, I, and H; C4-bp = C4-binding protein; MBL = mannose-binding lectin; MASPs = MBL-associated serine proteases.) The multiple sites at which inhibitory regulator proteins act are indicated by asterisks, emphasizing the delicate balance between action and control in this system that is required for host defense yet capable of mediating profound damage to host tissues.

Figure 125-1 Marrow grafts for aplastic anemia (AA). Kaplan-Meier estimates of survival in 78 patients with aplastic anemia given HLA-identical marrow transplants. Thirty-nine were conditioned with cyclophosphamide/antithymocyte globulin (current patients), and 39 received cyclophosphamide alone (historical patients). Tick marks indicate surviving patients. (From Storb R, Leisenring W, Anasetti C, et al: Long-term follow-up of allogeneic marrow transplants in patients with aplastic anemia conditioned by cyclophosphamide combined with antithymocyte globulin. *Blood* 1997;89:3890–91.)

Figure 125-2 The probabilities of rejection-free survival for 271 patients younger than 17 yr of age with thalassemia who received marrow transplants from HLA-identical family members after conditioning with busulfan and cyclophosphamide. (From Forman SJ, Blume KG, Thomas ED: *Bone Marrow Transplantation.* Boston, Blackwell, 1994.)

Figure 130-1 T-cell differentiation.

Figure 130-2 Role of Th2 cytokines in allergic cascade.

Figure 134-1 Spirometry. *A*, Spirometric flow-volume loops. A is an expiratory flow-volume loop of a nonasthmatic, without airflow limitation. B through E are expiratory flow-volume loops in asthmatic patients with increasing degrees of airflow limitation (B is mild; E is severe). Note the “scooped” or concave appearance of the asthmatic expiratory flow-volume loops; with increasing obstruction, there is greater “scooping.” *B*, Spirometric volume-time curves. Subject 1 is a nonasthmatic; subject 2 is an asthmatic. Note how the FEV_1 and FVC lung volumes are obtained. The FEV_1 is the volume of air exhaled in the 1st second of a forced expiratory effort. The FVC is the total volume of air exhaled during a forced expiratory effort. Note that subject 2's FEV_1 and FEV_1 /FVC ratio are smaller than subject 1's, demonstrating airflow obstruction. Also, subject 2's FVC is very close to what is expected.

Figure 134-2 Peak flow monitoring. *A*, Peak expiratory flows (PEFs) performed and recorded twice daily, in the morning (am) and evening (pm), over 1 mo in an asthmatic child. This child's “personal best” PEF is 220?L/min; therefore, *green zone* (<80–100% of best) is 175–220?L/min; *yellow zone* (50–80%) is 110–175?L/min; and *red zone* (<50%) is less than 110?L/min. Note that this child's pm PEFs are almost always in the green zone, whereas his am PEFs are often in the yellow or red zone. This illustrates the typical diurnal am-to-pm variation of inadequately controlled asthma. *B*, PEFs performed twice daily, in the morning (am) and evening (pm), over 1 mo in an asthmatic child who developed a viral respiratory tract infection. Note that the child's PEF values were initially in the green zone. A viral respiratory tract infection led to asthma worsening, with a decline in PEF to the yellow zone that continued to worsen until PEFs were in the red zone. At that point, a 4-day prednisone course was administered, followed by improvement in PEF back to the green zone.

Figure 143-1 Erythematous nodules and plaques are present over both shins. The skin overlying the lesions is red, smooth, and shiny. The nodules are usually tender. Erythema nodosum is considered a hypersensitivity reaction and can be associated with a variety of diseases, including sarcoidosis, group *A Streptococcus* infection, tuberculosis, coccidioidomycosis, and ulcerative colitis. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases; Copyright 1991, 1995, 1997. Used by permission of the American College of Rheumatology.)

Figure 145-1 Synovial biopsy from a 10-yr-old child with pauciarticular juvenile rheumatoid arthritis. There is a dense infiltration of lymphocytes and plasma cells in the synovium.

Figure 145-2 MRI scan with gadolinium of a 10-yr-old child with juvenile rheumatoid arthritis (same patient as in Fig. 145–1). The dense white signal in the synovium near the distal femur, proximal tibia, and patella reflects inflammation. MRI is useful to exclude ligamentous injury, chondromalacia of the patella, or tumor.

Figure 145-11 Chronic anterior uveitis, or iridocyclitis, of juvenile rheumatoid arthritis. Extensive posterior synechiae have resulted in a small, irregular pupil. There is a well-developed cataract and early band keratopathy at the medial and lateral margins of the cornea.

Figure 146-1 Loss of lumbodorsal spine mobility in a boy with ankylosing spondylitis: The lower spine remains straight when the patient bends forward.

Figure 146-2 Nail pitting (*arrow*) and "sausage digit" (dactylitis) of the left index finger of a girl with juvenile psoriatic arthritis. (From Petty RE, Malleson P: Spondyloarthropathies of childhood. *Pediatr Clin North Am* 1986;33:1079.)

Figure 146-3 Well-developed sacroiliitis in a boy with ankylosing spondylitis; both sacroiliac joints show extensive sclerosis, erosion of joint margins, and apparent widening of the joint space.

Figure 148-2 Erythematous lesion involving the hard palate in a patient with systemic lupus erythematosus. (From Moschella S, Hurley H [editors]: *Dermatology*, 3rd ed. Philadelphia, WB Saunders, 1992.)

Figure 148-3 Livedo reticularis. Lacelike bluish, purplish, or erythematous discoloration of the skin indicating vascular instability. (From Moschella S, Hurley H [editors]: *Dermatology*, 3rd ed. Philadelphia, WB Saunders, 1992.)

Figure 148-4 A 12-yr-old girl with systemic lupus erythematosus and antiphospholipid antibodies with painful cutaneous vasculitis of the right foot. Arterial thrombosis documented by angiography resulted in cyanosis of the large toe. Symptoms resolved with treatment with heparin and corticosteroids.

Figure 149-1 The facial rash of juvenile dermatomyositis. There is erythema over the bridge of the nose and malar areas, with violaceous (heliotropic) discoloration of the upper eyelids.

Figure 149-2 The rash of juvenile dermatomyositis. The skin over the metacarpal and proximal interphalangeal joints may be hypertrophic and pale red (Gottron papules).

Figure 149-3 Nailfold capillary pattern in rheumatic diseases. *A*, Normal nailfold capillary pattern in a healthy child, with a homogeneous distribution and uniform appearance of capillary loops. *B*, The nailfold capillary pattern in a child with juvenile dermatomyositis that shows dropout of capillary end-loops, resulting in a wide band of avascularity. Dilated, tortuous capillaries are also seen, some with terminal bush formation that is found in patients with juvenile dermatomyositis, with scleroderma, and with Raynaud phenomenon that may progress to scleroderma.

Figure 149-4 An MRI scan with T2 weighted image with fat suppression of the proximal muscle of the lower extremities of a child with juvenile dermatomyositis with normal muscle enzymes. There is focal inflammatory myopathy. The white areas reflect the inflammatory response in involved muscle; those areas that are darker are more normal. Identification of the involved areas by MRI aids in directing the location of the muscle biopsy or electromyogram.

Figure 150-1 Facial changes in a 16-yr-old boy with scleroderma. There is a small mouth with puckering of the lips, pinched nose, and hyperpigmentation of the neck. (From Uziel Y, Miller ML, Laxer RM: Scleroderma in children. *Pediatr Clin North Am* 1995;42:1177.)

Figure 150-2 Tiny digital pitting scars and loss of pulp space resulting from digital ischemia in a 15-yr-old boy with scleroderma. (From Uziel Y, Miller ML, Laxer RM: Scleroderma in children. *Pediatr Clin North Am* 1995;42:1178.)

Figure 150-3 Inability to make a full fist due to skin and soft tissue tightening in a 10-yr-old girl with scleroderma. (From Uziel Y, Miller ML, Laxer RM: Scleroderma in children. *Pediatr Clin North Am* 1995;42:1176.)

Figure 150-4 Extensive morphea involving the entire left leg causing shortening and flexion contractures. The skin has a shiny appearance with patches of hyperpigmentation and vitiligo.

Figure 155-1 Sarcoidosis in a white 10-yr-old girl. There are widely disseminated peribronchial infiltrations, multiple small nodular densities, hyperaeration of the lungs, and hilar lymphadenopathy.

Figure 157.1-1 Histopathology of a skin biopsy from a patient with Henoch-Schönlein purpura showing leukocytoclastic vasculitis with nuclear degeneration (“nuclear dust”).

Figure 157.1-2 Henoch-Schönlein purpura. (From Korting GW: *Hautkrankheiten bei Kindern und Jugendlichen*, 3rd ed. Stuttgart, FK SchattauerVerlag, 1982.)

Figure 157.2-3 Angiogram of a child with Takayasu arteritis showing massive bilateral carotid dilatation, stenosis, and poststenotic dilatation.

Figure 157.3-4 Biopsy of a medium-sized muscular artery that exhibits marked fibrinoid necrosis of the vessel wall (*arrow*). (From Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In *Textbook of Pediatric Rheumatology*, 3rd ed. Philadelphia, WB Saunders, 1995.)

Figure 157.3-5 Celiac angiography of an 18-yr-old boy showing aneurysms in multiple vessels. (From Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In *Textbook of Pediatric Rheumatology*, 3rd ed. Philadelphia, WB Saunders, 1995.)

Figure 157.4-6 Chest radiograph of a 14-yr-old girl with Wegener granulomatosis showing widespread infiltrates suggestive of pulmonary hemorrhage. There were considerable day-to-day variability and eventual total resolution of these abnormalities after treatment with prednisone and cyclophosphamide. (From Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In *Textbook of Pediatric Rheumatology*, 3rd ed. Philadelphia, WB Saunders, 1995.)

Figure 161-1 The pathogenesis of fever. Various infectious toxins and other mediators induce the production of endogenous pyrogens by host inflammatory cells. Endogenous pyrogens include the cytokines interleukin (IL)-1 and IL-6, tumor necrosis factor-a (TNFa), and interferon (IFN)-s and -?. Endogenous pyrogenic cytokines directly stimulate the hypothalamus to produce prostaglandin (PG) E_2 (PGE_2), which then resets the temperature regulatory set point. Neuronal transmission from the hypothalamus leads to conservation and generation of heat, thus raising core body temperature. (From Dinarello CA, Cannon JG, Wolff SM: New concepts on the pathogenesis of fever. *Rev Infect Dis* 1988;10: 168–89.)

Figure 163-1 Progression from infection to sepsis (systemic inflammatory response syndrome [SIRS]) and its complications. (Modified from Sáez-Llorens X, McCracken GH Jr: Sepsis syndrome and septic shock in pediatrics: Current concepts of terminology, pathophysiology, and management. *J Pediatr* 1993;123: 497–508.)

Figure 163-2 Hypothetical pathophysiology of the septic process. ACTH, adrenocorticotropic hormone; TNF, tumor necrosis factor; IL-1, interleukin-1; PAF, platelet-activating factor; PMN, polymorphonuclear lymphocytes; IFN, interferon gamma; MODS, multiorgan dysfunction syndrome. (From Sáez-Llorens X, McCracken GH Jr: Sepsis syndrome and septic shock in pediatrics: Current concepts of terminology, pathophysiology, and management. *J Pediatr* 1993;123:497–508.)

Figure 163-3 The hypothetical relationships between pro-inflammatory responses of the systemic inflammatory response syndrome (SIRS), compensatory anti-inflammatory syndrome (CARS), mixed anti-inflammatory syndrome (MARS), and the ensuing “CHAOS” are illustrated. (From Bone RC, Grodzin CJ, Balk RA: Sepsis: A new hypothesis for pathogenesis of the disease process. *Chest* 1997;112: 235–43.)

Figure 164-1 Guide to the initial management of the febrile neutropenic patient. *Recent studies suggest that cefepime or meropenem may be as effective as ceftazidime or imipenem as monotherapy. †Aminoglycoside antibiotics should be avoided if the patient is also receiving nephrotoxic, ototoxic, or neuromuscular blocking agents; has renal or severe electrolyte dysfunction; or is suspected of having meningitis (because of poor blood-brain perfusion). (Adapted from Hughes WT, Armstrong D, Bodey GP, et al: 2002 Guidelines for the use of antimicrobial agents in neutropenic patients with cancer. *Clin Infect Dis* 2002;34:730–51.)

Figure 166.1-1 Relationship of virulence factors to diseases associated with *Staphylococcus aureus*.

Figure 169-2 Empirical management of a newborn whose mother received intrapartum antimicrobial agents for prevention of early onset GBS disease or suspected chorioamnionitis. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate. If no maternal intrapartum chemoprophylaxis for GBS was administered despite an indication being present, there are insufficient data available upon which to recommend a single management strategy. *Full diagnostic evaluation includes a complete blood count (CBC) and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed. †Duration of therapy varies depending on the results of the cultures and laboratory testing and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48?hr. ‡CBC with differential and blood culture. §Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens. A healthy-appearing infant who was =38 wk gestational age at delivery and whose mother received =4?hr of intrapartum chemoprophylaxis before delivery may be discharged home after 24?hr if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48?hr and until criteria for discharge are achieved. (Adapted from Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease. Revised guidelines from CDC. *MMWR Morb Mortal Wkly Rep* 2002;51[RR-11]:1–22.)

Figure 282-1 Recommended childhood and adolescent immunization schedule, United States, 2003. [1] **Hepatitis B vaccine (HepB)**. All infants should receive the first dose of hepatitis B vaccine soon after birth and before hospital discharge; the first dose may also be given by age 2 mo if the infant's mother is HBsAg-negative. Only monovalent HepB can be used for the birth dose. Monovalent or combination vaccine containing HepB may be used to complete the series. Four doses of vaccine may be administered when a birth dose is given. The second dose should be given at least 4 wk after the first dose, except for combination vaccines which cannot be administered before age 6 wk. The third dose should be given at least 16 wk after the first dose and at least 8 wk after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before age 6 mo. Infants born to HBsAg-positive mothers should receive HepB and 0.5 mL Hepatitis B Immune Globulin (HBIG) within 12 hr of birth at separate sites. The second dose is recommended at age 1–2 mo. The last dose in the vaccination series should not be administered before age 6 mo. These infants should be tested for HBsAg and anti-HBs at 9–15 mo of age. Infants born to mothers whose HBsAg status is unknown should receive the first dose of the HepB series within 12 hr of birth. Maternal blood should be drawn as soon as possible to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 wk). The second dose is recommended at age 1–2 mo. The last dose in the vaccination series should not be administered before age 6 mo. [2] **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP)**. The fourth dose of DTaP may be administered as early as age 12 mo, provided 6 mo have elapsed since the third dose and the child is unlikely to return at age 15–18 mo. **Tetanus and diphtheria toxoids (Td)** is recommended at age 11–12 yr if at least 5 yr have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Subsequent routine Td boosters are recommended every 10 yr. [3] ***Haemophilus influenzae* type b (Hib) conjugate vaccine**. Three Hib conjugate vaccines are licensed for infant use. If PRP-OMP (PedvaxHIB® or ComVax® [Merck]) is administered at ages 2 and 4 mo, a dose at age 6 mo is not required. DTaP/Hib combination products should not be used for primary immunization in infants at ages 2, 4 or 6 mo, but can be used as boosters following any Hib vaccine. [4] **Measles, mumps, and rubella vaccine (MMR)**. The second dose of MMR is recommended routinely at age 4–6 yr but may be administered during any visit, provided at least 4 wk have elapsed since the first dose and that both doses are administered beginning at or after age 12 mo. Those who have not previously received the second dose should complete the schedule by the 11–12 yr old visit. [5] **Varicella vaccine**. Varicella vaccine is recommended at any visit at or after age 12 mo for susceptible children, i.e., those who lack a reliable history of chickenpox. Susceptible persons aged =13 yr should receive two doses, given at least 4 wk apart. [6] **Pneumococcal vaccine**. The heptavalent **pneumococcal conjugate vaccine (PCV)** is recommended for all children age 2–23 mo. It is also recommended for certain children age 24–59 mo. **Pneumococcal polysaccharide vaccine (PPV)** is

recommended in addition to PCV for certain highrisk groups. See *MMWR* 2000;49(RR-9);1–38. [7] **Hepatitis A vaccine**. Hepatitis A vaccine is recommended for children and adolescents in selected states and regions, and for certain high-risk groups; consult your local public health authority. Children and adolescents in these states, regions, and high-risk groups who have not been immunized against hepatitis A can begin the hepatitis A vaccination series during any visit. The two doses in the series should be administered at least 6 months apart. See *MMWR* 1999;48(RR-12);1–37. [8] **Influenza vaccine**. Influenza vaccine is recommended annually for children age =6 mo with certain risk factors (including but not limited to asthma, cardiac disease, sickle cell disease, HIV, diabetes, and household members of persons in groups at high risk; and can be administered to all others wishing to obtain immunity. See *MMWR* 2002;51(RR-3);1–31). In addition, healthy children age 6–23 mo are encouraged to receive influenza vaccine if feasible because children in this age group are at substantially increased risk for influenza-related hospitalizations. Children aged =12 yr should receive vaccine in a dosage appropriate for their age (0.25 mL if age 6–35 mo or 0.5 mL if aged =3 yr). Children aged =8 yr who are receiving influenza vaccine for the first time should receive two doses separated by at least 4 wk. This immunization schedule is updated annually. The current recommended schedule is available at www.nelsonpediatrics.com. For additional information about vaccines, including precautions and contraindications for immunization and vaccine shortages, please visit the National Immunization Program Website at *www.cdc.gov/nip* or call the National Immunization Information Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

Figure 290-1 Angle classification of occlusion. The typical correspondence between the facial-jaw profile and molar relationship is shown.

Figure 293-1 Schematic for different kinds of caries and ages when each can start. A significant percentage of children remain caries free. Nursing caries (early childhood caries [ECC]) begins between 1 and 2 yr of age; children with ECC are at significantly greater risk for future caries than are cariesfree children. Pit and fissure caries usually begins after about age 3, with caries of approximating tooth surfaces beginning shortly after. (From Johnsen DC: The role of the pediatrician in identifying and treating dental caries. *Pediatr Clin North Am* 1991;38: 1173.)

Figure 293-2 Early childhood caries, also called nursing bottle caries or baby bottle tooth decay.

Figure 293-3 Basic dental anatomy: 1 = enamel; 2 = dentin; 3 = gingival margin; 4 = pulp; 5 = cementum; 6 = periodontal ligament; 7 = alveolar bone; 8 = neurovascular bundle.

Figure 293-4 *A*, Facial inflammation-infection from the abscess of a maxillary primary molar. *B*, Resolution of the inflammation in 1 wk with a course of antibiotics and extraction of the tooth.

Figure 295-3 Occlusal radiograph documents intrusion of "missing tooth" presented in Figure 295–2 .

Figure 298-1 A panoramic radiograph of an 8-yr-old patient with a cleft palate showing abnormal numbers and position of teeth in the area of the cleft (*arrows*). Also shown are erupted primary teeth (ep), erupted permanent teeth (EP), and unerupted permanent teeth (UP).

Figure 299-1 A continuous tracing of esophageal motility showing 2 swallows, as indicated by the pharyngeal contraction associated with relaxation of the UES and followed by peristalsis in the body of the esophagus. The LES also displays a transient relaxation *(arrow)* unassociated with a swallow. There is an episode of gastroesophageal reflux (*) recorded by a pH probe at the time of the transient LES relaxation. (Courtesy of John Dent, FRACP, PhD, and Geoffrey Davidson, MD.)

Figure 300-1 Diagrams of the five most commonly encountered forms of esophageal atresia and tracheoesophageal fistula, shown in order of frequency.

Figure 300-2 Tracheoesophageal fistula. Lateral radiograph demonstrating a nasogastric tube coiled *(arrows)* in the proximal segment of an atretic esophagus. The distal fistula is suggested by gaseous dilatation of the stomach (S) and small intestine. The *arrowhead* depicts vertebral fusion, whereas a heart murmur and cardiomegaly suggest the presence of a ventricular septal defect. This patient demonstrated elements of the VATER anomalad. (From Balfe D, Ling D, Siegel M: The esophagus. In Putman CE, Ravin CE [editors]: *Textbook of Diagnostic Imaging*. Philadelphia, WB Saunders, 1988.)

Figure 302-1 Barium esophagogram of a patient with achalasia demonstrating dilated esophagus and narrowing at the lower esophageal sphincter. Note retained secretions layered on top of barium in the esophagus.

Figure 308.1-1 Radiographs of a coin in the esophagus. When foreign bodies lodge in the esophagus, the flat surface of the object is seen in the anteroposterior view *(A)* and the edge is seen in the lateral view *(B)*. The reverse is true for objects in the trachea. (Courtesy of Beverley Newman, MD.)

Figure 310.1-1 Gastric peristaltic wave in an infant with pyloric stenosis.

Figure 310.1-2 *A*, Transverse sonogram demonstrating a pyloric muscle wall thickness of greater than 4?mm (*distance between crosses*). *B*, Horizontal image demonstrating a pyloric channel length greater than 14?mm (*wall thickness outlined between crosses*) in an infant with pyloric stenosis.

Figure 310.1-3 Barium in the stomach of an infant with projectile vomiting. The attenuated pyloric canal is typical of congenital hypertrophic pyloric stenosis.

Figure 311.1-1 Abdominal radiograph of a newborn infant held upright. Note the "double bubble" gas shadow above and the absence of gas in the distal bowel in this case of congenital duodenal atresia.

Figure 311.2-2 *A* and *B*, Classification of intestinal atresia. Type I: Mucosal obstruction caused by an intraluminal membrane with intact bowel wall and mesentery. Type II: Blind ends are separated by a fibrous cord. Type IIIa: Blind ends are separated by a V-shaped mesenteric defect. Type IIIb: "Apple peel" appearance. Type IV: Multiple atresias. (From Grosfeld J: Jejunoileal atresia and stenosis. In Welch KJ, et al [editors]: *Pediatric Surgery*, 4th ed. Chicago, Year Book Medical Publishers, 1986.)

Figure 311.3-3 The mechanism of intestinal obstruction with incomplete rotation of the midgut (malrotation). The *dotted lines* show the course the cecum should have taken. Failure to rotate has left obstructing bands across the duodenum and a narrow pedicle for the midgut loop, making it susceptible to volvulus. (From Nixon HH, O'Donnell B: *The Essentials of Pediatric Surgery*. Philadelphia, JB Lippincott, 1961.)

Figure 312.2-1 Typical Meckel diverticulum located on the antimesenteric border.

Figure 312.2-2 Meckel scan demonstrating accumulation of technetium in the stomach superior bladder (inferior) and in the acid-secreting mucosa of a Meckel diverticulum.

Figure 313.3-1 Barium enema in a 14-yr-old boy with severe constipation. The enormous dilatation of the rectum and distal colon is typical of acquired functional megacolon.

Figure 313.3-2 Lateral view of a barium enema in a 3-yr-old girl with Hirschsprung disease. The aganglionic distal segment is narrow, with distended normal ganglionic bowel above it.

Figure 314.3-1 Intussusception in an infant. The obstruction is evident in the proximal transverse colon. Contrast material between the intussusceptum and the intussuscipiens is responsible for the coil-spring appearance.

Figure 320.1-2 Gluten-sensitive enteropathy. Growth curve demonstrates initial normal growth from 0–9 mo, followed by onset of poor appetite with intermittent vomiting and diarrhea after initiation of gluten-containing diet (*single arrow*). After biopsy-confirmed diagnosis and treatment with gluten-free diet (*double arrow*), growth improves.

Figure 322-1 Normal transport of nutrients and electrolytes across the gastrointestinal (GI) tract of an infant. The GI tract of the infant handles 285?mL/kg/day of dietary and endogenous fluids. Most of the nutrients and fluids are absorbed by means of transport protein, depicted schematically. NHE-2 and NHE-3 indicate Na^+ /H^+ exchanger isoforms 2 and 3. The colon absorbs mainly water and electrolytes through the electroneutral NaCl and the electrogenic Na+ process.

Figure 324-1 Graded compression ultrasonogram of acute appendicitis demonstrating edematous enlarged appendix compressed between the abdominal wall and the psoas muscle. int obl, internal oblique muscle; tr abd, transverse abdominis muscle; a, right iliac artery; v, right iliac vein. (From Puylaert JB, Rutgers PH, Laisang RI, et al: A prospective study of ultrasonography in the diagnosis of appendicitis. *N Engl J Med* 1987;317: 666.)

Figure 327-1 Hernia and hydroceles. (Modified from Scherer LR III, Grosfeld JL: Inguinal and umbilical anomalies. *Pediatr Clin North Am* 1993;40:1122.)

Figure 327-2 Image on laparoscopy of patent processus vaginalis on right side.

Figure 327-3 Image on diagnostic laparoscopy of obliterated processus vaginalis on left side.

Figure 332.1-1 Acute pancreatitis. Computed tomography (CT) through the body of the pancreas demonstrates a halo of decreased attenuation around the pancreas that represents a peripancreatic zone of edema and fluid *(curved arrows)*. Note the pancreatic ascites most obvious lateral to the liver *(small arrows)*. If intravenous contrast was administered before the CT scan, the inflamed pancreas would appear more dense (whiter). (L = liver; A = aorta; K = kidney; S = spleen; IVC = inferior vena cava; ST = stomach.) (From Freeny P, Lawson T: The pancreas. In Putman CE, Ravin CE [editors]: *Textbook of Diagnostic Imaging*. Philadelphia, WB Saunders, 1988.)

Figure 333-1 Pseudocyst. Follow-up computed tomographic scan 5 mo after the episode of acute pancreatitis demonstrates a large pseudocyst (PC). This large pseudocyst will probably not resolve spontaneously and may need drainage. (From Freeny P, Lawson T: The pancreas. In Putman CE, Ravin CE [editors]: *Textbook of Diagnostic Imaging*. Philadelphia, WB Saunders, 1988.)

Figure 335-1 Processes involved in early liver development. *A*, The ventral foregut endoderm acquires competence to receive signals arising from the cardiac mesoderm. *B*, Specific cells of the ventral foregut endoderm undergo *specification* and activation of liver-specific genes under the influence of mesodermal signals. *C*, The newly specified cells migrate into the septum transversum to initiate liver *morphogenesis*. (Reprinted from Zaret KS: Liver specification and early morphogenesis. Mech Dev 2000;92:83–88, with permission. ©2000.)

Figure 335-2 Hepatic morphogenesis. *A*, Ventral outgrowth of hepatic diverticulum from foregut endoderm in the 3.5-wk embryo. *B*, Between the two vitelline veins, the enlarging hepatic diverticulum buds off epithelial (liver) cords that become the liver parenchyma, around which the endothelium of capillaries (sinusoids) align (4-wk embryo). *C*, Hemisection of embryo at 7.5 wk demonstrating recanalization of the biliary tract. *D*, Three-dimensional representation of the hepatic lobule as present in the newborn. (Reprinted from Andres JM, Mathis RK, Walker WA: Liver disease in infants. Part I: Developmental hepatology and mechanisms of liver dysfunction. *J Pediatr* 1977;90:686–697.)

Figure 335-3 Schematic view of the ultrastructure and organelles of hepatocytes. (Reprinted from Sherlock S: Hepatic cell structure. In Sherlock S [editor]: *Diseases of the Liver and Biliary System*, 6th ed. Oxford, Blackwell Scientific, 1981, p 10, with permission from Blackwell Scientific.)

Figure 337.1-1 Neonatal cholestasis. Conceptual approach to the group of diseases presenting as cholestasis in the neonate. There are areas of overlap—patients with extrahepatic biliary atresia may have some degree of intrahepatic injury. Patients with “idiopathic” neonatal hepatitis may in the future be determined to have a primary metabolic or viral disease.

Figure 353-1 Congenital diaphragmatic hernia. *A*, Film exposed shortly after birth: Distortion of shadow of the left leaf of the diaphragm with huge, masslike density in left hemithorax displacing the heart to the right. *B*, Film exposed about 20?min after *A*. As the result of swallowed air, coils of air-filled small bowel are now demonstrated in the left hemithorax. The esophagus is outlined by swallowed contrast material. Operative correction was attempted because of extreme dyspnea. Infant died 5.5?hr after birth.

Figure 355-1 Development of various pulmonary structures during the five stages of prenatal lung development (see text).

Figure 357-1 Idealized elastic volume-pressure relationships of the lungs, chest wall, and respiratory system in the adult and the infant. Volume is expressed as a proportion of vital capacity (VC). At any volume, the pressure that the respiratory muscles generate to oppose the elastic recoil of the respiratory system is equivalent to the sum of the recoil pressures of lungs and chest wall. The intersection of each relationship with the volume axis corresponds to the relaxation volume of each component (the volume at which the elastic recoil is zero). The volume-elastic pressure relationships of the lungs are similar in the adult and infant. The volume-elastic pressure relationship of the chest wall is steeper in the infant, causing the relaxation volume of the respiratory system to be lower than in the adult. The *shaded area* represents the elastic work done by the respiratory muscles for a characteristic tidal volume. Note that this work is greater in the infant because the recoil of the chest wall does not contribute to inflate the lungs as it does in the adult. (From Pérez Fontán JJ: Mechanics of breathing. In Gluckman PD, Heymann MA [editors]: *Perinatal and Pediatric Pathophysiology: A Clinical Perspective.* London, Edward Arnold, 1993.)

Figure 357-2 Effects of restrictive and intrathoracic obstruction on the divisions of total lung capacity. Functional division of total lung capacity. Restrictive disease is usually characterized by a pattern of shallow, rapid breaths. All lung capacities (total lung capacity, functional residual capacity, and vital capacity) are reduced owing either to the increased recoil of the lungs or to the presence of a space-occupying lesion that limits lung inflation. Residual volume is often decreased (as shown in the illustration) but may also be increased if an abnormal configuration of the chest prevents the lungs from deflating completely. Intrathoracic obstruction impairs the ability of the lungs to deflate and thus causes gas trapping, increasing functional residual capacity and residual volume at the expense of vital capacity. The volume exhaled in the first second of a forced expiration ($FEV_{1.0}$) is reduced in both restrictive and obstructive disease. The ratio of $FEV_{1.0}$ to vital capacity, however, is maintained in the former and decreased in the latter.

Figure 357-3 Graphic analysis of the resistive behavior of the respiratory system during a tidal breath. In the presence of airway flow, energy dissipation causes the relationship between lung volume (expressed as a proportion of vital capacity) and the pressure that the respiratory muscles must generate to form a loop (hysteresis). The area enclosed by this loop represents the work done to overcome resistive pressures such as those caused by the friction of the air against the airway walls. Only the inspiratory portion of this work (W_{resI}), however, is performed by the respiratory muscles. The expiratory portion (W_{resE}) is done by the energy accumulated in elastic elements of the respiratory system during inspiration. (From Pérez Fontán JJ: Mechanics of breathing. In Gluckman PD, Heymann MA [editors]: *Perinatal and Pediatric Pathophysiology: A Clinical Perspective.* London, Edward Arnold, 1993.)

Figure 357-4 Flow volume loops obtained by plotting the gas flow generated during a forced vital capacity maneuver in which, after a forced exhalation, the subject inhales to vital capacity and exhales to residual volume. The direction of the loops is clockwise. Inspiration is downward; expiration is upward. $_{max}$ represents peak expiratory flow. $_{maxFRC}$ is the maximal flow recorded at functional residual capacity. Restrictive disease reduces lung volumes and both inspiratory and expiratory flow rates without changing the shape of the loop. Extrathoracic obstruction is exacerbated during inspiration and thus flattens the inspiratory limb of the loop without altering the expiratory limb. Intrathoracic obstruction increases functional residual capacity and reduces all expiratory flows. The flow reduction becomes more severe as lung volume decreases, creating a characteristic concavity or “scoop” in the expiratory limb of the loop.

Figure 357-5 Diagram demonstrating the effects of decreased ventilation-perfusion ratios on arterial oxygenation in the lungs. Three alveolar-capillary units are illustrated. Unit A has normal ventilation and an alveolar P_{O_2} of 100?mm Hg (shown by the number in the middle of the air space). The blood that circulates through this unit raises its oxygen saturation from 70% (the saturation of mixed venous blood) to 99%. Unit B has a lower ventilation-perfusion ratio and a lower alveolar P_{O_2} of 60?mm Hg. The blood that circulates through this unit reaches a saturation of only 90%. Finally, unit C is not ventilated at all. Its alveolar P_{O_2} is equivalent to that of the venous blood, which travels through the unit unaltered. The oxygen saturation of the arterial blood reflects the weighted contributions of these three units. If it is assumed that each unit has the same blood flow, the arterial blood would have a saturation of only 86%. Ventilation-perfusion mismatch is the most common mechanism of arterial hypoxemia in lung disease. Supplemental oxygen increases the arteriol P_{O_2} by raising the alveolar P_{O_2} in lung units that, like B, have a ventilation-perfusion ratio greater than zero.

Figure 357.1-6 Presentation profiles of respiratory failure in childhood. When a mechanical dysfunction is present (by far, the most common circumstance), arterial hypoxemia and hypercapnia (and hence pH) are sensed by peripheral (carotid bodies) and central (medullary) chemoreceptors. After being integrated with other sensory information from the lungs and chest wall, chemoreceptor activation triggers an increase in the neural output to the respiratory muscles (*vertical arrows*), which results in the physical signs that characterize respiratory distress. When the problem resides with the respiratory muscles (or their innervation), the same increase in neural output occurs (*arrow*), but the respiratory muscles cannot increase their effort as demanded; therefore, the physical signs of distress are more subtle. Finally, when the control of breathing is itself affected by disease, the neural response to hypoxemia and hypercapnia is absent or blunted and the gas exchange abnormalities are not accompanied by respiratory distress.

Figure 367-1 Retropharyngeal abscess in a 7-mo-old boy, with associated cellulitis and another involved node in the right lateral neck. The abscess was successfully treated with surgical drainage and antibiotics.

Figure 371.1-1 Radiograph of an airway of a patient with croup, showing typical subglottic narrowing (“steeple sign”).

Figure 371.1-2 Epiglottitis. Lateral roentgenogram of the upper airway reveals the swollen epiglottis (“thumb sign”).

Figure 373.1-1 *A*, Normal inspiratory chest radiograph in a toddler with a peanut fragment in the left main bronchus. *B*, Expiratory radiograph of the same child showing the classic obstructive emphysema (air trapping) on the involved (left) side. Air leaves the normal right side, allowing the lung to deflate. The medium shifts toward the unobstructed side.

Figure 380-1 Congenital left upper lobe emphysema. Note the extension of the emphysematous lobe into the left lower lobe and its displacement of the mediastinum toward the right.

Figure 382.3-1 Radiograph of the chest of a 7-yr-old boy with pulmonary alveolar microlithiasis. (From Clark RB III, Johnson FC: Idiopathic pulmonary alveolar microlithiasis: A case report and brief review of the literature. *Pediatrics* 1961;28:650.)

Figure 389-1 *A*, Radiographic findings characteristic of RSV pneumonia in a 6-mo-old infant with rapid respirations and fever. Anteroposterior (AP) radiograph of the chest shows hyperexpansion of the lungs with bilateral fine air space disease and streaks of density, indicating the presence of both pneumonia and atelectasis. An endotracheal tube is in place. *B*, One day later the AP radiograph of the chest shows increased bilateral pneumonia.

Figure 389-2 Radiographic findings characteristic of pneumococcal pneumonia in a 14-yr-old boy with cough and fever. Posteroanterior (*A*) and lateral (*B*) chest radiographs reveal consolidation in the right lower lobe, strongly suggesting bacterial pneumonia.

Figure 393-1 The net ion flow across normal and cystic fibrosis (CF) airway epithelia under basal conditions (large arrows). Because water follows salt movement, the predicted net flux of water would be from the airway lumen to the submucosa and would be greater across CF epithelia. The increased Na^+ absorption by CF cells is associated with an increased amiloride-sensitive Na^+ conductance across the apical (luminal) membrane and increased Na^+ ,K^+ -ATPase sites at the basolateral membrane. The cAMP-mediated apical membrane conductance of Cl^- associated with the CF transmembrane regulator (CFTR) does not function in CF epithelia, but an alternative, calcium-activated Cl^- conductance is present in normal and CF cells. It is postulated that CF cells have a limited ability to secrete Cl^- and absorb Na^+ in excessive amounts, limiting the water available to hydrate secretions and allow them to be cleared from the airways lumen. (From Knowles MR: Contemporary perspectives on the pathogenesis of cystic fibrosis. New Insights Cystic Fibrosis 1:1, 1993.)

Figure 393-2 The predicted structure of a cystic fibrosis transmembrane regulator (CFTR) shows that the molecule is anchored in the cell membrane by two membrane-spanning domains (MSD1, MSD2). These domains form a channel through which chloride and probably water can pass. Two nucleotide-binding domains (NBD1, NBD2) interact with ATP to provide energy for CFTR functions. The R domain has many sites for phosphorylation by cAMP-dependent kinases. This domain is involved in the regulation of CFTR functions such as chloride conductance. The most common CFTR mutation, ?F508, is localized to the NBD1 region. This region and the NBD2 site are particularly susceptible to mutation. However, mutations associated with typical manifestations of CF occur in all domains. (From Welsh MJ, Anderson MP, Rich DP, et al: Cystic fibrosis transmembrane conductance regulator. *Neuron* 8:821, 1992.)

Figure 393-3 *A* and *B*, Contrast enema in a newborn infant with abdominal distention and failure to pass meconium. Notice the small diameter of the sigmoid and ascending colon and dilated, air-filled loops of small intestine. Several air-fluid levels in the small bowel are seen on the upright lateral view.

Figure 393-4 Roentgenographic progression of cystic fibrosis lung disease from the diagnosis in infancy to 18 yr of age. *A*, Admitted with cough and wheezing at 2 mo of age. Notice the mild increase in bronchovascular markings, especially in the upper lobe areas. *B*, At age 4 yr, cough was minimal. Bronchovascular markings were mildly increased, and there was some improvement in the upper lobes. The wheeze never recurred. *C* and *D*, At age 13 yr, there was minimal cough and occasional sputum production. The bronchovascular markings were generally further increased, with early bronchiectatic changes in the right upper lobe. The lateral view does not suggest overinflation. *E* and *F*. Age 18 yr. During adolescence, cough and sputum production increased even though outpatient antibiotic therapy was intensified. Small-volume hemoptysis, occasional paroxysms of cough, and weight loss as well as increased nodular infiltrates (especially in the right upper lobe) and hyperinflation (as seen on the lateral view) led to the first hospitalization since infancy. Height and weight were maintained in the 25th–50th percentile.

Figure 415-3 Idealized diagram of the temporal events of a cardiac cycle.

Figure 416.2-1 Idealized diagrams showing normal position of the cardiac chambers and great blood vessels. P.A. = posteroanterior; SVC = superior vena cava; RA = right atrium; RV = right ventricle; PA = pulmonary artery; RPA = right pulmonary artery; LPA = left pulmonary artery; LA = left atrium; LV = left ventricle; IVC = inferior vena cava. (Adapted and redrawn from Dotter and Steinberg: *Radiology* 1949;53:513.)

Figure 416.2-2 Electrocardiogram in a normal neonate younger than 24?hr of age. Note the dominant R wave and upright T waves in leads V_3 R and V_1 (V_3 R paper speed = 50?mm/sec).

Figure 416.2-3 Electrocardiogram of a normal infant. Note the tall R and small S waves in V_4 R and V_1 and the inverted T wave in these leads. A dominant R wave is also present in V_6 .

Figure 416.2-4 Electrocardiogram of a normal child. Note the relatively tall R waves and inversion of the T waves in V_4 R and V_1 .

Figure 416.2-5 Normal adult electrocardiogram. Note the dominant S wave in lead V_1 . This pattern in an infant would indicate the presence of left ventricular hypertrophy.

Figure 416.2-6 Electrocardiogram of an infant with right ventricular hypertrophy (tetralogy of Fallot). Note the tall R waves in the right precordium and deep S waves in V_6 . The positive T waves in V_4 R and V_1 are also characteristic of right ventricular hypertrophy.

Figure 416.2-7 Electrocardiogram of a premature infant (weight 2?kg and age 5 wk at the time of the tracing). The cardiovascular system was clinically normal. Left ventricular dominance is manifested by R-wave progression across the chest, similar to tracings obtained from older children. Compare with the tracing from a normal full-term infant (Fig. 416–3).

Figure 416.2-8 Atrial enlargement. *A*, Peaked narrow P waves characteristic of right atrial enlargement. *B*, Wide bifid **M**-shaped P waves typical of left atrial enlargement.

Figure 416.2-9 Electrocardiogram showing right ventricular conduction delay characterized by an rsR' pattern in V_1 and a deep S wave in V_6 (V_3 R paper speed = 50?mm/sec).

Figure 416.2-10 Electrocardiogram showing left ventricular hypertrophy in a 12-yr-old child with aortic stenosis. Note the deep S wave in V_1 –V_3 and tall R in V_5 . In addition, T-wave inversion is present in leads II, III, aVF, and V_6 .

Figure 416.2-11 Electrocardiogram in hypokalemia (serum potassium, 2.7?mEq/L; serum calcium, 4.8?mEq/L at the time of the tracing). Note the prolongation of electrical systole as evidenced by a widened TU wave, as well as depression of the ST segment in V_4 R, V_1 , and V_6 .

Figure 416.2-12 Prolonged Q-T interval in a patient with long Q-T syndrome.

Figure 416.2-13 Electrocardiogram in hyperkalemia (serum potassium, 6.5?mEq/L; serum calcium, 5.1?mEq/L). Note the tall, tent-shaped T waves, especially in leads I, II, and V_6 .

Figure 416.4-14 M-mode echocardiogram. *A*, Diagram of a sagittal section of a heart showing the structures traversed by the echo beam as it is moved superiorly to positions (1), (2), and (3). AMC = anterior mitral cusp; APM = anterior papillary muscle; Dec. aorta = descending aorta; LA = left atrium; LV = left ventricle; PMC = posterior mitral cusp; PPM = posterior papillary muscle; RV = right ventricle. B, Echocardiogram from transducer position (1); this view is the best one for measuring cardiac dimensions and fractional shortening. RVED = RV dimension at end-diastole; LVED = LV dimension at end-diastole (Dd); Ds = LV dimension in systole. CW = chest wall. Fractional shortening is calculated as (LVED – LVES)/LVED.

Figure 416.7-22 Diagram of normal circulatory dynamics with pressure readings, oxygen content, and percent saturation. (Modified from Nadas AS, Fyler DC: *Pediatric Cardiology*, 3rd ed. Philadelphia, WB Saunders, 1972.)

Figure 419.2-1 Physiology of atrial septal defect (ASD). Circled numbers represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in $L/min/m^2$). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1. Desaturated blood enters the right atrium from the vena cavae at a volume of 3?$L/min/m^2$ and mixes with an additional 3?L of fully saturated blood shunting left to right across the ASD; the result is an increase in oxygen saturation in the right atrium. Six liters of blood flows through the tricuspid valve and causes a mid-diastolic flow rumble. Oxygen saturation may be slightly higher in the right ventricle because of incomplete mixing at the atrial level. The full 6?L flows across the right ventricular outflow tract and causes a systolic ejection flow murmur. Six liters returns to the left atrium, with 3?L shunting left to right across the defect and 3?L crossing the mitral valve to be ejected by the left ventricle into the ascending aorta (normal cardiac output).

Figure 419.5-2 Physiology of atrioventricular septal defect (AVSD). Circled numbers represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 3:1. Desaturated blood enters the right atrium from the vena cavae at a volume of 3?L/min/m^2 and mixes with 3?L of fully saturated blood shunting left to right across the atrial septal defect; the result is an increase in oxygen saturation in the right atrium. Six liters of blood flows through the right side of the common AV valve, joined by an additional 3?L of saturated blood shunting left to right at the ventricular level, further increasing oxygen saturation in the right ventricle. The full 9?L flows across the right ventricular outflow tract into the lungs. Nine liters returns to the left atrium, with 3?L shunting left to right across the defect and 6?L crossing the left side of the common AV valve and causing a mid-diastolic flow rumble. Three liters of this volume shunts left to right across the VSD, and 3?L is ejected into the ascending aorta (normal cardiac output).

Figure 419.5-3 Electrocardiogram from a child with an atrioventricular canal. Note the QRS axis of -60 degrees and the right ventricular conduction delay with an RSR' pattern in V1 and V3R (V3R paper speed = 50?mm/sec).

Figure 419.5-4 Echocardiogram of an atrioventricular septal defect. *A*, Four-chamber view demonstrating both an interatrial and an interventricular septal defect contributing to the large central communication of this lesion (arrows). *B*, Left ventricular long-axis projection demonstrating the typical gooseneck deformity created by the anterior leaflet of the mitral valve (arrows). RA = right atrium; LA = left atrium; RVI = right ventricular inflow; LV = left ventricle; R = right; L = left; S = superior; I = inferior; Ao = aorta.

Figure 419.6-5 Physiology of a large ventricular septal defect (VSD). Circled numbers represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1. Desaturated blood enters the right atrium from the vena cava at a volume of 3?L/min/m^2 and flows across the tricuspid valve. An additional 3?L of blood shunts left to right across the VSD, the result being an increase in oxygen saturation in the right ventricle. Six liters of blood is ejected into the lungs. Pulmonary arterial saturation may be further increased because of incomplete mixing at right ventricular level. Six liters returns to the left atrium, crosses the mitral valve, and causes a mid-diastolic flow rumble. Three liters of this volume shunts left to right across the VSD, and 3?L is ejected into the ascending aorta (normal cardiac output).

Figure 419.8-6 *A*, Preoperative roentgenogram in a patient with a ventricular septal defect with a large left-to-right shunt and pulmonary hypertension. Significant cardiomegaly, prominence of the pulmonary arterial trunk, and pulmonary overcirculation are evident. *B*, Three years after surgical closure of the defect, heart size is markedly decreased, and the pulmonary vasculature is normal.

Figure 420.1-1 Physiology of valvular pulmonary stenosis. *Boxed numbers* represent pressure in mm?Hg. Because of the absence of right-to-left or left-to-right shunting, blood flow through all cardiac chambers is normal at 3 L/min/m^2 . The pulmonary-to-systemic blood flow ratio (Qp:Qs) is 1:1. Right atrial pressure is increased slightly as a result of decreased right ventricular compliance. The right ventricle is hypertrophied, and systolic and diastolic pressure is increased. The pressure gradient across the thickened pulmonary valve is 60?mm Hg. The main pulmonary artery pressure is slightly low, and poststenotic dilatation is present. Left heart pressure is normal. Unless right-to-left shunting is occurring through a foramen ovale, the patient's systemic oxygen saturation will be normal.

Figure 420.1-2 Roentgenogram in a patient with valvular pulmonary stenosis and a normal aortic root. The heart size is within normal limits, but poststenotic dilatation of the pulmonary artery is present.

Figure 420.1-3 Balloon pulmonary valvuloplasty. *A*, Hourglass shape of the balloon at the start of inflation. *B*, Full balloon inflation. The left pulmonary artery is protected from the sharp tip of the catheter with a flexibly tipped guide wire. (From Lababidi Z: Neonatal catheter palliations. In Long WA [editor]: *Fetal and Neonatal Cardiology*. Philadelphia, WB Saunders, 1990.)

Figure 420.6-4 Metamorphosis of coarctation. *A*, Fetal prototype with no flow obstruction. *B*, Late gestation. The aortic ventricle increases its output and dilates the hypoplastic segment. Antegrade aortic flow bypasses the shelf via the ductal orifice. *C*, Neonate. Ductal constriction initiates the obstruction by removing the bypass and increasing antegrade arch flow. *D*, Mature juxtaductal stenosis. The bypass is completely obliterated, and intimal hypoplasia on the edge of the shelf is aggravating the stenosis. Collaterals develop. *E*, Persistence of the infantile-type fetal prototype. An intracardiac left-sided heart obstruction precludes an increase in antegrade aortic flow before or after birth. Both isthmus hypoplasia and a contraductal shelf are present. Lower body flow often depends on patency of the ductus. (From Gersony WM: Coarctation of the aorta. In Adams FH, Emmanouilides GC, Riemenshneider T [editors]: *Moss Heart Disease in Infants, Children, and Adolescents*, 4th ed. Baltimore, Williams & Wilkins, 1989.)

Figure 423.1-1 Physiology of the tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in L/min/m^2). Atrial (mixed venous) oxygen saturation is decreased because of the systemic hypoxemia. A volume of 3 L/min/m^2 of desaturated blood enters the right atrium and traverses the tricuspid valve. Two liters flows through the right ventricular outflow tract into the lungs, whereas 1?L shunts right to left through the ventricular septal defect (VSD) into the ascending aorta. Thus, pulmonary blood flow is two thirds normal (Qp:Qs of 0.7:1). Blood returning to the left atrium is fully saturated. Only 2?L of blood flows across the mitral valve. Oxygen saturation in the left ventricle may be slightly decreased because of right-to-left shunting across the VSD. Two liters of saturated left ventricular blood mixing with 1?L of desaturated right ventricular blood is ejected into the ascending aorta. Aortic saturation is decreased, and cardiac output is normal.

Figure 423.1-2 Roentgenogram of an 8-yr-old boy with the tetralogy of Fallot. Note the normal heart size, some elevation of the cardiac apex, concavity in the region of the main pulmonary artery, right-sided aortic arch, and diminished pulmonary vascularity.

Figure 423.1-3 Echocardiogram in a patient with the tetralogy of Fallot. This short-axis, subxiphoid, two-dimensional echocardiographic projection demonstrates anterior/superior displacement of the outflow ventricular septum that resulted in stenosis of the subpulmonic right ventricular outflow tract and an associated anterior ventricular septal defect (VSD). RV = right ventricle; AO = overriding aortic valve; LV = left ventricle.

Figure 423.1-4 Lateral view of a selective right ventriculogram in a patient with the tetralogy of Fallot. The *arrow* points to an infundibular stenosis that is below the infundibular chamber (C). The narrowed pulmonary valve orifice is seen at the distal end of the infundibular chamber.

Figure 423.1-5 Physiology of a Blalock-Taussig shunt in a patient with the tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The intracardiac shunting pattern is as described for Figure 423–1 . Blood shunting left to right across the shunt from the right subclavian artery to the right pulmonary artery increases total pulmonary blood flow and results in a higher oxygen saturation than would exist without the shunt (see Fig. 423–1).

Figure 423.3-6 Physiology of pulmonary atresia with an intact ventricular septum. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. A small amount of the blood entering the right atrium may cross the tricuspid valve, which is often stenotic as well. The right ventricular cavity is hypertrophied and may be hypoplastic. No outlet from the right ventricle exists because of the atretic pulmonary valve; thus, any blood entering the right ventricle returns to the right atrium via tricuspid regurgitation. Most of the desaturated blood shunts right to left via the foramen ovale into the left atrium, where it mixes with fully saturated blood returning from the lungs. The only source of pulmonary blood flow is via the patent ductus arteriosus. Aortic and pulmonary arterial oxygen saturation will be identical (definition of a total mixing lesion).

Figure 423.4-7 Physiology of tricuspid atresia with normally related great vessels. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. The tricuspid valve is nonpatent, and the right ventricle may manifest varying degrees of hypoplasia. The only outlet from the right atrium involves shunting right to left across an atrial septal defect or patent foramen ovale to the left atrium. There, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected either through the aorta or via a ventricular septal defect (VSD) into the right ventricle. In this example, some pulmonary blood flow is derived from the right ventricle, the rest from a patent ductus arteriosus (PDA). In patients with tricuspid atresia, the PDA may close or the VSD may grow smaller and result in a marked decrease in systemic oxygen saturation.

Figure 423.4-8 *A*, Bidirectional Glenn shunt showing the superior vena cava–right pulmonary anastomosis. *B*, A modified Fontan procedure (cavopulmonary isolation) is completed with placement of a baffle to convey inferior vena cava blood along the lateral wall of the right atrium to the superior vena cava orifice. A 4?mm fenestration is sometimes made on the medial aspect of the polytetrafluoroethylene baffle. (From Castaneda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

Figure 423.4-8 *A*, Bidirectional Glenn shunt showing the superior vena cava–right pulmonary anastomosis. *B*, A modified Fontan procedure (cavopulmonary isolation) is completed with placement of a baffle to convey inferior vena cava blood along the lateral wall of the right atrium to the superior vena cava orifice. A 4?mm fenestration is sometimes made on the medial aspect of the polytetrafluoroethylene baffle. (From Castaneda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

Figure 423.7-9 *A*, Taussig-Bing type of double-outlet right ventricle with subpulmonary stenosis necessitating repair by the Rastelli technique. *B*, The main pulmonary artery is divided and oversewn proximally. The pulmonary valve lies within the baffle pathway. *C*, Completion of the Rastelli repair with a right ventricle–pulmonary artery allograft conduit. (From Castaneda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

Figure 423.7-10 Physiology of Ebstein anomaly of the tricuspid valve. *Circled numbers* represent oxygen saturation values. Inferior displacement of the tricuspid valve leaflets into the right ventricle has resulted in a thin-walled, low-pressure "atrialized" segment of right ventricle. The tricuspid valve is grossly insufficient *(clear arrow)*. Right atrial blood flow is shunted right to left across an atrial septal defect or patent foramen ovale into the left atrium. Some blood may cross the right ventricular outflow tract and enter the pulmonary artery; however, in severe cases, the right ventricle may generate insufficient force to open the pulmonary valve, and "functional pulmonary atresia" results. In the left atrium, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected via the aorta. In this example, some pulmonary blood flow is derived from the right ventricle, the rest from a patent ductus arteriosus (PDA). Severe cyanosis will develop in neonates with a severe Ebstein anomaly when the PDA closes.

Figure 424.1-1 Physiology of d-transposition of the great arteries (d-TGA). *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the transposed aorta with resultant severe aortic desaturation. Fully saturated pulmonary venous blood flows into the left atrium, across the mitral valve into the left ventricle, and across the transposed pulmonary artery into the lungs. Pulmonary arterial oxygen saturation is thus increased. This lesion would not be compatible with life were it not for the ability of blood to shunt via two fetal pathways: the patent foramen ovale (PFO) and patent ductus arteriosus (PDA). Blood may shunt left to right or bidirectionally at the PFO. Because systemic vascular resistance tends to be higher than pulmonary vascular resistance, blood tends to shunt across the PDA mostly from the aorta to the pulmonary artery. As pulmonary resistance drops in the 1st few weeks of life, pulmonary blood flow will gradually increase in patients with d-TGA.

Figure 424.2-2 Rashkind balloon atrial septostomy. Four frames from a continuous cineangiogram show the creation of an atrial septal defect in a hypoxemic newborn infant with transposition of the great arteries and an intact ventricular septum. *A*, Balloon inflated in the left atrium. *B*, The catheter is jerked suddenly so that the balloon ruptures the foramen ovale. *C*, Balloon in the inferior vena cava. *D*, Catheter advanced to the right atrium to deflate the balloon. The time from *A* to *C* is less than 1 sec.

Figure 424.3-3 Method for translocating the coronary arteries in the arterial switch (Jantene) procedure. *A*, The aorta (anterior) and the pulmonary artery (posterior) have been transected to allow visualization of the left and right coronary arteries. The coronaries have been excised from their respective sinuses, including a large flap (button) of arterial wall. Equivalent segments of the wall of the pulmonary artery (which will become the neoaorta) are also removed. *B*, The aortocoronary buttons are sutured into the proximal portion of the neoaorta. With this technique all sutures are placed in the button of aortic wall rather than directly on the coronary arteries. *C*, Completed anastomosis of the left and right coronary arteries to the neoaorta. (Adapted from Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant. Philadelphia*, WB Saunders, 1994.)

Figure 424.4-4 Physiology of l- or corrected transposition of the great arteries (l-TGA) with a ventricular septal defect and pulmonic stenosis (VSD + PS). *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Blood from the right atrium flows through the mitral valve into the “inverted” left ventricle. However, the left ventricle is attached to the transposed pulmonary artery. Therefore, despite the anomalies, desaturated blood still winds up in the pulmonary circulation. Saturated blood returns to the left atrium, traverses the tricuspid valve into the “inverted” right ventricle, and is pumped into the transposed aorta. This circulation would be totally “corrected” were it not for the frequent association of other congenital anomalies, in this case, VSD + PS. Because of the stenotic pulmonary valve, some left ventricular blood flow crosses the VSD and into the right ventricle and the ascending aorta, and systemic desaturation results.

Figure 424.7-5 Roentgenograms of total anomalous pulmonary venous return to the left superior vena cava. *A*, Preoperative image. *Arrows* point to the supracardiac shadow, which produces the snowman or figure 8 configuration. Cardiomegaly and increased pulmonary vascularity are evident. *B*, Postoperative image showing a decrease in the size of the heart and the supracardiac shadow.

Figure 424.8-6 Physiology of truncus arteriosus. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the truncus. Saturated blood returning from the left atrium enters the left ventricle and is also ejected into the truncus. The common aortopulmonary trunk gives rise to the ascending aorta and to the main or branch pulmonary arteries. Oxygen saturation in the aorta and pulmonary arteries is usually the same (definition of a total mixing lesion). As pulmonary vascular resistance decreases over the 1st few weeks of life, pulmonary blood flow increases dramatically and mild cyanosis and congestive heart failure result.

Figure 424.10-7 Physiology of hypoplastic left heart syndrome (HLHS). *Circled numbers* represent oxygen saturation values. HLHS is not a single lesion but a constellation of different degrees of hypoplasia of the left-sided heart structures. This drawing shows a patent mitral valve, a small left ventricular cavity, and a diminutive ascending aorta. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the pulmonary artery. Because of the markedly decreased left ventricular compliance, most of the pulmonary venous blood returning to the left atrium shunts left to right at the atrial level. A small amount of left atrial blood will cross the mitral valve and be ejected into the tiny ascending aorta. The right ventricular oxygen saturation represents a mixing of desaturated systemic venous blood and saturated pulmonary venous blood. Pulmonary artery blood flows into the pulmonary arteries as well as right to left across the patent ductus arteriosus (PDA) into the aorta. Ductal blood flows prograde to the descending aorta as well as retrograde to the ascending aorta, where it supplies the head and neck vessels in addition to the coronary arteries (which arise off the small ascending aorta). Closure of the PDA results in profound hypoxia and circulatory collapse.

Figure 424.10-8 Current technique for first-stage palliation of hypoplastic left heart syndrome. *A*, Incisions used for the procedure incorporate a cuff of arterial wall allograft. The distal divided main pulmonary artery may be closed by direct suture or with a patch. *B*, Dimensions of the cuff of the arterial wall allograft. *C*, The arterial wall allograft is used to supplement the anastomosis between the proximal divided main pulmonary artery and the ascending aorta, aortic arch, and proximal descending aorta. *D* and *E*, The procedure is completed by an atrial septectomy and a 3.5?mm modified right Blalock shunt. *F*, When the ascending aorta is particularly small, an alternative procedure involves placement of a complete tube of arterial allograft. The tiny ascending aorta may be left in situ, as indicated, or implanted into the side of the neoaorta. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

Figure 424.10-8 Current technique for first-stage palliation of hypoplastic left heart syndrome. *A*, Incisions used for the procedure incorporate a cuff of arterial wall allograft. The distal divided main pulmonary artery may be closed by direct suture or with a patch. *B*, Dimensions of the cuff of the arterial wall allograft. *C*, The arterial wall allograft is used to supplement the anastomosis between the proximal divided main pulmonary artery and the ascending aorta, aortic arch, and proximal descending aorta. *D* and *E*, The procedure is completed by an atrial septectomy and a 3.5?mm modified right Blalock shunt. *F*, When the ascending aorta is particularly small, an alternative procedure involves placement of a complete tube of arterial allograft. The tiny ascending aorta may be left in situ, as indicated, or implanted into the side of the neoaorta. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

Figure 425.2-1 Double aortic arch. *A*, Small anterior segment of the double aortic arch (most common type). *B*, Operative procedure for release of the vascular ring.

Figure 425.2-2 Double aortic arch in an infant aged 5 mo. *A*, Anteroposterior view. The barium-filled esophagus is constricted on both sides. *B*, Lateral view. The esophagus is displaced forward. The anterior arch was the smaller and was divided at surgery.

Figure 425.3-3 Electrocardiogram of a 3-mo-old child with anomalous origin of the left coronary artery from the pulmonary artery. Lateral myocardial infarction is present as evidenced by abnormally large and wide Q waves in leads I, V_5 , and V_6 ; an elevated ST segment in V_5 and V_6 ; and inversion of TV_6 .

Figure 426.1-1 Roentgenogram in primary pulmonary hypertension. Note the moderate cardiac enlargement, dilatation of the pulmonary artery, and relative pulmonary undervascularity in the outer two thirds of the lung fields.

Figure 428.1-1 Sinus arrhythmia with a junctional escape beat. Note the variation in P-P interval with little change in P morphology or P-R interval. When the sinus rate is slow enough, the atrioventricular junction takes over and produces escape beats. This rhythm is normal.

Figure 428.1-2 Wandering atrial pacemaker. Note the change in P-wave configuration in the 7th, 9th, and 10th beats. The 7th P wave may represent a fusion between the sinus P and the ectopic atrial pacemaker seen in the 10th beat.

Figure 428.1-3 Premature atrial contraction (PAC). QRS complexes—the 8th, 10th, and final—in this strip are preceded by a P wave that is inverted, indicative of an ectopic origin of atrial depolarization. Note that the 8th and final QRS complexes resemble those of sinus origin whereas the 10th is aberrantly conducted. This shift in origin is a function of the preceding cycle length, which influences the refractory period of the bundle branches. The fact that the pause after the PAC is longer than two P-P intervals implies that the premature atrial depolarization has invaded and discharged the sinus node and then reset it so that it fires later.

Figure 428.1-4 Premature ventricular contractions (PVCs) induced by hyperventilation. Note that the premature beat is wide and has a completely different morphology from that of the sinus beat. The fact that the premature beat is not preceded by a P wave and the pause following it is fully compensatory (i.e., the P-P interval containing the PVC equals two sinus cycles) indicates that the sinus mechanism has not been disturbed by the premature beats.

Figure 428.2-5 Schematic representation of the heart with a right-sided anomalous pathway. The *asterisk* indicates initiation of the sinus beat. The *arrows* indicate the direction and spread of excitation. The electrocardiographic complex shown represents a fusion beat that combines activation over the normal (n) and accessory (a) pathways. The latter inscribes the delta wave. NSR = normal sinus rhythm.

Figure 428.2-6 The *upper tracing* shows paroxysmal supraventricular or atrial tachycardia with a ventricular rate of 230/min. The *lower tracing* shows sinus rhythm after DC cardioversion. Note that during the tachycardia the T wave is deformed by an inverted, presumably retrograde P wave. The QRS morphology is unchanged during the tachycardia. The low voltage is due to peripheral edema in a 1-day-old infant who had intrauterine tachycardia and hydrops fetalis.

Figure 428.2-7 *A*, Supraventricular tachycardia in a child with Wolff-Parkinson-White (WPW) syndrome. Note the normal QRS complexes during the tachycardia. *B*, Later, the typical features of WPW syndrome are apparent (short P-R interval, delta wave, and wide QRS).

Figure 428.3-8 Atrial fibrillation, characterized by the absence of P waves; presence of fibrillatory waves, which are grossly irregular, rapid undulations; and an irregular ventricular response. Fibrillatory waves may not be visible in all leads and should be carefully sought in every tracing with irregular R-R intervals. (The coexisting qR in V_1 is diagnostic of right ventricular hypertrophy in this patient with Eisenmenger syndrome.)

Figure 428.5-9 Wenckebach phenomenon (Mobitz I). The P-R interval gradually lengthens until the 4th P wave in the cycle is not conducted to the ventricle (*arrow*). The ensuing P-R interval is once again normal.

Figure 428.5-10 Complete atrioventricular (AV) block. The ventricular rate is regular at 53/min. The atrial rate varied from 65 to 95/min. The QRS morphology is normal, which is usual in congenital AV block.

Figure 428.7-11 Sick sinus syndrome with bradytachycardia. Note the bursts of supraventricular tachycardia, probably multifocal in origin, followed by long periods of sinus arrest and by sinus bradycardia.

Figure 431.5-1 Roentgenogram of a 7-mo-old girl with endocardial fibroelastosis. Note the enlargement of the heart, without a distinctive contour and clear lung fields.

Figure 432-1 Roentgenograms in acute nonspecific perticarditis. *A*, Increase in cardiopericardial shadow caused by pericardial effusion. *B*, One month later after complete recovery.

Figure 434-1 The Frank-Starling relationship. As left ventricular end-diastolic pressure (LVED) increases, the cardiac index increases, even in the presence of congestive heart failure, until a critical level of LVED is reached. Adding an inotropic agent (digoxin) shifts the curve from I and II. (From Gersony WM, Steep CN: In Dickerman JD, Lucey JF [editors]: *Smith's The Critically Ill Child: Diagnosis and Medical Management*, 3rd ed. Philadelphia, WB Saunders, 1984.)

Figure 435.1-1 Survival after pediatric heart transplantation. (Data based on over 4500 patients worldwide who received heart transplants from 1982 through 1999 as listed with the Registry of the International Society for Heart and Lung Transplantation.)

Figure 435.1-2 Major causes of death after pediatric heart transplantation. (Data from Stanford University.)

Figure 436.2-1 Two-dimensional echocardiogram showing giant coronary artery aneurysms in a patient with Kawasaki disease. PA = pulmonary artery; Ao = aorta; Cor = coronary artery

Figure 437-1 Algorithm for identifying children with high blood pressure (BP). Note that whenever BP measurement is stipulated, the average of at least two measurements should be used. (From Report of the second task force on blood pressure control in children—1987. Task Force on Blood Pressure Control in children. National Heart, Lung, and Blood Institute, Bethesda, Maryland. *Pediatrics* 1987;79:1. Copyright American Academy of Pediatrics 1987.)

Figure 438-1 Organization of the globin genes. The bottom line reflects the scale in kilobases. Transcription of mRNA takes place from the 5' to the 3' end. The upper segment represents the beta-like globin genes on chromosome 11, and the lower segment the alpha-like genes on chromosome 16. Regions of the gene that code for primary globin proteins are shown as shaded segments, and regions that code for pseudogenes ("?," nonexpressed remnants) are shown as hatched segments. The composition of embryonic, fetal, and adult hemoglobins is listed. a = alpha; ß = beta; ? = gamma; d = delta; e = epsilon; ? = zeta.

Figure 438-2 Changes in hemoglobin tetramers (*top*) and in globin subunits (*bottom*) during human development from embryo to early infancy. (From Polin RA, Fox WW: Fetal and Neonatal Physiology, 2nd ed. Philadelphia, WB Saunders, 1998, p 1769.)

Figure 438-3 Pre- and postnatal changes in the percentage of total hemoglobin represented by fetal hemoglobin (Hb F) (*shaded area*). The triangles represent postnatal production by reticulocytes in premature infants, and the dots represent cord blood and postnatal reticulocyte production in term infants. (From Brown MS: Fetal and neonatal erythropoiesis. In Stockman JA, Pochedly C [editors]: *Developmental and Neonatal Hematology*. New York, Raven Press, 1988.)

Figure 439-1 Morphologic abnormalities of the red blood cell. *A*, normal. *B*, Macrocytes (folic acid or vitamin B_{12} deficiency). *C*, Hypochromic microcytes (iron deficiency). *D*, Target cells (Hb CC disease). *E*, Schizocytes (hemolytic-uremic syndrome). (Courtesy Dr. E. Schwartz.)

Figure 449-1 Number of days for maturation of reticulocytes in the marrow and blood. The duration of maturation as blood reticulocytes is taken as µ. (Modified from Hillman RS, Finch CA: *Red Cell Manual*. Philadelphia, FA Davis, 1983.)

Figure 449-2 Red cell destruction and the catabolism of hemoglobin (Hb) based on the description by Hillman and Finch. (From Hillman RS, Finch CA: *Red Cell Manual*. Philadelphia, FA Davis, 1983.)

Figure 450-1 Vertical and horizontal interactions of membrane proteins and the pathobiology of the red cell lesion in hereditary spherocytosis (HS) and hereditary elliptocytosis/hereditary pyropoikilocytosis (HE/HPP). *Left*, A defect of vertical or transverse interactions as exemplified by the red cell membrane lesion in HS. Partial deficiencies of spectrin, ankyrin (band 2.1), or band 3 protein lead to uncoupling of the membrane lipid bilayer from the underlying skeleton *(arrow)* followed by a formation of spectrin-free microvesicles of 0.2–0.5?µm in diameter *(arrowheads)*. These vesicles can be visualized by transmission electron microscopy, but they are not seen during examination of blood films. The subsequent loss of cell surface and a decrease in the surface/volume ratio leads to spherocytosis. *Right*, Defect of horizontal or parallel interactions of skeletal proteins as exemplified by the membrane lesion in hemolytic forms of HE associated with a defect of spectrin heterodimer self-association. The molecular lesion involving a weakened self-association of spectrin heterodimers to tetramers represents a horizontal defect of the stress-supporting protein interactions. It leads to a disruption of the membrane skeletal lattice and, consequently, whole cell destabilization followed by red cell fragmentation and poikilocytosis. Such fragments are readily seen on stained blood films. (Modified from Palek J, Jarolim P: Clinical expression and laboratory detection of red blood cell membrane protein mutations. *Semin Hematol* 1993;30:249.)

Figure 450-2 Morphology of abnormal red cells. *A*, Hereditary spherocytosis; *B*, hereditary elliptocytosis; *C*, hereditary pyropoikilocytosis; *D*, hereditary stomatocytosis; *E*, acanthocytosis; *F*, fragmentation hemolysis.

Figure 454.1-1 Roentgenograms of an infant with sickle cell anemia and acute dactylitis. *A*, The bones appear normal at the onset of the episode. *B*, Destructive changes and periosteal reaction are evident 2 wk later.

Figure 454.1-2 Red blood cell (RBC) morphology associated with hemoglobin disorders. *A*, Sickle cell anemia (Hb SS): target cells and fixed (irreversibly sickled) cells. *B*, Sickle cell trait (Hb AS): normal RBC morphology. *C*, Hemoglobin CC: target cells and occasional spherocytes. *D*, Congenital Heinz body anemia (unstable hemoglobin): RBCs stained with supravital stain (brilliant cresyl blue) reveal intracellular inclusions. *E*, Homozygous B^0 -thalassemia: severe hypochromia with deformed RBCs and normoblasts. F, Hemoglobin H disease (a-thalassemia): anisopoikilocytosis with target cells. (Courtesy of Dr. John Bolles, The ASH Collection, University of Washington, Seattle.)

Figure 454.1-2 Red blood cell (RBC) morphology associated with hemoglobin disorders. *A*, Sickle cell anemia (Hb SS): target cells and fixed (irreversibly sickled) cells. *B*, Sickle cell trait (Hb AS): normal RBC morphology. *C*, Hemoglobin CC: target cells and occasional spherocytes. *D*, Congenital Heinz body anemia (unstable hemoglobin): RBCs stained with supravital stain (brilliant cresyl blue) reveal intracellular inclusions. *E*, Homozygous B^0 -thalassemia: severe hypochromia with deformed RBCs and normoblasts. Figure 454.9-3 Ineffective erythropoiesis in untransfused 3-year-old patient with thalassemia major. Massive widening of the diploic spaces of the skull on MRI, radiographic appearance of trabeculae seen on plain radiograph, and obliteration of the maxillary sinuses with hematopoietic tissue as seen on computed tomography.

Figure 455.1-1 Red cell metabolism. Glycolysis and the hexose monophosphate pathway. The enzyme deficiencies clearly associated with hemolysis are shown in bold type.

Figure 455.3-2 Nucleotide substitutions that cause G6PD deficiency. Solid squares denote mutations that cause hereditary nonspherocytic hemolytic anemia. Open squares indicate the location of mutations that cause enzyme deficiency but hemolytic anemia only under conditions of stress. The putative binding sites for glucose-6-phosphate (G6P) and nicotinamide-adenine dinucleotide phosphate (NADP) are indicated by arrows. Note that the mutations that produce nonspherocytic hemolytic anemia are almost all clustered between nucleotides 1089 and 1361, surrounding the NADP-binding domain. The exception is a mutation at nucleotide 637, which is adjacent to the putative G-6-P binding domain at nucleotide 605. (Modified from Beutler E: Glucose-6-phosphate deficiency. N Engl J Med 1991;324:169.)

Figure 467.1-1 Clotting cascade with sequential activation and amplification of clot formation. Many of the factors are activated by the clotting factor above them in the cascade. The activated factors are designated by the addition of an "a." *Right side*, The major anticoagulants and the sites that they regulate (TFPI regulates TF and VIIa; protein C and S regulate factors VIII and V; and AT-III regulates Xa and thrombin [Xa]). The dotted line illustrates that in vivo TF and VIIa activate both IX and X, but in vitro we measure only the activation of factor X. Unactivated factor VIII, when bound to its carrier protein, von Willebrand factor, is protected from protein C inactivation. When thrombin or Xa activates factor VII, it becomes unbound to von Willebrand factor, where it can participate with IXa in the activation of factor X in the presence of phospholipid and calcium. Factor XIII cross links the fibrin clot and thereby makes it more stable. HMWK = high molecular weight kininogen; PL = phospholipid; Ca^{++} = calcium; TF = tissue factor; TFPI = tissue factor pathway inhibitor; P-C/S = protein C and protein S; AT-III = antithrombin III.

Figure 467.1-2 Diagrammatic representation of the hemostatic mechanism. PGI_2 = prostacyclin; NO = nitric oxide; ADP = adenosine diphosphate; Epi = epinephrine; TXA_2 = thromboxane A_2 ; PAI = plasminogen activator inhibitor; GAGs = glycosaminoglycans; TAFI = thrombin activated fibrinolytic inhibitor.

Figure 469-1 Common variants of VWD and other related disorders. Laboratory testing is listed on the left and the results most commonly identified in patients with these conditions are shown. N is normal, ? is degree of increase, and ? is degree of decrease. A graph representing VWF multimers is shown at the bottom of each column. A lighter shade of color illustrates a reduction in staining intensity, and figure length represents the relative size of the multimers. PT-VWD = platelet-type pseudo VWD; BSS = Bernard Soulier syndrome; FVIII = factor VIII; VWF:Ag = von Willebrand antigen; VWF:RCo = ristocetin cofactor activity; BT = bleeding time; PFA = platelet function analyzer; VWF conc = VWF concentrate; Tx = treatment.

Figure 483-1 Age- and sex-specific cancer incidence rates per million children in the United States. (From Ries LAG, Smith MA, Gurney JG, et al (editors): *Cancer Incidence and Survival Among Children and Adolescents: United States SEER Program 1975–1995*. Bethesda, MD, National Cancer Institute, SEER Program, 1999. http://seer.cancer.gov/publications/ childhood/

Figure 530-3 Intrarenal reflux. Voiding cystourethrogram in a young infant male with a past history of a urinary tract infection. Note the right vesicoureteral reflux with ureteral dilatation, with opacification of the renal parenchyma representing intrarenal reflux.

Figure 530-4 DMSA renal scan showing bilateral photopenic areas indicative of acute pyelonephritis and renal scarring.

Figure 530-5 CT scan showing an area of parenchymal thinning corresponding to an underlying calyx, characteristic of pyelonephritic scarring or reflux nephropathy.

Figure 531-1 Normal and abnormal configuration of the ureteral orifices. Shown from *left to right*, progressive lateral displacement of the ureteral orifices and shortening of the intramural tunnels. *Top*, Endoscopic appearance. *Bottom*, Sagittal view through the intramural ureter.

Figure 531-2 Grading of vesicoureteral reflux. Grade I: reflux into a nondilated ureter. Grade II: reflux into the upper collecting system without dilatation. Grade III: reflux into dilated ureter and/or blunting of calyceal fornices. Grade IV: reflux into a grossly dilated ureter. Grade V: massive reflux, with significant ureteral dilatation and tortuosity and loss of the papillary impression.

Figure 531-3 Voiding cystourethrogram (VCUG) showing grade IV right vesicoureteral reflux with intrarenal reflux.

Figure 531-4 VCUG in male newborn with megacysticmegaureter syndrome. Note the massive ureteral dilatation due to high-grade vesicoureteral reflux. The bladder is very distended. There was no urethral obstruction or neuropathic dysfunction.

Figure 531-5 Various anatomic defects of the ureterovesical junction associated with vesicoureteral reflux.

Figure 531-8 *A*, Percent chance of reflux persistence, grades I, II, and IV, for 1–5 yr after presentation. *B*, Percent chance of reflux persistence by age at presentation, grade III, for 1–5 yr after presentation. (From Elder JS, Peters CA, Arant BS Jr, et al: Pediatric Vesicoureteral Reflux Guidelines Panel Summary Report on the management of primary vesicoureteral reflux in children. *J Urol* 1997;157:1846.)

Figure 531-9 Endoscopic correction of reflux. Through a cystoscope, a needle is inserted into the submucosal plane deep to the ureteral orifice and bulking agent is injected, creating a flap-valve to prevent reflux. (Adapted from Ortenberg J: Endoscopic treatment of vesicoureteral reflux in children. *Urol Clin North Am* 1998;25:152).

Figure 532-1 Ultrasonographic image of the left kidney with marked pelvic and calyceal dilatation (grade IV hydronephrosis) in a boy with ureteropelvic junction obstruction.

Figure 532-2 MAG-3 diuretic renogram in a 6-wk-old infant with right hydronephrosis detected by prenatal ultrasonography. The right kidney is on the right side of the image. *A*, Differential renal function: left kidney 70%, right kidney 30%. *B*, After administration of furosemide, drainage from the left kidney was normal and drainage from the right kidney was slow, consistent with right ureteropelvic junction obstruction. Pyeloplasty was performed on the right kidney.

Figure 532-3 Same patient as in Figure 532–2 . *A* and *B*, MAG-3 diuretic renogram at 14 mo of age shows equal function in the two kidneys and prompt drainage after the administration of furosemide.

Figure 532-4 Ureteropelvic junction obstruction. Excretory urogram in a boy, showing dilatation of the left renal pelvis and blunting of the calyces characteristic of a ureteropelvic junction obstruction.

Figure 532-5 Retrocaval ureter. Retrograde pyelogram showing medial deviation of a dilated upper ureter to the level of the 3rd lumbar vertebra, characteristic of a retrocaval ureter.

Figure 532-6 Ultrasonographic image of the right dilated ureter (*thin arrows*) extending behind and caudal to a nearly empty bladder (*arrow*) in a girl with urinary incontinence and ectopic ureter draining into the vagina.

Figure 532-7 *A*, Infant with ectopic ureterocele. Sonogram of left kidney shows massive dilatation of the upper pole and a normal lower pole. *B*, VCUG shows large ureterocele, draining the left upper pole, in the bladder. No reflux is present.

Figure 532-8 Simple intravesical ureterocele. Excretory urogram shows left hydronephrosis and a round filling defect on the left side of the bladder corresponding to a simple ureterocele causing left ureteral obstruction. This lesion was treated by transurethral incision and drainage of the ureterocele.

Figure 532-9 Obstructed nonrefluxing megaureter. Excretory urogram in a girl with a history of a febrile urinary tract infection. The right side is normal. The left side reveals hydroureteronephrosis with predominant dilatation of the distal ureter. Note the characteristic appearance of the distal ureter. There was no vesicoureteral reflux. The diagnosis of obstruction was confirmed by diuretic renography.

Figure 532-10 Neonate with primary nonrefluxing megaureter. *A*, Renal sonogram shows grade IV hydronephrosis. *B*, Dilated ureter. Renal scan showed equal function with the contralateral kidney and satisfactory drainage with diuresis stimulation. *C*, Follow-up sonogram at 10 months shows complete resolution of hydronephrosis.

Figure 532-10 Neonate with primary nonrefluxing megaureter. *A*, Renal sonogram shows grade IV hydronephrosis. *B*, Dilated ureter. Renal scan showed equal function with the contralateral kidney and satisfactory drainage with diuresis stimulation. *C*, Follow-up sonogram at 10 months shows complete resolution of hydronephrosis.

Figure 532-10 Neonate with primary nonrefluxing megaureter. *A*, Renal sonogram shows grade IV hydronephrosis. *B*, Dilated ureter. Renal scan showed equal function with the contralateral kidney and satisfactory drainage with diuresis stimulation. *C*, Follow-up sonogram at 10 months shows complete resolution of hydronephrosis.

Figure 532-11 Prune-belly syndrome. Photograph of a 1,600-g newborn with the prune-belly syndrome. Note the lack of tonicity of the abdominal wall and the wrinkled appearance of the skin.

Figure 532-12 Posterior urethral valves. Voiding cystourethrogram in an infant with posterior urethral valves. Note the dilatation of the prostatic urethra and the transverse linear filling defect corresponding to the valves.

Figure 533-1 Classic bladder exstrophy. The bladder is exposed in the midline; the umbilical cord is displaced caudad; the penis is epispadiac; and the scrotum is broad.

Figure 534-1 Grouping of neurogenic bladder dysfunction according to the innervation, tonicity, and coordination of the detrusor and sphincters described by Guzman. This grouping is based on data from imaging studies, cystometrography, and electromyography of the sphincters. Patients in group *B* are at risk of developing reflux and hydronephrosis. For guidance in the treatment of incontinence, group *A* benefits from procedures that increase outlet resistance, group *B* from anticholinergics or bladder augmentation surgery, and group *C* from intermittent catheterization and group *D* requires both increased outlet resistance and pharmacologic or surgical bladder enlargement. Most patients require intermittent catheterization to empty. (Modified from Gonzalez R: Urinary incontinence. In Kelalis PK, King LR, Belman AB [editors]: *Clinical Pediatric Urology*. Philadelphia, WB Saunders, 1992, p 387.)

Figure 534-2 Voiding cystourethrogram in an infant with myelodysplasia shows a severely trabeculated bladder with multiple diverticula and grade V (out of V) right vesicoureteral reflux. Evaluation showed severe detrusor-sphincter dyssynergia.

Figure 534-3 Buttocks of teenage boy with tethered cord secondary to lipomeningocele. Note sacral dimple and deviation of gluteal fold to the left.

Figure 535-1 Duplication of the right collecting system with ectopic ureter. Excretory urogram in a female presenting with a normal voiding pattern and constant urinary dribbling. The left kidney is normal, and the right side, well visualized, is the lower collecting system of a duplicated kidney. On the upper pole opposite the first and second vertebral bodies, note the accumulation of contrast material corresponding with a poorly functioning upper pole drained by a ureter opening in the vestibule.

Figure 535-2 Ectopic ureter. The photograph shows an ectopic ureter entering the vestibule next to the urethral meatus. The thin ureteral catheter with transverse marks has been introduced into this ectopic ureter. This girl had a normal voiding pattern and constant urinary dribbling.

Figure 536-1 Subcoronal hypospadias. Note the urethral meatus in the subcoronal position and the incomplete or hooded prepuce. There was no ventral curvature of the penis in this case.

Figure 536-2 Severe perineoscrotal hypospadias. Note the ventral curvature and the underdeveloped ventral surface of the penis, the hooded prepuce, and the urethral meatus in the mid-line of the bifid scrotum. This child had palpable gonads and a normal chromosome pattern.

Figure 536-5 Skin bridges between glans and penile shaft resulting from penile adhesions forming after newborn circum-cision. Skin bridges cause painful penile curvature during erection and predispose to infection under the adhesion and should be excised.

Figure 536-6 Concealed penis (*A*), which may be visualized by retracting skin lateral to penile shaft (*B*).

Figure 536-7 Concealed, trapped penis secondary to circumcision. This baby's penis is normal length; large hydroceles predisposed him to this complication.

Figure 536-8 Infant with microphallus. Also note the small scrotum, which was empty.

Figure 536-9 Urethral prolapse in a 4-yr-old black girl who had bloody spotting on her underwear.

Figure 536-10 Paraurethral cyst in a newborn girl.

Figure 537-2 Left testicular torsion in a newborn. Left hemiscrotum is ecchymotic, and the testis was slightly enlarged, quite firm, and nontender.

Figure 537-3 Torsion of the appendix testis, which is necrotic (*arrow*).

Figure 537-4 Left varicocele in an adolescent boy.

Figure 537-5 Newborn with large right hydrocele.

Figure 538-1 CT scan of girl who sustained major renal injury from falling off a bicycle demonstrates ruptured right kidney with urinary extravasation.

Figure 543-1 Polythelia.

Figure 552-1 Regulation of vasopressin secretion and serum osmolality. Hyperosmolality, hypovolemia, and hypotension are sensed by osmosensors, volume sensors, and barosensors, respectively. These stimulate both vasopressin (VP) secretion and thirst. Vasopressin, acting on the kidney, causes increased reabsorption of water (antidiuresis). Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or hypotension/hypovolemia. Additional stimuli for vasopressin secretion include nausea, hypoglycemia, and pain. (From Muglia LJ, Majzoub JA: Disorders of the posterior pituitary. In Sperling MA (editor): *Pediatric Endocrinology,* 2nd ed. Philadelphia, WB Saunders, 2002.)

Figure 554-1 Cerebral gigantism in an 8-yr-old boy. The height age was 12 yr; the bone age was 12 yr. IQ was 60. The electroencephalogram had abnormal findings. Notice the prominence of the forehead and the jaw and the large hands and feet. Sexual development was consistent with chronological age. Hormone study results were normal. The adult height was 208?cm (6?ft 10?in); his sexual development was normal. He wears size 18 shoes.

Figure 556.2-3 MRI of a central nervous system lesion in a child with central precocious puberty. A 6-yr-old girl was referred for stage IV breast development and growth acceleration. Serum luteinizing hormone and estradiol concentrations were in the adult range. The midsagittal T1-weighted image shows an isointense hypothalamic mass (*arrowheads*), typical of a hamartoma. (From Sharafuddin M, Luisiri A, Garibaldi LR, et al: MR imaging diagnosis of cerebral precocious puberty: Importance of changes in the shape and size of the pituitary gland. *Am J Roentgenol* 1994;162:1167.)

Figure 559-1 Congenital hypothyroidism in an infant 6 mo of age. The infant ate poorly in the neonatal period and was constipated. She had a persistent nasal discharge and a large tongue; she was very lethargic; she had no social smile and no head control. *A,* Notice the puffy face, dull expression, and hirsute forehead. Tests revealed a negligible uptake of radioiodine. Osseous development was that of a newborn. *B,* Four mo after treatment, notice the decreased puffiness of the face, the decreased hirsutism of the forehead, and the alert appearance.

Figure 559-2 Congenital hypothyroidism. *A,* Absence of distal femoral epiphysis in a 3-mo-old infant who was born at term. This is evidence for the onset of the hypothyroid state during fetal life. *B,* Epiphyseal dysgenesis in the head of the humerus in a 9-yr-old girl who had been inadequately treated with thyroid hormone.

Figure 559-3 *A,* Acquired hypothyroidism in a girl 6 yr of age. She was treated with a wide variety of hematinics for refractory anemia for 3 yr. She had almost complete cessation of growth, constipation, and sluggishness for 3 yr. The height age was 3 yr; the bone age was 4 yr. She had a sallow complexion and immature facies with a poorly developed nasal bridge. Serum cholesterol, 501?mg/dL; radioiodine uptake, 7% at 24?hr; PBI, 2.8?mg/dL. *B,* After therapy for 18 mo, notice the nasal development, the increased luster and decreased pigmentation of hair, and the maturation of face. The height age was 5.5 yr; the bone age was 7 yr. There was a decided improvement in her general condition. Menarche occurred at 14 yr. The ultimate height was 155?cm (61 in). She graduated from high school. The disorder was well controlled with sodium-L-thyroxine daily.

Figure 561-1 Congenital goiter in infancy. *A,* Large congenital goiter in an infant born to a mother with thyrotoxicosis who had been treated with iodides and methimazole during pregnancy. *B,* A 6-wk-old infant with increasing respiratory distress and cervical mass since birth. The operation revealed a large goiter that almost completely encircled the trachea. Notice the anterior deviation and posterior compression of the trachea. Partial thyroidectomy completely relieved the symptoms. It is apparent why a tracheostomy is not adequate treatment for these infants. The cause for the goiter was not found.

Figure 562.1-1 A 15-yr-old girl with classic Graves disease. Clinical features include a goiter and exophthalmos. She was treated with antithyroid drugs, to which she had a good response.

Figure 562.2-2 Twin boys with neonatal hyperthyroidism confirmed by abnormal thyroid function tests. Clinical features include lack of subcutaneous tissue due to a hypermetabolic state and a wide-eyed, anxious stare. They were given the diagnosis of neonatal Graves disease, but, in fact, their mother did not have Graves disease; they had persistent, not transient, hyperthyroidism. At age 8 yr, they were treated with radioiodine. They are now believed to have had some other form of neonatal hyperthyroidism, such as a constitutive activation of the TSH receptor.

Figure 564-1 Some components involved in calcium homeostasis. (From Thakker RV: Genetic development in hypoparathyroidism. *Lancet* 2001;357:974–76, with permission.)

Figure 568.2-1 Pathways of steroid biosynthesis. The pathways for adrenal synthesis of mineralocorticoids (aldosterone), glucocorticoids (cortisol) and androgens (DHEA, androstenedione) are arranged vertically. The enzymatic activity for each bioconversion is indicated. The systematic name for the activities mediated by specific cytochromes P450 is indicated in parentheses. The reactions shown with dotted arrows occur primarily in gonads, not in adrenals. P450c11ß mediates 11ß-hydroxylase activity in the zona fasciculata to convert DOC to corticosterone and 11-deoxycortisol to cortisol. P450c18 mediates 11ß-hydroxylase, 18-hydroxylase and 18-oxidase activities in the zona glomerulosa for the conversion of DOC to aldosterone.

Figure 568.4-2 Biosynthesis *(above dashed line)* and metabolism *(below dashed line)* of the catecholamines norepinephrine and epinephrine. Enzymes: 1, tyrosine hydroxylase; 2, dopa decarboxylase; 3, dopamine ß-oxidase; 4, phenylethanolamine-*N*-methyltransferase; 5, catechol-O-methyltransferase; 6, monoamine oxidase.

Figure 570.1-1 *A,* A 6-yr-old girl with congenital virilizing adrenal hyperplasia. The height age was 8.5 yr; the bone age was 13 yr; and urinary 17-ketosteroids were 50?mg/24?hr. *B,* Notice the clitoral enlargement and labial fusion. *C,* Five-yr-old brother of girl in *A* was not considered to be abnormal by the parents. The height age was 8 yr; the bone age was 12.5 yr; and the urinary 17-ketosteroids were 36?mg/24?hr.

Figure 570.1-2 Three female pseudohermaphrodites with untreated congenital adrenal hyperplasia. All were erroneously assigned male sex at birth, and each had normal female sex-chromosome complement. Infants *A* and *B* were salt losers and were diagnosed in early infancy. Infant *C* was referred at 1 yr of age because of bilateral cryptorchidism. Notice the completely penile urethra; such complete degrees of masculinization in females with adrenal hyperplasia are rare; most of these infants are salt losers.

Figure 577.1-1 A 12-yr-old boy with 48,XXXY/49,XXXXY mosaicism who has prognathism, epicanthal folds, scoliosis, very small testes, severe mental retardation, clinodactyly, and radioulnar synostoses.

Figure 580.1-1 Turner syndrome in a 15-yr-old girl exhibiting failure of sexual maturation, short stature, cubitus valgus, and a goiter. There is no webbing of the neck. Karyotyping revealed 45,X/46,XX chromosome complement, and the urinary gonadotropin level was over 96 mouse units/24?hr; T_4 was 2.2?µg/dL.

Figure 582.2-1 Biosynthesis of androgens. The *dotted lines* indicate enzymatic defects associated with male pseudohermaphroditism. The *vertical dotted line* indicates a defect in 3ß-hydroxysteroid dehydrogenase. A single polypeptide, P450c17, catalyzes both 17a-hydroxylase and 17,20-lyase activities.

Figure 583.2-1 Incidence rates of type 1 diabetes mellitus by region and country. (From LaPorte RA, et al: The DiaMond Project. *Pract Diabetes Int* 1995;12:93.)

Figure 583.2-2 Proposed model of the pathogenesis and natural history of type 1 DM. IVGTT = intravenous glucose tolerance test; GADA = glutamic acid decarboxylase antibody; IAA = insulin autoantibodies; ICA = islet cell antibody. (Adapted from Atkinson MA, Eisenbarth GS: Type 1 diabetes: New perspectives on disease pathogenesis and treatment. *Lancet* 2001; 358:221–9.)

Figure 583.2-3 Schematic representation of the autoimmune response against the pancreatic ß cells. An insult on the pancreas leads to the release of ß-cell antigens (GAD65), which are taken up by antigen-presenting cells (APCs) and the epitopes presented to the CD4 T cells. Type and stages of activation of APCs as well as the cytokine environment, in which the CD4 T cell priming takes place, dictate the differentiation of autoreactive T cells toward diabetogenic T helper-1 (Th1) cells, Th2 cells, or antigen-specific regulatory T cells. A predominant Th1 autoimmune response results in the recruitment and differentiation of cytotoxic CD8 cells, which attack the pancreatic ß cells, leading to a massive release of ß-cell antigens, epitope spreading, and destruction of the pancreatic islets. B, B cell; DC, dendritic cell; M, macrophage; CTL, cytotoxic cell; TGF-ß, tumor growth factor-ß; INF?, interferon-?; IL, interleukin. (Adapted from Casares S, Brumeanu TD: Insights into the pathogenesis of type 1 diabetes: A hint for novel immunospecific therapies. *Curr Molec Med* 2001;1:357–78.)

Figure 583.2-4 Approximate composite insulin effect profiles. Meals are shown as rectangles below time axis. Injections are shown as labeled triangles. L/A = lispro or aspart. Even though the fast and long-acting insulins are shaded differently to show the addition of one insulin effect to another, the profile is changed to show the combined effect. For example, in the breakfast injection in C, the quick decline of L/A effect is blunted by the rising NPH/lente effect, producing a broad tail, which slowly declines to baseline at supper. All profiles are idealized using average absorption and clearance rates. In typical clinical situations, these profiles vary among patients. A given patient has varying rates of absorption depending on the injection site, physical activity, and other variables. *A,* L or A pre-meal; glargine at bedtime. The rapid onset and short duration of L or A reduce overlap between pre-meal injections, and there is no extended nighttime action. This reduces the risk of hypoglycemia. Glargine provides a steady basal profile that simplifies prediction of bolus insulin effect. *B,* L or A pre-meal; ultralente at breakfast and supper. Ultralente produces a basal profile similar to that seen with glargine. Some excessive insulin effect, however, is seen before supper and at nighttime. *C,* L or A pre-meal; NPH or lente at breakfast and supper. The broad peak of NPH or lente produces substantial risk of hypoglycemia before lunch and during the early hours of the night. The waning insulin effect before supper and breakfast may also allow breakthrough hyperglycemia. *D,* L or A pre-meal; NPH or lente at breakfast and bedtime. Moving the evening long-acting insulin helps to cover the pre-breakfast hours, but the risk of nighttime lows persists. *E,* Regular and NPH or lente at breakfast and supper. This produces the least physiologic profile, with large excesses before lunch and during the early night, combined with poor coverage before supper and breakfast.

Figure 583.2-4 Approximate composite insulin effect profiles. Meals are shown as rectangles below time axis. Injections are shown as labeled triangles. L/A = lispro or aspart. This produces the least physiologic profile, with large excesses before lunch and during the early night, combined with poor coverage before supper and breakfast.

Figure 583.2-5 Approximate insulin effect profiles. *A,* The following relative peak effect and duration units are used: lispro/aspart, peak 20 for 4 hours; regular, peak 15 for 7 hours; NPH/lente, peak 12 for 12 hours; ultralente, peak 9 for 18 hours; glargine, peak 5 for 24 hours. ?,Injection time. *B,* Two ultralente injections given at breakfast and supper. Note overlap of profiles. *C,* Composite curve showing approximate cumulative insulin effect for the two ultralente injections. This composite view is much more useful to the patient, parents, and medical personnel because it shows important combined effects of multiple insulin injections with variable absorption characteristics and overlapping durations.

Figure 584-1 *A,* Mild papilledema. Blurred disc margins and venous congestion. *B,* Moderate papilledema. Disc edematous and raised. Vessels buried within substance of nerve tissue. *C,* Severe papilledema. Hemorrhages are evident within disc (*arrow*), and there are microinfarcts (soft exudates) in the nerve fiber layer. *D,* Macular star (*arrow*) with edema residues distributed within the Henle layer of the macula.

Figure 584-2 Gowers sign. A boy with hip girdle weakness due to Duchenne muscular dystrophy.

Figure 584-3 Opisthotonus in a brain-injured infant.

Figure 585.3-1 Diagrammatic illustration of the developing nervous system. *A,* Transverse sections of the neural plate during the 3rd wk. *B,* Formation of the neural groove and the neural crest. *C,* The neural tube is developed. *D,* Longitudinal drawing showing the initial closure of the neural tube in the central region. *E,* Cross-sectional drawing of the embryonic neural tube (primitive spinal cord).

Figure 585.3-1 Diagrammatic illustration of the developing nervous system. *A,* Transverse sections of the neural plate during the 3rd wk. *B,* Formation of the neural groove and the neural crest. *C,* The neural tube is developed. *D,* Longitudinal drawing showing the initial closure of the neural tube in the central region. *E,* Cross-sectional drawing of the embryonic neural tube (primitive spinal cord).

Figure 585.4-2 A lumbar myelomeningocele is covered by a thin layer of skin.

Figure 585.7-3 T1 weighted MRI scan demonstrating band heterotopia. A thin layer of white matter (*black arrow*) lies between the band of heterotopic gray matter and the cortical surface. Failure of cortical organization with lissencephaly is present in both frontal lobes (*white arrow*).

Figure 585.7-4 MRI of an infant with lissencephaly. Note the absence of cerebral sulci and the maldeveloped sylvian fissures associated with enlarged ventricles.

Figure 585.8-5 Lobar holoprosencephaly. T1 weighted MRI scan demonstrates failure of separation of the hemispheres and a persistent fused ventricle.

Figure 585.11-6 A midsagittal T1 weighted MRI of a patient with type II Chiari malformation. The cerebellar tonsils (*white arrow*) have descended below the foramen magnum (*black arrow*). Note the small slitlike 4th ventricle, which has been pulled into a vertical position.

Figure 585.11-7 Dandy-Walker cyst. *A,* Axial CT scan (preoperative) showing large posterior fossa cyst (Dandy-Walker cyst; *large arrows*) and dilated lateral ventricles (*small arrows*), a complication secondary to CSF pathway obstruction at the 4th ventricular outlet. *B,* Same patient, with a lower axial CT scan showing splaying of the cerebellar hemispheres by the dilated 4th ventricle (Dandy-Walker cyst). The dilated ventricles proximal to the 4th ventricle again show CSF obstruction due to the Dandy-Walker cyst. *C,* MRI of the same patient showing decreased size of the Dandy-Walker cyst and temporal horns (*arrows*) following shunting. The incomplete vermis (*small arrow*) now becomes recognizable.

Figure 585.11-8 Hydranencephaly. MRI scan showing the brainstem and spinal cord with remnants of the cerebellum and the cerebral cortex. The remainder of the cranium is filled with CSF.

Figure 586.3-1 *A,* An EEG of partial seizures: (i) spike discharges from the left temporal lobe (*arrow*) in a patient with CPS, (ii) left parietal central spikes (*arrow*) characteristic of BPEC. *B,* Representative EEGs of generalized seizures: (i) 3/sec spike and wave discharge of absence seizures with normal background activity, (ii) complex myoclonic epilepsy (Lennox-Gastaut syndrome) with interictal slow spike waves, (iii) juvenile myoclonic epilepsy showing 6/sec spike and waves enhanced by photic stimulation, and (iv) hypsarrhythmia with an irregular high-voltage spike and wave activity.

Figure 586.6-2 An approach to the child with a suspected convulsive disorder.

Figure 586.6-3 Pharmacologic effects of antiepileptic drugs at $GABA_A$ receptor. GABA = ?-aminobutyric acid; GAD = glutamic acid decarboxylase; GABA-T = GABA transaminase. Barbiturates bind to ß-subunit of $GABA_A$ receptor to potentiate action of endogenous agonist GABA and prolong opening time of chloride ion channel. Benzodiazepines bind to an a-subunit of $GABA_A$ to potentiate action of GABA and increase frequency of opening of chloride ion channel. Vigabatrin irreversibly binds to GABA-transaminase to inhibit degradation of inhibitory neurotransmitter GABA. Tiagabine blocks uptake of synaptically released GABA into both presynaptic neurons and glial cells, allowing GABA to remain at site of action for longer periods. (From Leach JP, Brodie MJ: Tiagabine. *Lancet* 1998;351:203.)

Figure 589.1-1 T2 weighted MRI scan of a patient with neurofibromatosis. Note the high-signal areas in the basal ganglia (*black arrows*), which represent hamartomas.

Figure 589.3-2 Tuberous sclerosis. *A,* CT scan with subependymal calcifications characteristic of tuberous sclerosis. *B,* The MRI demonstrates multiple subependymal nodules in the same patient (*black arrow*). Parenchymal tubers are also visible on both the CT and the MRI scan as low-density areas in the brain parenchyma.

Figure 589.3-3 An astrocytoma of the retina (mulberry tumor) in a patient with tuberous sclerosis.

Figure 589.3-4 A CT scan of a patient with Sturge-Weber syndrome showing unilateral calcification and atrophy of a cerebral hemisphere.

Figure 592.1-1 A cherry red spot in a patient with GM_1 gangliosidosis. Note the whitish ring of sphingolipid-laden ganglion cells surrounding the fovea.

Figure 592.5-2 Multiple sclerosis. *A,* T2 weighted MRI scan of brain demonstrates multiple lesions located in the white matter characteristic of multiple sclerosis (*white arrow*). *B,* T1 weighted MRI scan of spine indicates a demyelinating plaque of multiple sclerosis in the midcervical region (*white arrow*).

Figure 593.3-1 Cerebral angiogram showing idiopathic supraclinoid-internal carotid arteriopathy with classic moyamoya collaterals (*arrow*).

Figure 595-1 CT with contrast. Note the large wall-enhancing abscess in the left frontal lobe. The lesion is causing a shift of the brain to the right. The patient had no neurologic signs until just before the CT scan because the abscess is located in the frontal lobe, a “silent” area of the brain.

Figure 597.1-1 Diagram of the location of spinal cord tumors in children.

Figure 597.2-2 T1 weighted MRI scan of a spinal cord tumor (*white arrow*). The fusiform expansion of the cervical cord enhances following intravenous gadolinium injection.

Figure 597.6-3 T1 weighted MRI scan of upper spinal cord showing an extensive syringomyelia (*white arrow*).

Figure 598-1 Undescended testes are common in male neonates with neuromuscular disease already symptomatic at birth, regardless of the cause. The gubernaculum is a cylinder of striated muscle surrounding a core of smooth muscle that actively pulls the testis into the scrotum in late gestation. Weakness of the gubernaculum in a generalized myopathy of fetal life prevents or delays the descent of the testis. (Reproduced with permission from Sarnat HB, Sarnat MS: Disorders of muscle in the newborn. In Moss AJ, Stern L [editors]: *Pediatrics Update,* 4th ed. New York, Elsevier-North Holland, 1983.)

Figure 599.1-1 *A,* Cross-section of muscle from a 14-wk-old human fetus; *B*, normal full-term neonate; and *C*, term neonate with X-linked recessive myotubular myopathy. Myofibers have large central nuclei in the fetus and in myotubular myopathy, and nuclei are at the periphery of the muscle fiber in the term neonate as in the adult. (Hematoxylin & eosin, ×500.)

Figure 599.1-1 *A,* Cross-section of muscle from a 14-wk-old human fetus; *B*, normal full-term neonate; and *C*, term neonate with X-linked recessive myotubular myopathy. Myofibers have large central nuclei in the fetus and in myotubular myopathy, and nuclei are at the periphery of the muscle fiber in the term neonate as in the adult. (Hematoxylin & eosin, ×500.)

Figure 599.3-2 Electron micrograph of the muscle from a patient shown in Figure 599–4 . Nemaline rods (nr) are seen within many myofibrils. They are identical in composition to the normal Z bands (z). (×6000.)

Figure 599.3-3 Back of a 13-yr-old girl with juvenile form of nemaline rod disease. The paraspinal muscles are very thin, and winging of the scapulae is evident. The muscle mass of the extremities is also greatly reduced both proximally and distally.

Figure 599.3-4 Infantile form of nemaline rod disease in a 6-yr-old boy. Facial weakness and generalized muscle wasting are severe. The head is dolichocephalic. The mouth is usually open because the masseters are too weak to lift the mandible against gravity for more than a few seconds.

Figure 600.1-1 Muscle biopsy of a 4-yr-old boy with Duchenne muscular dystrophy. Both atrophic and hypertrophic muscle fibers are seen, and some fibers are degenerating (deg). Connective tissue (c) between muscle fibers is increased. (Hematoxylin & eosin, ×400.)

Figure 600.1-2 Dystrophin is demonstrated by immunohistochemical reactivity in the muscle biopsies of a normal term male neonate *(A)*; a 10-yr-old boy with limb-girdle muscular dystrophy *(B)*; a 6-yr-old boy with Duchenne muscular dystrophy *(C)*; and a 10-yr-old boy with Becker muscular dystrophy *(D)*. In the normal condition and also in non–X-linked muscular dystrophies in which dystrophin is not affected, the sacrolemmal membrane of every fiber is strongly stained, including atrophic and hypertrophic fibers. In Duchenne dystrophy, most myofibers express no detectable dystrophin, but a few scattered fibers known as “revertant fibers” show near-normal immunoreactivity. In Becker muscular dystrophy, the abnormal dystrophin molecule is expressed as thin, pale-staining of the sarcolemma in which reactivity varies not only between myofibers but also along the circumference of individual fibers (×250).

Figure 600.1-3 Quadriceps femoris muscle biopsy specimens from a 4-yr-old boy with Becker muscular dystrophy. *A*, Myofibers vary greatly in size, with both atrophic and hypertrophic forms; at the right is a zone of degeneration and necrosis infiltrated by macrophages, similar to Duchenne muscular dystrophy. (Hematoxylin-eosin, ×250.) Immunoreactivity using antibodies against the dystrophin molecule in the rod domain *(B)*, carboxyl-terminus *(C)*, and amino terminus *(D)* all show deficient but not totally absent dystrophin expression; most fibers of all sizes retain some dystrophin in parts of the sarcolemma but not around the entire circumference in cross section. Alternatively, the prominence of dystrophin is less, appearing weak, when compared with the simultaneously incubated normal control from another child of similar age *(E)*. *F*, Merosin expression is normal in this patient with Becker dystrophy, in both large and small myofibers, and is lacking only in frankly necrotic fibers. Compare with classic Duchenne muscular dystrophy illustrated in Figure 600–2*C* and with Figure 600–5.

Figure 600.3-4 Facial weakness, inverted V-shaped upper lip, and loss of muscle mass in the temporal fossae are characteristic of myotonic muscular dystrophy, even in infancy, as seen in this 8-mo-old girl.

Figure 600.6-5 Quadriceps femoris muscle biopsy of a 6-mo-old girl with congenital muscular dystrophy associated with merosin (a_2 -laminin) deficiency. *A*, Histologically, the muscle is infiltrated by a great proliferation of collagenous connective tissue; myofibers vary in diameter, but necrotic fibers are rare. *B*, Immunocytochemical reactivity for merosin (a_2 -laminin) is absent in all fibers, including the intrafusal myofibers of a muscle spindle seen at bottom. *C*, Dystrophin expression (rod domain) is normal. Compare with Figures 600–2 , 600–3 , and 600–6 .

Figure 600.6-5 Quadriceps femoris muscle biopsy of a 6-mo-old girl with congenital muscular dystrophy associated with merosin (a_2 -laminin) deficiency. *A*, Histologically, the muscle is infiltrated by a great proliferation of collagenous connective tissue; myofibers vary in diameter, but necrotic fibers are rare. *B*, Immunocytochemical reactivity for merosin (a_2 -laminin) is absent in all fibers, including the intrafusal myofibers of a muscle spindle seen at bottom. *C*, Dystrophin expression (rod domain) is normal. Compare with Figures 600–2 , 600–3 , and 600–6 .

Figure 600.6-6 Quadriceps femoris muscle biopsy of a 2-yr-old girl with congenital muscular dystrophy. *A*, The fascicular architecture of the muscle is severely disrupted, and muscle is replaced by fat and connective tissue; remaining small groups of myofibers of variable size are seen, including a muscle spindle at top. *B*, Merosin expression is normal in both extrafusal fibers of all sizes and in intrafusal spindle fibers. The severity of the myopathy does not relate to the presence or absence of merosin in congenital muscular dystrophy. Compare with Figure 600–5 .

Figure 603.2-1 Muscle biopsy of neonate with infantile spinal muscular atrophy. Groups of giant type I (darkly stained) fibers are seen within muscle fascicles of severely atrophic fibers of both histochemical types. This is the characteristic pattern of perinatal denervation of muscle. Myofibrillar ATPase, preincubated at pH 4.6. (×400.)

Figure 620-2 Focal atrophic and pigmented scars of chorioretinitis.

This procedure restores subtalar joint motion and relieves discomfort.

Figure 664.10-3 *A*, Bilateral curly toe deformities in a 4-yr old. There is flexion and varus rotation of the lateral three toes. *B*, The frontal view better demonstrates the curling of the toes, especially the third toes.

Figure 665.1-1 Graph demonstrating the normal development of the tibiofemoral or knee angle during growth. (Adapted from Salenius P, Vankka E: The development of the tibiofemoral angle in children. *J Bone Joint Surg Am* 1975;57A:259.)

Figure 665.2-2 Range of normal values by age and sex with respect to the alignment of the lower extremity. *A*, Torsional profile. *B*, Foot progression angle (FPA) to determine the degree of in-toeing and out-toeing during ambulation. *C* and *D*, Medial (MR) or internal rotation of the hips in girls (*C*) and boys (*D*). *E*, Lateral (LR) or external rotation of the hips. *F*, Thigh-foot angle (TFA) to determine the degree of tibial torsion. Internal or medial tibial torsion is present if the angle is more than 20–30 degrees. (From Staheli LT: Torsional deformities. *Pediatr Clin North Am* 1986;33: 1373.)

Figure 665.2-2 Range of normal values by age and sex with respect to the alignment of the lower extremity. *A*, Torsional profile. *B*, Foot progression angle (FPA) to determine the degree of in-toeing and out-toeing during ambulation. *C* and *D*, Medial (MR) or internal rotation of the hips in girls (*C*) and boys (*D*). *E*, Lateral (LR) or external rotation of the hips. *F*, Thigh-foot angle (TFA) to determine the degree of tibial torsion. Internal or medial tibial torsion is present if the angle is more than 20–30 degrees. (From Staheli LT: Torsional deformities. *Pediatr Clin North Am* 1986;33: 1373.)

Figure 665.4-3 Foot progression angle. The long axis of the foot is compared with the direction in which the child is walking. If the long axis of the foot is directed outwardly, the angle is positive. If the foot is directed inwardly, the angle is negative and is indicative of in-toeing. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Figure 665.4-4 Hip rotation in extension. This is measured with the child in the prone position and the knee flexed 90 degrees. The lower leg is vertically oriented. This is considered the neutral position. On outward rotation *(A)*, the leg produces internal hip rotation; and on inward rotation *(B)*, the leg produces external hip rotation. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Figure 665.6-5 Thigh-foot angle. With the child in the prone position and the knees flexed and approximated, the long axis of the foot can be compared with the long axis of the thigh. The long axis of the foot bisects the heel and the second toe or lies between the second and third toes. External tibial torsion *(A)* produces excessive outward rotation. Normal alignment *(B)* is characterized by slight external rotation. Internal tibial torsion produces inward rotation of the foot and is a negative angle *(C)*. (From Thompson GH: Gait disturbances. In Kliegman RM, Nieder ML, Super DM [editors]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Figure 665.6-6 Foot shape. Using the same position for measurement of the thigh-foot angle, the shape of the foot can also be evaluated. In this illustration, the left foot has normal alignment, whereas the right foot demonstrates metatarsus adductus. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Figure 665.6-7 *A*, A 5-yr-old girl with bilateral internal femoral torsion. She has approximately 80 degrees of internal rotation bilaterally. *B*, External rotation is limited to approximately 15 degrees for a total arc of hip rotation of 90–95 degrees. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Figure 665.6-8 *A*, A 6-mo-old girl with an excessive external tibial torsion. This reverse, or anterior, thigh-foot angle shows approximately 50 degrees of external tibial torsion. *B*, The same infant demonstrates a calcaneovalgus foot with forefoot abduction and increased hindfoot valgus. There is also hyperdorsiflexibility of the foot in the ankle mortise. (From Thompson GH: Gait disturbances. In Kliegman RM [editor]: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia, WB Saunders, 1996.)

Figure 665.7-9 Infant with bilateral genu varum at 18 mo of age. This resolved spontaneously before 7 yr of age. *A*, Clinical photograph. *B*, Standing anteroposterior radiograph of the lower extremities. (From Tachdjian MO: *Pediatric Orthopedics*, 2nd ed. Philadelphia, WB Saunders, 1990.)

Figure 665.7-9 Infant with bilateral genu varum at 18 mo of age. This resolved spontaneously before 7 yr of age. *A*, Clinical photograph. *B*, Standing anteroposterior radiograph of the lower extremities. (From Tachdjian MO: *Pediatric Orthopedics*, 2nd ed. Philadelphia, WB Saunders, 1990.)

Figure 665.7-10 *A*, A 13-yr-old boy with late-onset, or adolescent, tibia vara. There is marked obesity and mild genu varum deformity of the left knee. *B*, Posterior view of the same child. *C*, Standing anteroposterior radiograph of the left knee demonstrating the tibia vara deformity but with less obvious changes than in the infantile form. The medial aspect of the proximal tibial epiphysis is narrow and the growth plate is irregular. The typical metaphyseal “beaking” is not present.

Figure 665.7-11 *A*, A 4-yr-old girl with infantile tibia vara. She is obese and has a moderate left genu varum deformity. *B*, Anteroposterior radiograph of the left knee demonstrating the genu varum deformity. There is narrowing and irregularity of the medial aspect of the proximal tibial epiphysis and beaking of the medial metaphysis. *C*, Repeat radiograph 2 yr after proximal tibial and diaphyseal fibular corrective osteotomy. The osteotomy is healed, and relatively normal growth is occurring in the proximal tibial epiphysis. *D*, Postoperative clinical photograph demonstrating symmetric alignment of the lower extremities.

Figure 665.7-11 *A*, A 4-yr-old girl with infantile tibia vara. She is obese and has a moderate left genu varum deformity. *B*, Anteroposterior radiograph of the left knee demonstrating the genu varum deformity. There is narrowing and irregularity of the medial aspect of the proximal tibial epiphysis and beaking of the medial metaphysis. *C*, Repeat radiograph 2 yr after proximal tibial and diaphyseal fibular corrective osteotomy. The osteotomy is healed, and relatively normal growth is occurring in the proximal tibial epiphysis. *D*, Postoperative clinical photograph demonstrating symmetric alignment of the lower extremities.

Figure 665.7-11 *A*, A 4-yr-old girl with infantile tibia vara. She is obese and has a moderate left genu varum deformity. *B*, Anteroposterior radiograph of the left knee demonstrating the genu varum deformity. There is narrowing and irregularity of the medial aspect of the proximal tibial epiphysis and beaking of the medial metaphysis. *C*, Repeat radiograph 2 yr after proximal tibial and diaphyseal fibular corrective osteotomy. The osteotomy is healed, and relatively normal growth is occurring in the proximal tibial epiphysis. *D*, Postoperative clinical photograph demonstrating symmetric alignment of the lower extremities.

Figure 665.7-11 *A*, A 4-yr-old girl with infantile tibia vara. She is obese and has a moderate left genu varum deformity. *B*, Anteroposterior radiograph of the left knee demonstrating the genu varum deformity. There is narrowing and irregularity of the medial aspect of the proximal tibial epiphysis and beaking of the medial metaphysis. *C*, Repeat radiograph 2 yr after proximal tibial and diaphyseal fibular corrective osteotomy. The osteotomy is healed, and relatively normal growth is occurring in the proximal tibial epiphysis. *D*, Postoperative clinical photograph demonstrating symmetric alignment of the lower extremities.

Figure 666-1 The Moseley straight-line graph for the assessment of leg-length inequalities. This allows simultaneous correlation of the normal leg, short leg, and bone age of the child. It will accurately predict lengths of each extremity at skeletal maturity. The reference slopes are used as a guide in determining when appropriate treatment should be performed.

Figure 668.1-2 Newborn hip examination. *A*, The infant is laid on her back with the hips and knees flexed, and the examiner places the middle finger of each hand over each greater trochanter. *B*, The thumb of each hand is applied to the inner side of the thigh opposite the lesser trochanter. *C*, In a difficult infant, the pelvis may be steadied between a thumb over the pubis and fingers under the sacrum while the hip is tested (Barlow and Ortolani test) with the other hand. *D*, Limitation of hip abduction is also an early sign of developmental dislocation of the hip. Note the restriction in abduction of the right hip.

Figure 668.3-3 Pelvic radiographs demonstrating development dysplasia of the left hip. *A*, The Hilgenreiner method for identification of dysplasia of the hip before ossification of the capital femoral epiphysis; a' is greater than a, indicating greater obliquity of the acetabular roof. d', is greater than d, indicating lateral displacement of the femur. h is greater than h', indicating cephalad displacement of the femur. These relationships indicate dysplasia of the patient's left hip. *B*, Developmental dislocation of the left hip. The bony roof of the left acetabulum is quite oblique, and there is the beginning of a false acetabulum above its most lateral aspect. The left femur is displaced laterally and superiorly. The ossification center of the left capital femoral epiphysis is smaller than that of the right.

Figure 668.3-3 Pelvic radiographs demonstrating development dysplasia of the left hip. *A*, The Hilgenreiner method for identification of dysplasia of the hip before ossification of the capital femoral epiphysis; a' is greater than a, indicating greater obliquity of the acetabular roof. d', is greater than d, indicating lateral displacement of the femur. h is greater than h', indicating cephalad displacement of the femur. These relationships indicate dysplasia of the patient's left hip. *B*, Developmental dislocation of the left hip. The bony roof of the left acetabulum is quite oblique, and there is the beginning of a false acetabulum above its most lateral aspect. The left femur is displaced laterally and superiorly. The ossification center of the left capital femoral epiphysis is smaller than that of the right.

Figure 668.3-4 Anteroposterior radiograph of the right hip of an 8-yr-old boy with Legg-Calvé-Perthes disease. There is a collapsed yet dense capital femoral epiphysis with early fragmentation. The small medial triangle of the capital femoral epiphysis is uninvolved in the disease process.

Figure 668.4-5 Slipped capital femoral epiphysis, anteroposterior view. A line superimposed on the superior femoral neck normally intersects part of the head (*B* and *D* are normal). With a slipped epiphysis, the line does not intersect the femoral head (*A* and *C*). Occasionally, the frog-leg view (*C* and *D*) is needed to demonstrate the slip. (From Chung S: Diseases of the developing hip joint. *Pediatr Clin North Am* 1986;33:1457.)

Figure 668.4-6 Anteroposterior radiograph of the right hip of a 13-yr-old boy with a moderately severe chronic (stable) slipped capital femoral epiphysis. Observe the physeal widening and the distorted relationship between the capital femoral epiphysis and femoral neck.

Figure 669.1-1 Structural changes in idiopathic scoliosis. *A*, As curvature increases, alterations in body configuration develop in both the primary and compensatory curve regions. *B*, Asymmetry of shoulder height, waistline, and elbow-to-flank distance are common findings. *C*, Vertebral rotation and associated posterior displacement of the ribs on the convex side of the curve are responsible for the characteristic deformity of the chest wall in scoliosis patients. *D*, In the school screening examination for scoliosis, the patient bends forward at the waist. Rib asymmetry of even a small degree is obvious. (From Scoles PV: Spinal deformity in childhood and adolescence. In Behrman RE, Vaughn VC III [editors]: *Nelson Textbook of Pediatrics*, Update 5. Philadelphia, WB Saunders, 1989.)

Figure 669.1-2 Criteria for curve classification. (From Edgar M: A new classification of adolescent idiopathic scoliosis. *Lancet* 2002; 360:270–1, with permission.)

Figure 669.2-3 *A*, Preoperative standing posteroanterior radiograph of a 13-yr-old girl with a severe right thoracic section. Note the Cobb measurement technique. The numbers in parentheses indicate the degree of correction of the deformity on side-bending radiographs. *B*, Postoperative radiograph demonstrating a selective right thoracolumbar fusion and instrumentation from T3 to L2. Note the spontaneous improvement in the compensatory left lumbar curve after correction of the structural right thoracolumbar curve.

Figure 669.2-3 *A*, Preoperative standing posteroanterior radiograph of a 13-yr-old girl with a severe right thoracic section. Note the Cobb measurement technique. The numbers in parentheses indicate the degree of correction of the deformity on side-bending radiographs. *B*, Postoperative radiograph demonstrating a selective right thoracolumbar fusion and instrumentation from T3 to L2. Note the spontaneous improvement in the compensatory left lumbar curve after correction of the structural right thoracolumbar curve.

Figure 669.4-4 Standing lateral radiograph of a 14-yr-old boy with severe Scheuermann kyphosis. This measures 92 degrees between T3 and T12. Note the wedging of the vertebrae at T6, T7, T8, and T9. The normal thoracic kyphosis is 40 degrees or less.

Figure 671.3-1 The pathology of nursemaid's, or pulled, elbow. The annular ligament is partially torn when the arm is pulled. The radial head moves distally and, when traction is discontinued, the ligament is carried into the joint. (From Rang M: *Children's Fractures*, 2nd ed. Philadelphia, JB Lippincott, 1983, p 193.)

Figure 673.1-1 Illustration of fracture patterns. *A*, Longitudinal—fracture line parallel to bony axis. *B*, Transverse—fracture line perpendicular to bony axis. *C*, Oblique—fracture line at angle to bony axis. *D*, Spiral—fracture line runs curvilinear course to bony axis. *E*, Impacted—fractured bone ends compressed together. *F*, Comminuted—fragmentation of bone into three or more parts. *G*, Greenstick—bending of bone with incomplete fracture of convex side. *H*, Bowing—bony plastic deformation. *I*, Torus—buckling fracture. (From White N, Sty J: Radiological evaluation and classification of pediatric fractures. *Clin Ped Emerg Med* 2002;3:94–105.)

Figure 674-1 Pelvic osteomyelitis of the left iliac bone in a 12-yr-old girl with pain in the left hip region for 1–2 wk. *A,* Frontal radiograph of the pelvis shows mild demineralization of the acetabular portion of the iliac bone adjacent to the triradiate cartilage. There is very subtle periosteal reaction (*arrow*) along the margin of the sciatic notch. *B,* Technetium-99m bone scan shows increased uptake in the left iliac bone and mild increased uptake in the femoral head. *C,* Coronal MRI shows decreased signal from the marrow of the left iliac bone compared with the bright signal from the normal fatty marrow on the right. The femoral head is normal, and there is no joint effusion. Needle aspiration of the iliac bone yielded *Staphylococcus aureus;* the patient responded well to antimicrobial therapy. (From Markowitz RI: Diagnostic imaging. In Jenson HB, Baltimore RS [editors]: *Pediatric Infectious Diseases: Principles and Practice.* Norwalk, CT, Appleton & Lange, 1995.)

Figure 674-1 Pelvic osteomyelitis of the left iliac bone in a 12-yr-old girl with pain in the left hip region for 1–2 wk. *A,* Frontal radiograph of the pelvis shows mild demineralization of the acetabular portion of the iliac bone adjacent to the triradiate cartilage. There is very subtle periosteal reaction (*arrow*) along the margin of the sciatic notch. *B,* Technetium-99m bone scan shows increased uptake in the left iliac bone and mild increased uptake in the femoral head. *C,* Coronal MRI shows decreased signal from the marrow of the left iliac bone compared with the bright signal from the normal fatty marrow on the right. The femoral head is normal, and there is no joint effusion. Needle aspiration of the iliac bone yielded *Staphylococcus aureus;* the patient responded well to antimicrobial therapy. (From Markowitz RI: Diagnostic imaging. In Jenson HB, Baltimore RS [editors]: *Pediatric Infectious Diseases: Principles and Practice.* Norwalk, CT, Appleton & Lange, 1995.)

Figure 676.8-2 Inversion stress tilt test for ankle instability. (From Hergenroeder AC: Diagnosis and treatment of ankle sprains: A review. *Am J Dis Child* 1990;144:809.)

Figure 683-1 Stillborn with achondrogenesis type II. Note poor ossification of calvaria, vertebral bodies, and sacrum; hypoplasia of pelvic bones; and short tubular bones with cupped metaphyses.

Figure 683-2 Spondyloepiphyseal dysplasia congenita is shown in infancy and early childhood. Note the short extremities, relatively normal hands, flat facies, and exaggerated lordosis.

Figure 683-5 Female patient with metaphyseal dysplasia, type Schmid. The facies are normal and stature is mildly reduced. Mild tibia vara is present.

Figure 683-6 Radiograph of lower extremities in Schmid metaphyseal dysplasia showing short tubular bones and metaphyseal flaring and irregularities, abnormal capital femoral epiphyses, and femoral necks. The epiphyses are normal. Coxa vara is present.

Figure 683-8 *A,* Lateral thoracolumbar spine radiograph of patient with pseudoachondroplasia showing central protrusion (tonguing) of the anterior aspect of upper lumbar and lower thoracic vertebrae. Note reduced vertebral body heights (platyspondyly) and secondary lordosis. *B,* Lower extremity radiograph of patient with pseudoachondroplasia showing large metaphyses, poorly formed epiphyses, and marked bowing of the long bones.

Figure 684-1 Stillborn infant with thanatophoric dysplasia. Limbs are very short, with upper limbs extending only two thirds of the way down the abdomen. The chest is narrow, exaggerating the protuberance of the abdomen. The head is relatively large.

Figure 684-2 *A*, Neonatal radiograph of a child with thanatophoric dysplasia. Note medial acetabular spurs *(black arrow)*, hypoplastic iliac bones, bowed femora with rounded protrusion of proximal femurs, hypoplastic thorax, and wafer-thin vertebral bodies. *B*, Lateral radiograph of the thoracolumbar spine in thanatophoric dysplasia, showing marked vertebral flattening and short ribs. Ossification defect of the central portion of the vertebral bodies is present.

Figure 684-3 Infant with achondroplasia. The cranium is large and the forehead prominent. The nasal bridge is moderately flat, and the chest is small compared with the abdomen. Note medial arm and forearm creases, which reflect bowing at the sharpest concavity of the limbs.

Figure 684-4 Radiograph of infant with achondroplasia, demonstrating interpedicular narrowing of the first through fifth lumbar vertebrae, short round iliac bones, and flat acetabular roofs. The tubular bones are short and show mild irregularities of the metaphyses.

Figure 685-1 Child with diastrophic dysplasia. The extremities are dramatically shortened *(top)*. Clubfoot is commonly observed *(middle left)*. The fingers are short, especially the index finger; the thumb characteristically is proximally placed and has a hitchhiker appearance *(middle right)*. The upper helix of the ears becomes swollen 3–4 wk postnatally *(lower left)*, and this inflammation spontaneously resolves, leaving a cauliflower deformity of the pinnae *(lower right)*.

Figure 685-2 Radiograph of hands in diastrophic dysplasia. The metacarpals and phalanges are irregular and short. The first metacarpal is ovoid.

Figure 686-1 Radiograph of lower extremities of a child with campomelic dysplasia. Note bowed femurs, which are not particularly wide as compared with the thick bowed tibiae and fibulae.

Figure 688-1 Radiograph of lower extremities in Ellis-van Creveld syndrome. Tubular bones are short, and proximal fibula is short. Ossification is retarded in lateral tibia epiphyses, causing a knock-knee deformity.

Figure 688-2 Radiograph of lower extremities in cartilage hair hypoplasia. The tubular bones are short and the metaphyses are flared and irregular. The fibula is disproportionately long compared with the tibia. The femoral necks are short.

Figure 688-3 *A*, Radiograph of the lateral thoracolumbar spine in metatropic dysplasia showing severe platyspondyly. *B*, Radiograph of lower extremities in metatropic dysplasia showing short tubular bones with widened metaphyses. The femurs have a dumbbell appearance.

Figure 689-1 Infant with type III OI displays shortened bowed extremities, thoracic deformity, and relative macrocephaly.

Figure 689-2 Typical features of type III OI radiographs in 6-yr-old child. *A*, Lower long bones are osteoporotic, with metaphyseal flaring, “popcorn” formation at growth plates, and placement of intramedullary rods. *B*, Vertebral bodies are compressed and osteoporotic.

Figure 689-3 Typical features of basilar invagination shown in the sagittal MRI of an asymptomatic child with type III OI. There is invagination of the odontoid above the Chamberlain line causing compression and kinking at the pontomedullary junction *(arrow)*.

Figure 690-1 Marfan syndrome. Note the elongated facies, droopy lids, apparent dolichostenomelia, and mild scoliosis.

Figure 691-1 The metabolic pathway of vitamin D, indicating its conversion to the hormone 1,25$(OH)_2$ D_3 and to 24,25$(OH)_2$ D_3 . Vitamin D_2 (ergosterol) of plant origin appears to undergo similar metabolic steps.

Figure 700-1 T2-weighted MRI of a child after radiotherapy shows white matter changes (*arrows*).

Figure 700-2 Generalized brain changes after radiotherapy. T1-weighted MRI of a child shows both central and cortical atrophy as well as high signal areas (*arrows*), owing to mineralizing microangiopathy.

Figure 704.2-1 Rumack-Matthew nomogram for acetaminophen poisoning. Semilogarithmic plot of plasma acetaminophen levels versus time. *Cautions for the use of this chart*: (1) The time coordinates refer to time *after ingestion*. (2) Serum levels drawn before 4?hr may not represent peak levels. (3) The graph should be used only in relation to a single acute ingestion. (4) The lower *solid line* 25% below the standard nomogram is included to allow for possible errors in acetaminophen plasma assays and estimated time from ingestion of an overdose. (From Rumack BH, Hess AJ [eds]: Poisindex. Denver, 1995. Adapted from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. *Pediatrics* 1975;55:871.)

Figure 708-1 Identification of venomous snakes. (Modified from Rosen P, et al [editors]: *Emergency Medicine*, 3rd ed. St. Louis, CV Mosby, 1992.)

Figure 708-2 Decision process for treating pediatric black widow spider envenomation. (Courtesy of Robin Woestman, Loma Linda Children's Hospital, Loma Linda, CA.)

Figure 710-1 Nomogram for estimation of surface area. The surface area is indicated where a straight line that connects the height and weight levels intersects the surface area column; or, if the patient is roughly of average size, from the weight alone (*enclosed area*). (Nomogram modified from data of E. Boyd by CD West.) (See also Briars G, Bailey B: Surface area estimation: Pocket calculator v nomogram. *Arch Dis Child* 1994;70:246.)

Figure 710-2 Relationship between body weight in pounds, body surface area, and adult dosage. The surface area values correspond with those set forth by Crawford and associates (1950). Note that the 100% adult dose is for a patient weighing about 140?lb and having a surface area of about 1.7?m^2 . (From Talbot NB, et al: *Metabolic Homeostasis—A Syllabus for Those Concerned with the Care of Patients*. Cambridge, Harvard University Press, 1959.)
